AMERICAN GEOLOGICAL SURVEYS *

THE volumes which record the progress of the United States Geological Survey of the Territories since its commencement in 1867 contain much information of great value to geologists, as well as to those who watch with intelligent interest the advance of the wave of human civilisation into the far West. Each of them is full of fresh illustrations of the principles of geology, such as the dependence of scenery upon rocky structure, the order of succession of formations, the plication of mountain-chains, the phenomena of volcanic action, the functions of rivers and glaciers as geological agents—illustrations which have already to some extent found their way into general text-books and are no doubt destined ere long to be made in that way familiar even to tyros in the science all over the world. In each of them too we have such information as could be gathered as to the agricultural value of the countries, the practicable routes for roads and railways, the mineral resources to be looked for, the facilities for general commerce—information which will probably serve as the basis for the future development of the regions into settled States.

During the years 1871 and 1872 Dr. Hayden's parties were at work about the sources of the Missouri and Yellowstone Rivers. They had gradually pushed on into that wild region, stimulated by the variety and interest of its scenery and geology, but they had got far from any civilised base-line, including railroads and other conveniences of transport and subsistence. Beyond them lay the lands of the Indians, who manifested no disposition to treat the peaceful work of the Survey in another light than as some insidious part of the designs of the grasping central power at Washington. It seemed desirable therefore in the meantime to discontinue the further prosecution of the Survey in the north-west until by the establishment of railroad communication it could be resumed with much less labour and cost. This delay, however, will probably not be of long continuance, when we consider with what marvellous rapidity the tide of American energy is travelling towards the Pacific.

The region recommended by Dr. Hayden and approved of by the Government as the scene to which the operations of the Survey should be transferred was that portion of the Rocky Mountain range which runs through Colorado and New Mexico—a region as yet unsurveyed and likely in a few years to be rapidly developed by some of the most important railroads of the West. The survey of the fortieth parallel by Mr. Clarence King, to which allusion has been already made, and of which some account will be given in a subsequent paper, had done good service in making known the physical features and geology of a belt of country stretching across the northern limits of the tract which Dr. Hayden now proposed to examine. That survey would form the starting-point of the new explorations which it was arranged should sweep westward across the watershed of the continent to the left bank of the Green and Colorado Rivers, eastward across the sources and higher course of the Platte, Arkansas, and other tributaries of the Mississippi, and southwards to the boundary-line between the United States and Mexico.

The first instalment of results from this transference of area has appeared in the Annual Report of the Geological Survey of the Territories for 1873—a thick volume of 718 pages, with numerous and excellent sections, maps, and views. This Report is divided into four parts, devoted respectively to—I. Geology, Mineralogy, and Mining Industry; II. Palæontology; III. Zoology; IV. Geography and Topography. An appendix contains papers on some mineral fields, while detailed descriptions of a large number of new species of fossil plants and animals are given in Part II. Taking the general supervision of the whole operations of the Survey, Dr. Hayden furnishes some chapters in reference to the geological features of part of the eastern slope of the Rocky Mountains, and introductory to those of the officers placed by him in charge of the three subdivisions into which, as already remarked, the work of the year was arranged. It appears that the first division, under the charge of Mr. A. R. Marvine, surveyed, topo-

* See vol. xii. p. 267.

graphically and geologically, an area of 5,600 square miles during the period between the end of May and the latter part of October; the third division, under Dr. F. M. Endlich, accomplished the survey of nearly 7,600 square miles, "particular attention being paid to the agricultural and mineralogical resources of the country traversed." Allowing 130 full working days for the period during which these two parties were at work, we find that on an average 100 square miles were surveyed topographically and geologically each day, and that this was performed by some seven or eight observers! And if it be further noted that only half of that number were geologists, and that in the case of the San Luis, or third division, the geological work appears to have been done by one man, we shall form some notion of the rate at which scientific surveys advance in the far West. We have not the same precise statements of the area actually surveyed by the second or South Park division, under Dr. A. C. Peale; but it seems to have been on the same extensive scale.

Now by those who take interest in the progress of topographical and geological surveying some explanation will naturally be required as to the almost incredibly large area examined in one season by Dr. Hayden's corps. Compared with his rate of progress, our Ordnance and Geological Surveys creep on at a snail's pace. His geologists, for instance, get over in a single day an amount of ground which the most hard-working and experienced members of the Geological Survey of Great Britain could hardly accomplish in a year's campaign. Evidently the two kinds of work cannot properly be compared with each other. That of the British Surveys is minutely detailed, and meant to be, for the time, exhaustive. The American Survey of the Territories, on the other hand, cannot be regarded as, and does not pretend to be, more than a rapid but intelligent reconnaissance, wherein the positions of the leading landmarks are correctly determined, and those of the intermediate features are fixed as nearly as may be; while, acting in concert with the topographer, and availing himself of the same points of observation, the geologist ascertains the nature and order of the rocks in a few traverses from which he infers what must be the structure of the surrounding districts. It is no disparagement to this work to say that it must in the end be superseded by more accurate and detailed surveys. It is in the meanwhile doing a notable service by pioneering in vast and unknown or little known regions, and giving the world a first outline of the main features of their geography and geology. In the territory of Central Colorado investigated in 1873, the geologists had the advantage of comparatively simple structure to deal with. So clearly does the skeleton of the continent protrude in that region through the surface, that from each main hill-top it was not difficult to follow for many miles on successive ridges and spurs the crags and hollows marking the lines of outcrop of particular strata. The extent to which this peculiarity and simplicity of geological physiography has been useful, may be inferred from the numerous diagram-sections of the belt of country surveyed, showing the relation of the surface-contour to the arrangement of the underlying rocks.

Space cannot be given here for a detailed account of this Report, but reference may be made to some of its features which have a general interest. Mountain-structure, especially in relation to the plications of the crust of the earth, receives much notice from the various members of the Survey. They have followed the gradual swelling of the flat formations of the plains, first into gentle ridges or "hog backs," then into more marked and crested ranges, until they have traced them in vertical or even inverted masses reposing against the central core of granite. Crossing this latter they have caught up again the same formations on the other side, and followed them in like order and position from the disrupted and highly-inclined central mass down to their gradual subsidence into the flat plains. The rocks next to the granite are metamorphosed, and, what must strike European geologists as curious, have huge intercalated sheets and dykes or veins of trachyte associated with them. The elevation of the mountain ranges has upraised cretaceous rocks, and even some parts of later geological formations.

The length of time, however, which has passed since the upheaval of the Rocky Mountains and their subsidiary spurs has allowed a vast amount of work to be done upon their slopes and crests by the weather, rain, torrents, frost, snow, and glaciers. It would seem hardly possible indeed to find a region where it would be more easy to appraise exactly the amount of waste from a given area due to this cause. The geological structure of the anticlinal and synclinal folds is so simple, the rocks are so well exposed, and the limits of sub-aërial erosion seem so sharply marked off from those of subterranean movement, that the flanks of the Rocky Mountains might be selected as a typical region for the study of this branch of physiographical geology. Sometimes the corries or cirques ("gulches" is their American name) have been cut back so as to leave a steep hardly-traversible crest between them, while now and then a valley has been cut completely across the watershed, so as to draw its first waters from the other side. In some places the rocks have been so weathered as to stand up in extraordinary pillars and capped statuesque masses like those for which Saxon Switzerland has been so long famous.

The former presence of extensive glaciers descending from the mountains of Colorado has been proved by the evidence of huge moraine mounds, admirable ice-worn domes of granite, and scattered glacier-lakes. It would seem, indeed, that no very great diminution of temperature might suffice to restore glaciers to these valleys. Dr. Hayden describes vast masses of snow and ice, which, melting in summer on the steep slopes and saturating the rocks and soil, slide down like glaciers and cumber the declivities and valleys with piles of rubbish.

The now well-known geysers of the Yellowstone region have made known the extent and comparative recentness of volcanic action in that region. We learn some further facts of interest on this subject from the present report. Dykes and streams of basalt have been found in proximity to their parent cones. In some cases the lava beds form the cappings of isolated hills, or project as terraced bars from the sides of the slopes. In other instances they occur in the bottoms of the valleys, and even appear to have sometimes crossed the present river-courses and formed lakes. Recent, therefore, though these lava-eruptions must be, they were evidently continued during a period of time long enough for deep and wide valleys to be cut

out of the older flows, while *coulées* were poured down the excavated hollows. In these respects the history of this late North American volcanic action recalls the succession of events so long ago and so admirably described by Mr. Poulett Scrope as traceable among the volcanic masses of Central France.

The mines now in operation, as well as indications of probable positions for new ones, are carefully noted in the Report. The geologists, indeed, have constantly had before them the consciousness that the future development of these territories would not be helped so much by their making out all geological details at present as by their ascertaining what practicable places could be found for the establishment of mining industry. At the same time, they deserve great credit for keeping the thoroughly scientific character of their duty so conspicuous in their reports; for undoubtedly the only way to make an exploration which shall be of real value as a guide in mining operations is to do it in the strictest sense geologically. With the area and relations of the different rock-formations mapped out for him, the mining prospector may save much time and money by learning what tracts to avoid as well as which to explore.

Each of the geologists in command of a division under Dr. Hayden furnishes a report, which appears in the present volume. These are remarkably well done, that of Mr. Marvine being specially interesting from the variety of phenomena with which he had to deal and the clearness with which he tells his story. Besides the geological reports, Prof. Lesquereux supplies one of great value on the Lignitic formation and its fossil flora, in which he enters anew into the vexed question of the true age of that formation. As the result of his long study of its large and well-marked flora, he concludes that the formation is of Tertiary date, a conclusion which agrees also with that to which Dr. Hayden has been led. A large list of new species of fossil plants from the Lignitic strata is described by him in his report. Under the head of Zoology are gathered a number of communications on insects, crustacea, mollusca, and other invertebrata, collected or observed during the progress of the Survey. The part devoted to Geography and Topography contains the reports of the geographer and his colleagues on the system of triangulation employed, the heights of various places, the practicable routes, and other matters. The book is well printed and well illustrated. It deserves the heartiest commendations both for the Government which supports such good work and for the men by whom it is practically done. ARCH. GEIKIE

ALIX ON THE LOCOMOTION OF BIRDS

Essai sur l'Appareil Locomoteur des Oiseaux. By Edmond Alix, M.D. (Paris: G. Masson.)

THIS considerable volume, the first independent work of any pretensions on the osteology and myology of birds, is a valuable addition both to zoological and to ornithological literature. As far as the latter is concerned it would have been more distinctly useful if the author had been better acquainted practically with birds' skins, as well as with the binomial nomenclature and the importance of specific distinctions. If he had, such a sentence as the following would have been modified in a manner which would have made it of greater value to future investigators, at the same time that the precision would have added weight to the points brought forward. We are told with reference to the accessory femoro-caudal muscle that "this fasciculus, represented in the Cormorant by an aponeurotic band, is found uncomplicated in the Grebe, Flamingo, Heron, Bustard, and Secretary Bird," in which remark the fact that what are there termed Grebe, Bustard, &c., are general terms, seems to be entirely ignored; as is therefore the possibility of there being structural differences among the members of the included groups. It may even be mentioned that respecting the very point referred to in the above quotation, the statement therein made does not generally apply, being correct as far as the Little Grebe (*Podiceps minor*) and the Common Heron (*Ardea cinerea*) are concerned, but being inaccurate when said of the Eared Grebe (*Podiceps cristatus*) and the Giant Heron (*Ardea goliath*). Most works on the anatomy of birds suffer from the same imperfection; the importance of specific and even generic distinctions being generally disregarded, by all but pure ornithologists.

The work is divided into three sections—the three in which the consideration of the locomotive apparatus of birds most naturally falls; namely, the consideration of birds firstly as vertebrated animals (zoologically); secondly, as a special organised type (anatomically); and thirdly, as flying animals (physiologically). An excellent *résumé* of previous investigations on the several subjects prefaces each section, in which due credit is on nearly all occasions given to foreign workers.

Under the first heading, following the teaching of De Blainville and Gratiolet, Dr. Alix describes the typical skull on the hypothesis of its vertebral origin; of the fourth or nasal vertebra, considering the perpendicular plate of the ethmoidal as the centrum, the lateral masses of that bone as the laminæ, and the nasals as the spinous element.

In the treatment of the osteology of birds, most of the important subjects which have of late attracted most considerable attention are fully discussed. We are rather surprised to find no reference to the point so forcibly put forward by Prof. Parker, and laid stress on by Prof. Huxley, with regard to the anchylosis of the palatine bones with the vomer in the Tinamous. The vomer as a separate bone is also rather neglected. As to the light thrown by a study of the skull on the classification of birds, we read that "the examination of the head of birds confirms the major divisions established originally from a consideration of the beak and the feet. It proves that Raptores, Passeres, Gallinæ, &c., exist in reality: but it also renders it evident that there are divisions beyond these not capable of being included among these primary forms. For instance, the Parrots form a well-marked group of themselves . . . the Raptores Nocturnæ are clearly distinct from the Raptores Diurnæ, the Pigeons can in no way be confounded either with the Passeres or with the Fowls." As to the sternum, "the results arrived at by De Blainville and confirmed by subsequent authors (are said to) prove that Cuvier has narrowed the question too much in affirming that the indications afforded by the sternum cannot serve for more than generic distinctions. But it must be admitted that, with the exception of the cha-

racters indicated by the presence or absence of the carina, it is almost impossible to recognise in the sternum any of those distinguishing features which may be stated in a single word, or may be incorporated as a definition in any tabular arrangement. The sternums of most birds, even those which are most peculiar, must be considered in their entirety, and a complete description is necessary for their differentiation." We would feel disposed to go even further than this, and to say that in the sternum there are characters from which, with a little extraneous assistance, more considerable generalisations may be arrived at. It is true that in the passerine *Pteroptochus* the posterior margin is doubly notched on either side, but in how different a manner from that in the piciform birds and owls! What more than the sternum proves the closeness of the relationship between the Toucans, Woodpeckers, and Capitoes, also between the Swifts and the Humming Birds, as well as the small kinship between the gallinaceous birds and the Sand Grouse? On the other hand, the sternum does not aid us much in the determination of more distant relationships, such as those of families one to the other. From it alone we should not feel justified in placing the Tinamous near the Apteryx, nor the Stormy Petrels near the Fulmars.

In the *Bulletin de la Société Philomathique* and in the *Journal de Zoologie* Dr. Alix has published his dissections of the Rhea and of a Tinamou (*Nothura major*). His myological investigations are based on the descriptions given by Vic d'Azyr and Meckel. Following the latter of these, he mentions that in the Cormorant the ambiens muscle (*accessoire iliaque du fléchisseur perforé*) is absent, which is decidedly not the case in the common species (*Phalacrocorax carbo*). With reference to this bird, the accessory femoro-caudal is said to be represented by an aponeurotic band, which we have failed to detect; and the same remark applies to the muscle itself in the Heron (*Ardea cinerea*), in which it is also said to be developed; from which we may infer that the author has evidently not clearly recognised the characters which distinguish this fleshy fasciculus from the obturator externus (*carré*); and that such is the case is further proved by his statement that the latter named muscle is enormous in the ostrich, in which it is in reality very small, being almost hidden by the former.

The flexor tendons of the toes are specially dwelt on. The flexor perforatus digitorum is shown to present peculiarities sufficiently important to deserve special names. This muscle in birds is not a single one, but is formed of a superficial and a deep group; the latter having two separate origins, an internal and an external, of which the relative proportionate bulks vary. Those birds in which the outer head is the larger are termed *ectomyens*; those with a larger internal head, *entomyens*; and those with equal heads, *homœomyens*. "The palimpeds, the longirostral and pressirostral Waders, the Flamingoes, the Storks, the Tinamous, the struthious birds and the Parrots, are entomyen; the Herons, the Rails, the gallinæ, Pigeons and passeres, are homœomyen; whilst the diurnal and nocturnal birds of prey are ectomyen." The deep flexors are said not to offer such remarkable differences as those just referred to, but as none of their most striking peculiarities are mentioned, we presume that the author is unacquainted with them. The long flexor tendon to the hind toe, we are told, is absent in the swan; it may be so in *Cygnus olor*, such is certainly not the case in *C. nigricollis*.

The last section of the work is almost entirely devoted to the flight of birds, this subject being viewed from a theoretical standpoint only. It is demonstrated in a fairly conclusive manner that the assumption of Borelli, in which the wing is considered to strike directly downwards and to turn backwards simply on account of the yieldingness of its posterior margin, is insufficient to explain the different movements observed; at the same time that it is opposed to the results arrived at from a study of the shape of the articular surfaces of the shoulder, and the arrangement of the fibres of the muscles acting on that joint. This, we think, is the tendency of modern investigation, notwithstanding the support, by M. Marey, of the opposite view. The results of the elaborate investigations of this latter able physiologist are as easily explained upon the one assumption as the other, perhaps better on the anti-Borellian theory, which no doubt is not required to account for the movements of the wings in the much less intricate problem of insect flight.

The following are Dr. Alix's propositions on this subject:—"*First.* The wing in the down-stroke begins by moving forward to attain its basis of support; after which it strikes briskly from above downwards, and at the same time from before backwards, as a result of which the bird is projected forwards. *Second.* At the moment at which the wing commences to descend, its lower surface looks forwards; but as it descends, this surface gradually turns to look directly downwards, and ultimately more and more backwards. *Third.* During the ascent of the wing, it moves upward and forward, its inferior surface at the same time looking forward." The nearly complete agreement of these observations with the results of M. Marey's previously published experiments is worthy of note, considering the differences in the starting-points of the two authors. The question of avian locomotion, as it now stands, is therefore not so much as to what are the positions of the wing during the different parts of the stroke, but as to whether the variations in the direction of its plane depend for their origin on the movements imparted to the humerus by the muscles acting on the shoulder, or on the influence of the resisting air upon a vertically moving plane which is more yielding behind than in front. This question requires further elucidation, though, as we have just remarked, we think, with Dr. Alix, that the balance of evidence is considerably in favour of the former view.

In conclusion, we strongly recommend this complete and able exposition of the locomotor apparatus of birds to all students both of physiology as well as of zoology.

"THE ABODE OF SNOW"

The Abode of Snow. Observations on a Journey from Chinese Tibet to the Indian Caucasus, through the upper valleys of the Himalayas. By Andrew Wilson. (Edinburgh and London: W. Blackwood and Co., 1875.)

LAST week we noticed Mr. Drew's almost exhaustive work on Jummoo and Kashmir; Mr. Wilson's work is to a large extent concerned with the same region, as

the greater part of the journey recorded was through Kashmirian territory. But the two works differ in many respects in design and plan. Mr. Drew has brought together so full and trustworthy a mass of information of all kinds about Kashmir as must render his work the great authority on the subject for a long time to come; his style is perfectly plain and unadorned; nearly every sentence is a positive statement of fact; he does not spend many words in admiration of the unparalleled scenery in the midst of which he lived for ten years, and he is never tempted into rapture. The attraction of Mr. Drew's work, and it is distinctly attractive, lies in the high interest and value and frequent novelty of the information contained in it. Mr. Wilson's aim, on the other hand, is to enable the reader to share, as far as words can go, the sensations which he himself felt in journeying for weeks in the midst of scenery whose grandeur cannot be adequately expressed, to present an impressive panoramic view of the "peaks, passes, and glaciers," and the fearful ravines of the highest mountains in the world, and to picture the scanty life which lurks in their lofty valleys or clings to their steep and rugged sides. His work is written, he tells us, "for those who have never seen and may never see the Himalaya. I have sought," he says, "to enable such readers in some degree to realise what these great mountains are, what scenes of beauty and grandeur they present, what is the character of the simple people who dwell among them, and what are the incidents the traveller meets with, his means of conveyance, and his mode of life?" Mr. Wilson has accomplished this task as successfully as it is possible to do it by means of language. Without apparent effort or artifice the current of his narrative flows on with delightful sweep; his style is vigorous, clear, and really eloquent, never bombastic or stilted, and with an under-current of genuine humour. He follows the only scientific method of reproducing in his readers the impressions made upon himself by the Himalayan scenery—by representing in simple but striking language the features which stirred his admiration and awe, never indulging in those futile and vague expressions of ecstasy which are a mark of the feeble observer, unscientific thinker, and unskilled writer. At the same time Mr. Wilson manages to convey a very considerable amount of information, and whoever reads his work with care will have realised to some extent the character of the region which it attempts to describe.

Mr. Wilson's main object in undertaking his toilsome tour among the Western Himalayas was to invigorate a constitution prostrated by the trying climate of India. His original intention was simply to visit Masuri and Simla, "but the first glimpse of the Jumnotri and Gangotri peaks excited longings which there was no need to restrain," and he plunged into the heart of the Himalayas. His journey lasted from June to November 1873. His real starting-point was Simla, though he gives valuable information as to other routes, and makes many shrewd comments on the men and manners of the various places through which he passed before reaching this point, on society and politics, and on certain burning questions connected with our Indian Empire. From Simla he proceeded up the stifling valley of the Sutlej to Shipki, where he made a vain attempt to get into Chinese Tibet; he was worsted by the women of the place. Hence he proceeded in a generally north-west direction by the Lee River, through the Schinkal pass, past Padam in Zanskar, to Dras, visiting Sirinagar and the Vale of Kashmir, and on westwards by the Jhelam River to the Khyber Pass. This is easily told, but the difficulties Mr. Wilson had to encounter are almost incredible, especially when it is considered that he was an invalid in search of health; for a month he was laid up at Pu, not far north from Simla, by an attack which nearly proved fatal. He camped out nearly all the time, had frequent difficulty in procuring provisions for himself and his small retinue, had often to scramble along paths not much broader than a mantel-shelf, overhanging ravines many thousands of feet deep, had to risk being lost in glaciers and frozen to death on passes upwards of 16,000 feet high. He bore it all with infinite good humour, and reached the Khyber Pass, we have no doubt, a stronger and a wiser, and quite as cheerful a man as when he started from Simla.

Mr. Wilson's work, as we have hinted, is something more than a fascinating tale of travel. While he gave himself up unrestrainedly to the scenic influences in the midst of which he sojourned for five months, he was quite alive to all the principal features of interest which presented themselves. There are frequent references to the animal and vegetable life of the region, to its grand physical and geological phenomena, and especially to the characteristics of the interesting people who inhabit the not infrequent villages on the route. He has added something to our knowledge of the glaciers of this part of the Himalayas. Mr. Wilson had several opportunities of observing closely the life of the people, and the information he gives will be found of value even by those who are familiar with the literature of the subject. He speaks, as might be expected, at considerable length on the polyandry and Lamaism which prevail over a considerable part of his route, and his remarks are characterised by great moderation and good sense. We wish we had space to quote the exquisite picture of domestic life which Mr. Wilson witnessed while snowed up at the village of Phe, in Zanskar. He seriously suggests the possibility of the Turanian Zanskaris being "congeners of the Celtic race."

He tells us a good deal, of course, about the Vale of Kashmir, and, like Mr. Drew and other geologists, concludes that it was at one time, and that not very remote, a great lake; he enters into some interesting speculations on the prehistoric inhabitants and condition of Kashmir. When near the end of his journey he made a bold raid across the Afghan frontier, and has a chapter on Afghan ethnology and the Afghan character.

In a chapter written under the influences of a moonlight midnight among the Himalayas—and how awe-inspiring and "other-worldly" such influences must be, one can easily imagine—Mr. Wilson indulges in some curious speculations on the struggle for life in the organic, and especially in the animal world, as contrasted with the inorganic. We think he has struck quite a wrong key here, and has not an adequate grasp of the facts of the case; but even if we had space we could not enter into his argument, as it is mixed up with certain subjects that are beyond the sphere of NATURE.

"The Abode of Snow" will, we believe, take its place as one among the few of our really classic works of travel.

OUR BOOK SHELF

Further Researches in Mathematical Science, embracing the Appendix of "The Two Discoveries." By the author of "The Two Discoveries." (Clement Pine, Taunton Road, Bridgwater, 1875.)

OUR readers may ask, who is the author of "The Two Discoveries," and what are the Discoveries? An advertisement informs us that Mr. Clement Pine himself is the former, and that the subjects of "The Two Discoveries" are "The Mathematical Discovery, the Spiritual Telegraph, Astronomy, Cause of the Changes of the Seasons, Botany, Capillary Attraction, or the Principle of Growth; Religion, Progression, Scenery in the Spirit Realm, &c., and a variety of other topics." A suggestive list! We shall extract a *morceau* here and there which will indicate the nature of the present pamphlet. There are "important discoveries in a science in which very slight advances have been made since its foundation was laid by Euclid." We commend this to the "Improvement of Geometrical Teaching Association." To his scholastic ignorance and to his loss of sight, Mr. Pine attributes the fact of his attention having been turned to these subjects and of his having hit upon shorter, simpler, and more effectual modes of obtaining certain results.

After a personal narrative, he tells us he bought a guitar. "The guitar having only six strings to perform a melody which may require sixteen whole tones, besides semi-tones, to be effected by shortening the strings by fingering, I had now a fair field open for my calculations. So I conceived a musical instrument of sixteen strings similar to the guitar, which would require no shortening of the strings by fingering, but which could be played straight ahead, each string representing a different note, like the harp. Now, all my stock-in-trade in mathematical science was a knowledge of the properties of the right-angled triangle, which, connected with the rule of proportion known as the Rule of Three in arithmetic, seemed like a magic key to unlock the mysteries connected with geometry and trigonometry." He then dwells on the properties of the right-angled triangle. The especial property is the discovery imputed to Pythagoras. This he expects is of "greater value than any other axiom in mathematics." He simplifies "this simple axiom, and if you want it any plainer, the only way is to set your own brains to work." With his Minstrel (the musical instrument) he has plenty of amusement. "I would be so absorbed in calculating and committing the numbers arrived at to memory as to be quite unconscious I had lost my sight. The outer world was invisible, but the inner world of the spirit was transparent." He then comes to his main point, viz., the true mode of obtaining the distances of remote objects by observation. "My mind must have been occupied on this theorem for five or six years, and it was not until a year after the recovery of the sight of one eye that I discovered the principle. At length it came to my mind like a flash of lightning, first to find the correspondence of the circle to the square; and then to obtain the distance by the proportion of the paralax (*sic*) to the length of the square for a divisor, and the length of the base line measured or obtained as the multiplier. . . . The principle itself is perfect, and the approximation to perfection in its application depends altogether on the comparative perfection of the instrument used and of the observations made."

There are two diagrams and long descriptions. We have preferred to let our author speak for himself, and so to show that if he is not affected with the *morbus cyclometricus*, the diagnosis points to a disease nearly allied to it. Further, we have hardly dared to discuss the pamphlet in other fashion on account of the paragraphs on p. 12, prefaced with the remark, "But what is to come will startle you." "I have been receiving from my honoured father in the Spirit Realm, John Pine, senior, some two dozen essays on philosophical subjects. He was giving his views on religion in very forcible language, and thinking I was becoming too excited, he made a sudden change to trigonometry, and then referred to my diagrams, and the importance of my discovery in mathematics; and that it was my duty to lay it before the world. I said it seemed to me very complete for terrestrial observations, but I was not aware that it would apply to astronomy. He remarked that it was equally applicable to astronomical as terrestrial observations; and he insisted that I should continue my researches on the subject. I have taken his advice, and have continued my mental researches; and shall now present them for public scrutiny." His father further states: "Two years ago, or more, when you used to be showing them to ——, I was with you all the time when you were studying on the subject, and am better acquainted with the diagrams than you are yourself." With the announcement of this "Imprimatur" we close our notice of this singular farrago.

Notes on Forestry. By C. F. Amery, Deputy Conservator, N.W. Provinces, India. Pp. 119. (London: Trübner and Co.)

THIS is a little book written by a forest officer for the benefit of those Englishmen who, having been trained in the schools of forestry in France and Germany, require a convenient handbook written in their mother tongue to guide them in their future operations in forest work. Bulky books in the languages of the two countries just alluded to already exist, but these, as the author says, deal so largely in details that the student has frequently to wade through a great mass of matter before he can get a clear view of the individual facts he is specially in search of, or of the broad general principles which govern forest administration. Considering the number of educated and intelligent men now employed in the Forest Department of India, we might suppose that some would be tempted to record their experience for the benefit of those who may be working in the same cause. Dr. Brandis's "Forest Flora" is the first trustworthy work devoted to the scientific and economic aspects of the Indian forests, but besides a knowledge of the trees themselves the practical forester requires to know more than a little about the planting and thinning of trees, the transport and measurement of timber, &c., and it is upon these matters that Mr. Amery's "Notes" deal. He points out that Nature's method to foster the growth of the young seedlings is to allow the admission of sufficient light and air. The practice prevailing in Germany is to thin out the young plants at first only lightly to assist germination, then to admit more light to encourage healthy development. "The period between the first thinning and final clearing varies from ten to thirty years. On the plains of India, such is the rapid growth of some of the trees in their earlier stages as compared with the rate of growth in Europe, that it will probably not be desirable to extend the period beyond two or three years; but this difference of conditions does not affect the principle, which is the admission of as much light and no more than is necessary to the well-being of the young crop at every stage." The seedlings of some of the finest timber trees are of so delicate a nature that they have not power to struggle through any kind of undergrowth, even through rank grass: to overcome these difficulties it is recommended that in ordinary grass land the sods should be removed and inverted grass to grass, and the seeds sown on the inverted sod, which should be from five to six inches thick. The advantages of this system are, that the seedling plants are elevated a few inches above the surrounding soil, so that they have no foes to contend with in the early stages of their growth. From these remarks it will be seen that the book is entirely practical, and will, we have no doubt, be consulted by young foresters.

J. R. J.

Nebraska; its Advantages, Resources, and Drawbacks. Illustrated. By Edwin A. Curley. (London: Sampson Low and Co., 1875.)

MR. CURLEY acted as the Special Commissioner of the *Field* to the emigrant fields of N. America, and the present work appeared originally, we believe, as a series of papers in that journal. Mr. Curley has evidently done his work as Commissioner thoroughly, and the present volume is an almost exhaustive account of Nebraska from an emigrant point of view, and we would strongly recommend all intending emigrants to study it carefully. The author sets forth with perfect impartiality all the advantages and disadvantages of Nebraska as a field for emigration, with the result that for those who can command a small capital, and are able and willing to do the necessary work, there is every chance of success. Mr. Curley describes the Geography of Nebraska, and has two chapters of statistics. There is a chapter on the Climate, two chapters on the Surface Geology, and one on the Wild Fruits of Nebraska, by Prof. Aughey. In a series of chapters the author describes in considerable detail the principal districts of the State, and has chapters on Timber and Fuel, the Pastoral Capacities of the State, Co-operative Colonisation, and Land. Indeed, the work seems to contain answers to every inquiry that an emigrant is likely to make, down even to routes, steamship lines, and fares. It is illustrated with many well-executed woodcuts, lithographs, maps, and plans; and even those who have no intention of emigrating will find it pleasant and instructive reading.

A Series of Twelve Maps for Map-Drawing and Examination. By Charles Bird, B.A., F.R.A.S., Science Master in Bradford Grammar School. (London: Stanford, 1875.)

THE twelve maps are Europe, Asia, Africa, North and South America, England, Scotland, Ireland, France, Germany, India, and Australia. They are simple outlines, showing the courses of the chief rivers, the run of the mountains indicated by black lines, and the situation of the principal lakes. The maps, instead of names, are covered with a large number of figures which refer to a copious index at the end. The intention is, that after the student has become thoroughly familiar with the situations of the principal mountains, rivers, towns, and other features of a country, his knowledge should be tested by his being required to fill in, in these or similar skeleton maps, the names corresponding to the figures furnished or pointed out by the teacher. It is also intended to provide a handy method for drawing maps. We believe that if judiciously used, the method here indicated will be of good service for both purposes. The maps are well drawn, and, so far as we have tested them, accurately constructed.

LETTERS TO THE EDITOR

Observation of Cirrus Cloud

I HAVE just received from the Meteorological Observatory at Upsal, Sweden, a number of blank forms (with instructions in English) for observations of the directions of the cirrus cloud. Copies of these forms I shall have much pleasure in supplying to anyone who may be willing to make observations of these clouds, the systematic and extensive observation of which is, as you pointed out in a recent number of NATURE, of such importance in numerous meteorological inquiries.

ALEXANDER BUCHAN, Secretary

Scottish Meteorological Society, Edinburgh, Nov. 2

Mr. Mallet's Paper on Prismatic Basalt

IN a paper published in the *Geological Magazine* for September last, and entitled "Note on Mr. R. Mallet on the Prismatic Structure of Basalt," by Mr. Scrope, that author conceives he has found a refutation of the explanation which I have given of the production of the transverse joints in prismatic basalt in my paper on the subject published in the *Philosophical Magazine* for August and September 1875, and Proc. R. S. 158, 1875. For this he appeals to the features presented by the transverse joints in a group of three prisms stated to be from the Giant's Causeway, existing in the hall of the Geological Society of London. In one of these three prisms it is stated that the convex surfaces of the two top joints point in opposite directions, so that the upper articulation "is found to be biconcave in the fashion of a double concave lens. In another of the prisms the convex surfaces of the joints point downwards, while in the third the convex surfaces point upwards."

I will assume that these three prisms occupy the same relative position with respect to each other vertically that they did when *in situ*, and that Mr. Scrope's description of the jointing is exact, which, however, is not the case; *e.g.*, the top surfaces of the three prisms are not alternately concave and convex, but all are concave, though in different degrees. The entire length of the prisms referred to is about $4\frac{1}{2}$ feet, and the group must have been taken from a mass cooled both from above and below. The phenomena presented by the joints of these prisms do not conflict with the views which I have enunciated. The prisms referred to have come from some portion of the original mass in which occurred the dividing plane between that part cooled from the top and that cooled from the bottom, as is proved by the existence in one of the columns of a joint having surfaces curved in opposite directions; such plane, in fact, passing transversely through the articulation said to be in the form of a double concave lens. Other adjacent prisms may have their joints, within a limited vertical height above or below this plane, either convex upwards or downwards, for the slightest differences in the conductivity or in the conditions and rates of cooling, will suffice either to depress or to elevate in them, by a greater or less degree, the plane already spoken of. It is also not difficult to see that several alternations in the directions of the concave and convex surfaces may occur in the neighbourhood of the meeting plane of cooling in opposite directions, where, as in the case of other divergent or opposite heat waves, more or less confusion in normal structure must occur.

I have not examined the group myself, nor should I care to appeal to such fragments either in refutation or support of any theory. Mr. Scrope's imaginary refutation appears to resolve itself into a confirmation of the exactness of my views, and is the product of his imperfect grasp of the physical conditions involved in the question which he undertakes to discuss. That Mr. Scrope has got but a very incomplete grasp of my views as to the production of the cross-joints in prismatic basalt, is evident from the inaccurate language in which he professes to describe that portion to which he refers, as may be seen by those who take interest enough in the subject to compare his note with my paper (*Philosophical Magazine* for August and September 1875), and more especially from p. 134 to p. 205.

Oct. 18 ROBT. MALLET

Plagiarism

MAY I ask you to allow me a very small portion of your space to anticipate a charge of plagiarism which might otherwise be made against my work on Cave-hunting, by the readers of the article in the *Leisure Hour*, entitled "The Early Geography of the British Islands, by Henry Walker, F.G.S., July 1874," which I now see for the first time.

In this article there is a map (p. 423) so exactly like my own that it is obvious that one is copied from the other, and it might be believed (it has been suggested) that mine was taken without acknowledgment from Mr. Walker, since his was published in July, and mine in October, 1874.

The facts are as follows:—In October 1871 I published a map in the *Popular Science Review*, and this is reproduced, with certain details left out, by Mr. Walker, without allusion to my previous publication. I reprinted my map of 1871 in "Cave-hunting."

Now, I would willingly and heartily allow any map of mine, in which the labours of others are combined with my own, to be used by others without acknowledgment; but that in consequence of this I should be open to the charge of plagiarism, as in this case, I do not feel justified in letting pass without a word as to the facts. W. BOYD DAWKINS

City of Melbourne s.s., off San Francisco, Sept. 16

The Internal Heat of the Earth

On looking over the account, contained in vol. xii. p. 545, of Prof. Mohr's interesting observations on the internal heat of the earth, I found that, according to the law which seems to prevail between the depths of 700 and 3,390 feet, there will cease to be any increase at all in the temperature exactly at the depth of one English mile, or 5,280 feet.

The reason of the discrepancy between this result and that previously given, is to be found in the last entry in your table, where only the upper part of the stratum between the depths of 3,300 and 3,500 feet, is taken, instead of the whole 200 feet, as in the other strata.

The following continuation of the table will make this evident:—

Depth.	Increase per 100 feet
3300 to 3500 feet	0·445° R.
3500 ,, 3700 ,, ...	0·395 ,,
3700 ,, 3900 ,, ...	0·345 ,,
3900 ,, 4100 ,, ...	0·295 ,,
4100 ,, 4300 ,, ...	0·245 ,,
4300 ,, 4500 ,, ...	0·195 ,,
4500 ,, 4700 ,, ...	0·145 ,,
4700 ,, 4900 ,, ...	0·095 ,,
4900 ,, 5100 ,, ...	0·045 ,,
5100 ,, 5280 ,, ...	0· ,,

By adding the various increments of temperature below the depth of 3,390 feet to the temperature there observed of 36·756° R., we obtain 40·81° R., or 123·82° F. as the maximum temperature.

To temperature at		
	3390 feet =	36·756° R.
Add at	3400 ,, ...	·044 ,,
,,	3500 ,, ...	·445 ,,
,,	3700 ,, ...	·790 ,,
,,	3900 ,, ...	·690 ,,
,,	4100 ,, ...	·590 ,,
,,	4300 ,, ...	·490 ,,
,,	4500 ,, ...	·390 ,,
,,	4700 ,, ...	·290 ,,
,,	4900 ,, ...	·190 ,,
,,	5100 ,, ...	·090 ,,
Between	5100 and 5280	·045 ,,
		40·810

There is a further remark called for by the manner of filling up the gap above 700 feet. If we compare the increment given for the stratum between 600 and 700 feet, namely 1·10, with that of the next stratum, namely, 1·097, we get a difference of only 0·003 instead of 0·05, as in all other parts of the table. It would be more in accordance with the lower part of the table if we could proceed thus:—

Depth.	Increase per 100 feet.
Above 100 feet	1·30°
100 to 300 ,, ...	1·25
300 ,, 500 ,, ...	1·20
500 ,, 700 ,, ...	1·15
700 ,, 900 ,, ...	1·097 = 1·10 nearly.

Whether the facts observed will warrant such an extension of the table is a question into which I forbear to enter.

Bradford, Oct. 27 JOHN WILLIS

OUR ASTRONOMICAL COLUMN

40 ERIDANI.—Prof. Winnecke measured, in addition to the well-known distant companion of this star, which is affected with nearly the same large proper motion, two small stars which he calls D and E. It would be interesting to ascertain if these stars are fixed, or if they also follow the principal one in its rapid motion through space, and measures taken during the present season may be expected to decide the point.

The results obtained in 1864 are:—

AD	1864·842	Position	185°·04	Distance	75″·85
AE	,,	,,	312·48	,,	89·45

If we adopt Mädler's proper motions for 40 Eridani, from the Dorpat Observations vol. xiv., or −2″·188 in R.A. and −3″·470 in declination, we find for 1875, Nov. 15, if D and E are fixed—

AD	..	Position	155°·2	... Distance	41″·1
AE	..	,,	336·9	... ,,	107·3

Sir John Herschel had probably in view the physical connection of D and E with their bright neighbour when he suggested that at least a diagram of the relative situation of the small stars near it should be made.

The *comes* B which partakes of the large proper motion of A is itself a close double-star, II. 80 of Sir W. Herschel and Σ 518, and Struve first notified its probable binary nature. Dawes refers to the difficulty attending measures in 1851, but the list of epochs is decisive as to rapid orbital motion. We have for comparison—

Herschel	1783·08	Position	326°·7	Distance	4″—8″
Struve	1825·12	,,	287·7	,,	...
O. Struve	1850·94	,,	160·2	,,	3·93
Dawes	1851·06	,,	160·0	,,	3 ±
O. Struve	1851·50	,,	160·2	,,	3·85
Winnecke	1864·85	,,	147·6	,,	4·46

Dawes estimated the magnitudes of the components 10½ and 11, but there is a suspicion of variability of the smaller one.

PROPER MOTION OF α^2 CENTAURI.—The values given in our catalogues for the proper motion of this star in declination are not so accordant as might be expected if only the more reliable or modern observations are used. Thus the Cape General Catalogue has + 0″·83, the Melbourne General Catalogue + 0″·49.

Perhaps as reliable a figure as any that can be derived from data so far published will be obtained by comparing the declination of the Melbourne Catalogue with that given by the Astronomer Royal's reduction of the observations of the Rev. Fearon Fallows at the Royal Observatory, Cape of Good Hope, 1829-31. With Prof. Peters' elements for precession, this comparison gives + 0″·4399. If we similarly compare with Johnson's observations at St. Helena, we find + 0″·4867. Probably La Caille's declination has been used in working up the adopted Cape value, as on comparing it with the Melbourne declination for 1870, we should have for the proper motion, + 0″·723.

For proper motion in right ascension, the comparison of Fallows and Melbourne General Catalogue gives −0·5235s., and the substitution of Johnson for Fallows alters this to −0·5462s.

THE "ASTRONOMISCHE NACHRICHTEN."—A General Register of the contents of this publication, so indispensable to every practical astronomer, from vols. lxi. to lxxx., by Dr. C. F. W. Peters, is announced (Mauke, Leipsic).

The last number contains the Washington observations of the satellites of Uranus and Neptune during the first five months of the present year, with numerous measures of the position of the companion of Sirius in the years 1873-75; also, remarks by Prof. Asaph Hall on the determination of the mass of Mars from perturbations of the minor planets, in which Massalia, Echo, Beatrix, and Peitho are mentioned as the planets best adapted for this purpose. Magnifying powers of 610 and 890 were generally used for the satellite-observations, but on a few occasions one of 1,290 was employed; the companion of Sirius was generally measured with 400, all the observations being taken with illuminated wires in a dark field.—The death of Dr. August Reslhuber, so long director of the Observatory at Kremsmünster, is announced.

A NEW PALMISTRY

DR. ALEXANDER ECKER, the well-known authority on matters prehistorical, as well as Professor of Comparative Anatomy in Freiburg, Baden, contributes to

a recent number of the periodical, of which he is a joint editor, a most suggestive paper, entitled "Some Remarks upon a Fluctuating Character in the Human Hand." * As the line of research is somewhat uncommon, and may, for aught we know, be productive of important results, the substance of Prof. Ecker's paper is here presented to English readers in an abridged form.

Henle, in his work on Anatomy, has made the observation that people have very vague ideas about objects even which are assumed to be well known; *e.g.* the query is often put, How many feet has a crab? or, How many toes has a cat?—questions which receive most varying answers even in well-informed and educated circles.

If, then, the question be put in the company of half a dozen people, which finger is the longest—the index (forefinger) or the "ring" (fourth) finger?—the query can but seldom be answered before the members in question have been looked at. It seems, further, very probable that the authors of well-known anatomical works have laid down as being the rule that which they have observed on their own hands, so that we are enabled to tell in what respect, as to digital arrangement, such and such *savant* is endowed. For instance—Weber says that the "ring" finger is only slightly shorter than the index; Carus holds that the latter digit is shorter than the ring finger; Henle is of the same opinion; while, according to Hyrtl, it is the index which comes next to the middle finger (the longest) in length; and Langer, lastly, says that the index is generally shorter than the "ring" finger, but that there are individuals in whom they are nearly of the same length.

Have these variations a morphological significance or not? For the solution of this, answers to the following questions are necessary:—

(*a*) How are the animals which come next after man, in other words, the apes, and especially the anthropomorphous apes,† off in this particular?

(*β*) What is the case with the lower races of mankind in the same particular?

(*γ*) What is the most usual digital arrangement in this respect among the European races of man? and lastly,

(*δ*) Which proportion of the two digits in question has been accepted as the most beautiful and symmetrical, and either knowingly or unknowingly adopted in art?

1. With regard to the Ape, the index is—and often considerably—shorter than the "ring" finger. The difference in length is much more considerable in the Chimpanzee than in the Gorilla; the greatest difference, that of 20 mm., having been found in the cast of a hand of a male Chimpanzee.

2. Drawings—made by placing the hand upon paper, the axis of the middle digit coinciding with a straight line at right angles to the front or hind margin of the paper, supposing the latter to be a parallelogram, and then following the outline of the fingers with a pencil—were made of twenty-five male and twenty-four female negroes, with the following result:—

(*a*) Among the males twenty-four had the "ring" finger longest, the average difference being 8 mm., while in the remaining instance both fingers were of the same length.

(*b*) Out of the females the "ring" finger was longest in fifteen, the difference varying from 2 to 14 mm.; in three the fingers were of the same length; while in six the index was the longer, the difference being from 2 to 6 mm.

Prof. Ecker has further found the "ring" finger longest in casts and in several photographs of the hands of negroes; but in the hand of a "Turco" negro the index was the longer of the two digits. In photographs of a Hottentot and of an Australian female, the "ring" finger was the longer, while in a photograph of a female Sandwich Islander the reverse was the case.

* "Einige Bemerkungen über einen schwankenden Character in der Hand des Menschen." *Archiv für Anthropologie*, viii^er Bd. s. 67.

† Such as the Orang, Gorilla, Chimpanzee, and Gibbons.

3. As for Europeans, no conclusions have as yet been arrived at; but it appears probable that there is a relatively greater length of the index finger in the female than in the male sex; and further, among the latter, in the slight and highly developed, than in the short and underset.

4. Lastly, as regards Art. In that which is left to us of the productions of the ancients, there are variations in the relative length of the two digits, though it appears that the index finger, and especially so in the female, ought to be the longest. In the Dying Gladiator the index (of the left hand supported upon the knee) is the longer; while in the Apollo "Belvedere" (right hand) there is no appreciable difference. In the Venus "Medici,"* in the Venus "pudica" of the Gallérie Chiaramonti, in Rome, as well as in the Venus by Praxiteles, in the Vatican, the index is obviously the longest. In modern art there seems to be no evidence of rule or canon; among painters, for instance, there being, it appears, no fixed tradition on this point. In Schadow's "Polyklet, oder von den Maassen des Menschen nach dem Geschlecht und Alter" (2^te Aufl. Fol., Berlin, 1867) no rule is laid down. In the extended hand of a powerful man, by Albrecht Dürer, the "ring" finger is the longest.

It is not probable that a difference in the length of the fingers in question is a merely individual, so-called chance (zufällige) variation, for the reason that the whole form of the hand is in relation with this. In the variety of hand termed *elementary*, by Carus ("Ueber Grund und Bedeutung der verschiedenen Formen der Hände in verschiedenen Personen;" 4to., Stuttgart, 1846), the index is shortest; in the *motor* variety the difference is not considerable, the index being slightly the longer; in the *sensible* form the index is longer, but not much so; while in the *intellectual* (seelische) this finger is considerably the longer. The opinion just given is further supported by the fact that in the Mammalia the length of the various digits is very constant.

It may be concluded, then, that—

a. In the Apes as yet examined, the difference being least marked in the Gorilla, the index finger is the shorter.

β. In Negroes, also, the index appears to be the shorter. No sexual difference can as yet be established.

γ. In Europeans the variation is so great that at present no rule can be laid down.

δ. When a great artist has attempted to represent a beautiful and ideally perfect hand, he has never made the index strikingly shorter than the "ring" finger.

May it then not be possible,—

1. That an index relatively longer than the "ring" finger is the attribute of a higher form of beauty? †

2. That here, as in many other particulars, the female form appears to be morphologically the purest?

The longest and least mobile finger is the middle one; the shortest, and most capable of motion, is the thumb, or "pollex;" next in order in the scale of mobility come the little, "ring," and lastly the index, or forefinger.

The question which Prof. Ecker has here raised, and into which he intends to inquire further, may appear to some trivial and unworthy of serious study; but, far from this, the satisfactory solution of it will, there is but little doubt, be of the greatest interest not only to the philosophical anatomist, but also to the sculptor and painter who would fain go a little below the mere surface of his art. It is certainly a subject in which, were they yet alive, such men as Goethe and Winkelmann would take the deepest interest.

JOHN C. GALTON

* The famous Medician Venus has been said to be a copy by Cleomenes, a son of Apollodorus, of the Venus of Cnidos, by Praxiteles. *Vide* Winckelmann's "Geschichte der Kunst des Alterthums."—J. C. G.

† The hands of the writer are, unfortunately, specimens of the lower type, each index being considerably shorter than the "ring" finger in the same series. It is a curious fact that in each hand the radial artery at its termination, instead of plunging beneath the volar muscles, takes a superficial and somewhat dangerous course as far as the skin web which passes from the pollex to the index. It would be interesting to know whether these phenomena are correlative or not.

SCIENCE IN GERMANY

(*From a German Correspondent.*)

HERR NEESEN, assistant to Prof. Helmholtz, has recently published a memoir on the phenomena of attraction and repulsion by light and heat-rays, observed by Mr. Crookes. He states in it that he had already for two years observed such phenomena, which at first seemed to be a case of mechanical action of light-rays, *i.e.* of the effect of their impinging and rebounding on the surface of a mirror suspended by a cocoon-fibre. He now thinks, however, from the experiments he has made, that the effects of light and heat-rays in question are to be regarded as merely produced through air-currents arising from heating of the air in certain parts of the apparatus in which the movements of the mirror take place. Neesen first shows that in the phenomena observed such air-currents have, in fact, influence. He used for his experiments a rectangular case of sheet iron, in the upper cover of which was a peculiar arrangement for hanging a cocoon fibre. In the lower part of one of the sides of the case was a rectangular aperture closed by a plāne parallel glass plate, and behind this plate was the suspended mirror. The air-currents above referred to arise not only from the fact that the air in contact with the glass plate through which the light must pass to reach the mirror, or the air in contact with the mirror, is heated. The air-particles also between glass plate and mirror are heated by conduction of the heat; and so, by their heating also, air-currents are produced which tend to turn the mirror.

In favour of Neesen's explanation are the facts (1) that the movements of the mirror always decrease when the air in which it is enclosed is rarefied; and (2) that these movements also become less if adiathermanous substances (*e.g.* a column of water) absorb the light-rays before these can reach the mirror.

The considerations which seem to be against this explanation are the following:—(1) The reversal of the movement, observed by Mr. Crookes, on a certain small air pressure being reached; (2) a fact appearing from Neesen's own experiments, viz., that according as the direction in which the light-rays fell on the mirror was varied, was the direction of rotation of the mirror changed, though the light fell on the same part of the mirror. Both these peculiarities, however, may also be explained by air-currents. First, as regards the fact observed by Neesen, it is clear that, according as the lamp is placed to one side or the other of the mirror, different parts of the glass plate in front are heated, and different parts of the air-layer between glass plate and mirror; and accordingly the currents and the rotation of the mirror must have an opposite direction. To explain the reversal of the motion on a certain low pressure being reached, Neesen calls to mind that the conductivity of air for heat, as Kundt and Warburg have shown, decreases with extraordinary rapidity on decrease of pressure (well observed with low pressures); so that with as perfect a vacuum as possible, it entirely disappears, and only radiation of heat remains. Now, as long as the heat is conducted, the air-particles conducting the heat are themselves heated. On the other hand, no such heating takes place when the heat passes only by radiation. That with such very different conditions the currents may be different is probable in a high degree. W.

MÜLLER ON BEES AND FLOWERS*

IN this communication Dr. Müller calls attention to the interesting facts presented by various groups of Hymenoptera, in which we find a series of forms presenting more and more complex life relations, accompanied by a higher and higher mental organisation. The consideration of these gradations is calculated to throw much light on the question, "How has the Honey Bee acquired its remarkable instincts?" a question which the study of that species alone would, in his opinion, do little to solve, but on which the habits and organisation of other groups throw much light. The Sawflies (*Tenthredo*) are amongst the lowest of Hymenoptera. They merely choose a plant of the species on which they have themselves lived, cut a hole in the leaf with their curious saw, and deposit therein an egg. The young larvæ thus find themselves on their food and live like ordinary caterpillars, which in general appearance they much resemble, and like which they are exposed to destruction by various enemies.

Passing on to the Gall Insects (*Cynips*), we meet with a new mode of life which is very instructive. The incision made in the plant by the Sawfly causes little abnormal growth, while in the case of the Cynipidæ, on the contrary, it gives rise to the well-known galls.

Some species, however, pierce not plants, but animals, and have thus opened out for themselves many more possibilities of existence, since there is scarcely any group of insects which is free from these attacks; neither the thick-skinned beetle, nor the active and powerful wasp, nor the woodboring larvæ of Cerambyx, nor even the aquatic larvæ of the Phryganeas.

This passage from phytophagous to carnivorous habits has not only led to the formation of many new species, but also to a greater complexity in the relations of the parents to their young, and to a higher intellectual development, which is shown especially in the arrangements made for the nourishment of the larvæ, since it certainly requires both greater energy and more intelligence to discover and attack a particular species of insect than merely to lay an egg on the plant which has served the mother herself for nourishment. The passage from the gall insects to these insect-piercing species must, in M. Müller's opinion, have been slow and gradual. The genus Synergus, which deposits its eggs in the galls of the true gall insects, constitutes, perhaps, a link between the two groups.

On the basis of this increased energy, intelligence, and adaptability, certain groups then made a still further advance by which some of the drawbacks incident to such a mode of life were avoided. For it of course frequently occurs that caterpillars and other insects in which these insect-piercing Hymenoptera have deposited their eggs, are devoured by birds or other enemies. Certain species, however, meet this danger by transporting their victims to a place of security. To effect this, however, certain conditions are necessary. The aggressor must be sufficiently large to overpower his victim, but the latter must not be killed, or it would decay and thus become unsuitable for food. Dr. Müller considers that many insect-boring species have probably endeavoured to secure their prey, but have under these circumstances found it impossible to do so. Thus, the ovipositor of the Tenthredo became the sting of the wasp, and thus those species which carried off their victim to a place of concealment would abandon the habit of laying their eggs inside the victim. Dr. Müller expresses the opinion that the various proceedings by which the solitary wasps thus protect their young against contingencies to which the insect-piercing species are liable, must have at first been arrived at with a consciousness of the object to be effected, but that they have gradually become instinctive, and are now unconsciously inherited from generation to generation. Still it is, he observes, impossible to watch a wasp at work without feeling that, with these inherited customs, or so-called instinct, much individual effort also comes into play. Dr. Müller proposes to discuss this interesting part of the subject in detail in a future communication. J. L.

* "Die Bedeutung der Honigbiene für unsere Blumen," in the *Bienen Zeitung* for July 15.

FAYE ON THE LAWS OF STORMS*

Mechanical Identity of Waterspouts and Eddies.—The question then is reduced to this, viz., whether, when in the middle of the most profound calm these destructive waterspouts are seen to appear, the form of which corresponds so well to the eddies formed in streams of water, we can point to any current by which the phenomenon has been originated. Now this is precisely what we intended to set in strong relief in describing the general currents of the atmosphere. The counter-trades clearly show that there exist above our heads unmistakable currents of air in motion. Without even recurring to considerations of this nature, it is enough to cast our eyes over the heavens on the appearance of a waterspout, in order to see by the march of the clouds that in spite of the calm below, powerful horizontal currents prevail aloft, which, as their different parts cannot advance at the same rate, must consequently give rise to whirling movements of a more or less decided character. If one of these whirls meet with the favourable circumstances so often seen in water-streams, it will be regularly developed by taking the form which analysis assigns to it; by its downward movement it will even penetrate through into the calm strata, the resistance of which will gradually alter its form and its course, and end by reaching the ground. This simple notion of the mechanical identity of gyrations, whether of liquids or gases, furnishes at once the explanation of phenomena which meteorologists have laboured to find in an entirely different range of ideas. Waterspouts contain powerful forces in action, because they draw the force from a medium above, where it is in abundance; they march onwards because they follow the current which originates them; at their base they are slightly curved, not forwards but backwards, because the comparatively still medium they traverse offers a certain amount of resistance; they act nevertheless in the same manner both on the ground and over water, whatever be the curvature of the conical tube which descends from the clouds, because this curvature never interferes with the direction of the axis of rotation of each spiral, but only with the succession of these spirals in space, &c.

This identity of waterspouts in air and of eddies in water, which is so complete in a mechanical and geometrical point of view, is no longer to be looked at altogether from the physical standpoint, on account of the differences which in this respect exist between water and gas. Indeed, the temperature of a stream of water is almost the same at all depths; in the air, on the contrary, heat decreases markedly as we rise to the higher strata. Further, the moisture of the air is liable to be condensed for a fall of temperature often very slight. Thence the cold air of the high regions, drawn gradually downward by the whirling movement into the low and moist strata, generates a thin mist all round the waterspout. This mist serves as an outer envelope or sheath, the form of which is more or less sharply marked, being rendered visible by its opacity. There is no doubt that the air in its descent is subjected to an increasing pressure and gradually rises in temperature; but it is lower than the temperature of the surrounding air, and it is enough if it falls to the dew-point of the general mass of air surrounding it in order that the nebulous sheath may be immediately produced. If the difference of the two temperatures is insufficient, or if the humidity is too low in any particular stratum, the misty sheath will not be formed, and the waterspout will in part be invisible. None the less, however, will it be there, though it seem cut in two, or appear only in its upper part in a truncated form. This is the appearance so often presented by waterspouts at their commencement, when the upper and lower portions are seen, but not the intermediate portion. Soon these detached portions meet, the outside sheath completing itself as the stratum traversed by it becomes slightly more humid, or as the air whirled more rapidly downwards by the waterspout becomes slightly colder than the air it meets.

Just as happens in the case of the water which gradually descends down an eddy in its whirling course, the air, which gradually descends with a violent whirling motion down the waterspout, escapes from it on coming into contact with the ground, and thereafter rises again in an irregular manner outside the waterspout. But the volume of air which enters into ordinary waterspouts is far from being sufficient to give rise, at a distance, to a wind of any appreciable force; it is only in proximity to and immediately around the base of the waterspout, where this irregular upward movement of the air manifests itself by the ascent of the dust or spray already raised by the lower spires of the meteor. The base of the waterspout is then enveloped in a sort of confused cloud ceaselessly renewed, unless the end of the waterspout ceases to reach down to the ground. This is especially the case when a waterspout suddenly meets a valley in its course; its lower end goes on lengthening, and with little delay is again joined with the ground; but if the movement of translation is too rapid, it will not resume its destructive work till it has cleared the valley and gained the opposite higher ground. Thus in gases as in liquids, whirling movements observe exactly the same laws. The idea is simple and clear: let us, then, without hesitation, put it in place of that of an aërial column with boundaries formed doubtless of misty vapour, but really treated as solid and impenetrable like the crystal spheres of antiquity, through which the cloud draws up the water of the sea, trees, and other objects; or, to put it differently, through which a centripetal updraught violently draws skywards sea-water, trees, &c. In accordance to our idea, all becomes clear and simple in the history of waterspouts; with prejudice, on the other hand, all remains astounding, incomprehensible, and contrary to the simplest notions of mechanics. There, are, however, two points of detail yet to be discussed: we have to return to the appearances from which eye-witnesses have drawn such remarkable conclusions, and to the part played by electricity, a force which meteorologists, till quite recently, were always so ready to resort to in the explanation of phenomena.

As the purely physical appearances of waterspouts differ widely from each other, some have failed to observe the slightest trace of an internal movement; others have attributed to them a descending movement without rotation; and lastly, others, and these the most numerous attribute to them a whirling ascending movement. A little reflection easily explains these contradictions. What is seen and what is related by eye-witnesses whose impressions are vitiated by old-standing prejudice, has no reference to the waterspout itself, which, like air, is transparent and invisible, but to its external envelope of mist, which is more or less opaque. The envelope is exterior, we repeat; it does not therefore partake in the internal gyrations, which, moreover, are too rapid to be visible. Only the surrounding air which is brought into contact with the waterspout is rapidly drawn from some distance by lateral communication with the whirling movement, the result of which is a sort of whirling or spiroidal agitation in the outside sheath of the waterspout. The degree in which movements of this sort favour illusion is well known. It is thus that the slight movements of the cilia of rotifers have the appearance of a rapidly revolving wheel, and the simple rotation of a spirally-cut cylinder of glass produces the impression of a flowing stream of water. Further, the air which is thrown out at the base rises again outside the waterspout. The aqueous vapour imperfectly condensed in the outside of the sheath has itself an ascending tendency sufficient to raise some of the small cloudlets of mist found there. Here are the real movements, complex and changing, but slow enough

* Concluded from vol. xii. p. 538.

to be visible. The illusion of the observer lies in attributing to the interior of the waterspout the movements which really take place round and outside its exterior margin.

The part played by electricity has been thus stated by Peltier, who supposed he had detected traces of this force in the well-known waterspout of Monville. The sheath of vapour is in some sort a continuation of the electrically-charged clouds; it forms a long conductor of about eight hundred feet between the clouds and the ground, a conductor doubtless very imperfect, but on a great scale, and capable of affording to some extent a passage to the electricity. It is, however, far from being comparable with the destructive characteristics of the thunderbolt. The way in which trees overturned by whirlwinds are sometimes broken up has been recognised as resembling more or less that of trees struck by lightning and shattered into splinters; but this effect is only the result of the violent torsion exerted by the gyratory movement of the whirlwind, and not of the sudden passage of an electrical current. Men and animals have often been caught by whirlwinds and injured, without ever experiencing the least electrical shock.

Thus the essential characteristic of these remarkable movements which produce waterspouts or great tornadoes is a circular gyration, the spirals being slightly inclined to the horizon. Wherever you make a section of it, you only find there concentric circles with the radii always converging towards a centre. In representing them geometrically you need not hesitate between the circular diagrams of Reid, Redfield, and Piddington, and the diagrams with converging rays of some learned meteorologists, the victims of a hypothesis and old prejudice. The former diagrams reproduce the mechanical phenomenon in its essentials; the latter answer to a mere illusion which a little reflection should ages since have exploded.

Extension of this Identity to Cyclones.—The last step only remains to extend these conclusions to great tornadoes, that is, typhoons, and lastly to cyclones, which often overspread a vast extent of territory. It is one of the characteristic properties of the eddies generated in currents of water, that they are formed on every scale, even the largest, without undergoing any essential change. Eddies may be a few inches in diameter, a few yards, a few furlongs, or even of still larger dimensions; it is the breadth of the currents where they are generated which alone limits their size. In the ocean there are gyrations on a still vaster scale, or even on a scale altogether colossal, such as the vast currents of the Atlantic which circle round the calm region of the Sargasso Sea. The sun presents the phenomena of whirling movements still better defined and of all dimensions, from large openings equalling our cyclones, even to those large spots which are five or six times greater than the earth itself. In like manner, in the whirling movements of our atmosphere are found small, short-lived eddies of a few feet in diameter, whirlwinds and waterspouts, which last longer, from 10 to 200 yards across, and tornadoes from about ½ to 1½ mile in diameter. Beyond this the eye cannot take in the forms of the whirling columns; these receive another name, but in all essential points they remain the same. When the dimensions are still greater, the diameters measuring 300 miles and upwards, they bear the name of hurricanes or cyclones; but notwithstanding this, their mechanism remains unchanged. They are always gyratory, circular movements increasing in velocity as they near the centre; are generated in the upper currents of the atmosphere, through the inequalities of their velocities; are propagated downwards through the lower strata in spite of the calm or independently of the winds which there prevail; ply their destructive energy when they reach the obstacle offered by the ground; and follow in their march the upper currents, so that the track of their devastations marks out on the surface of the globe the route of the viewless currents of the upper regions of the atmosphere.

There is, however, a difference between whirlwinds and tornadoes on the one hand, and typhoons and hurricanes on the other. As regards the former, note in the first place, the upper portion (*embouchure*), which is a sort of truncated cone inverted and very much widened out above, and in the second place the descending column which prolongs the meteor even to the ground. If the atmosphere was a gaseous mass of air of indefinite height like that of the sun, cyclones would always present these two features. As regards cyclones, however, the ground is very near in proportion to the extent of area they cover, and is reached before they can be subjected to the prolonged contracting process seen in waterspouts and whirlwinds. A cyclone is then a vast whirlwind, but reduced by the obstacle offered by the ground, to the upper part, or to what may be called the funnel-shaped portion of the phenomenon strictly so called. Thence, doubtless, the constant presence in the former of a calm space about the centre, of which the analogue is to be found only in the circling movements of the ocean on their grandest scale; and thence also certain important peculiarities of cyclones to be more particularly insisted on, after having examined the movements of translation of these phenomena.

Course of the Upper Trade Winds.—When the attention is directed to whirlwinds which appear most frequently to be accidental phenomena of short duration and merely superadded to other phenomena of a more general character and much more lasting, it must be allowed that the short lines marking out their course have scarcely been studied from a geographical point of view. These lines probably follow no simple law. In this respect it is otherwise with cyclones; their course recurves, as we saw at the beginning of these articles, on the globe in accordance with a particular law the constancy of which Fig. 2 (vol. xii. p. 402) reveals at a glance. From this chart, the upper currents, whence cyclones derive their origin and mechanical power, do not proceed directly from the equator to the poles. They are deflected at the outset toward the west, then toward the east, thus describing over the surface of the globe parabolic curves whose apices lie somewhere within a few degrees of the polar limits of the surface trade-winds. Clearly these upper currents, which are true aërial rivers, ought to form a part of the upper trades whose existence is assumed, but their actual course is not directly known. If this assumption be correct, then Fig. 2 presents at once the projections of the double system of trades and counter-trades over both hemispheres; and it only remains to explain the singular recurving course taken by the upper trades. This explanation we shall attempt, though the question lies a little out of our way.

If the atmosphere were withdrawn from the influence of the solar heat, it would remain in equilibrium; its successive strata would arrange themselves according to surfaces of level, and would become part and parcel, so to speak, of the solid globe itself; at least it would, even as regards the highest strata, exactly follow the earth's rotation. The effect of the solar heat is constantly to disturb this equilibrium, by the introduction of movements which are the more curious inasmuch as they do not essentially destroy the normal stratification of the strata of the atmosphere. The air incumbent over the hemisphere actually facing the sun is expanded in its lower strata, where the opacity arising from dust floating in the air, and above all the aqueous vapour, absorbs a large part of the heat-rays of the sun. The intervention of this aqueous vapour which ascends vertically from stratum to stratum, has in a special manner the effect even of rendering the diurnal variation of temperature perceptible at heights at which it would not be felt if the air was dry. The maximum of

this general dilatation in the torrid zone takes place under the vertical rays of the sun. In this manner the centre of gravity of the lower strata rises vertically; these raise the strata above them, which being specifically lighter, dry and transparent, are consequently less sensitive to the sun's rays. All the strata in succession, thus thrust upward above their surface of normal height, tend to flow with accelerated motion along these surfaces in the direction of the two poles, where the temperature is relatively low. This effect is still further increased by the peculiar march of the aqueous vapour which is principally condensed about the poles, whence it returns to the equator by another way than that of the atmosphere, viz., along the surface of the earth in the liquid state.

The atmosphere cannot exactly follow the diurnal rotation. A half of its mass, or from about 30° lat. S. to 35° lat. N., lags somewhat behind, since all the molecules in this region being thrust upward describe circles continually increasing in size with the linear velocity from the lower level from which they started in their ascent. To this retardation must be superadded that of the surface trades resulting from their general flow towards the equatorial region. Beyond the tropics, on the contrary, in the temperate zones where the air advances into parallels of latitude continually diminishing in size, the other half of the atmosphere flows in advance of the earth's rotation. Towards the polar circles this advance is converted into a circling movement round the two poles from west to east.

The unequal distribution of land and water over the globe modifies this general aërial current, so that it does not flow on in one current, but is broken up into many currents—the equalities of the surface throwing the current of the counter-trades into several currents more or less distinct from each other. We can easily imagine the behaviour of the counter-trades by combining their march toward the poles with the two opposite transverse tendencies of which we are about to speak. Between the tropics, the resulting currents do not blow straight to the equator, but wear round more toward a westerly direction. Beyond the tropics, they do not blow directly toward the poles, but take a course inclined more to eastward. The two following figures will explain our meaning:—

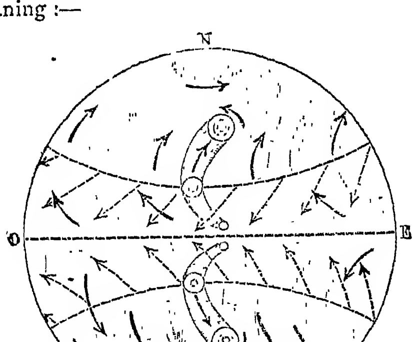

FIG. 13.

Fig. 13 represents the whole upper currents for both hemispheres on a projection of the meridian; and Fig. 14 for the northern hemisphere on a projection of the equator. The dotted arrows mark the surface counter-currents; in other words, the trade-winds blowing obliquely towards the equator, making nearly a right angle with the upper trades of the torrid zone. A slow whirling movement may also be seen around both poles resulting from the counter-trades. These really exist, for the meteorologists of the United States have recently described them under the name, a little fanciful, perhaps, of polar cyclones.

The aërial rivers which are marked out in the midst of these great movements, by which the equilibrium, incessantly disturbed, tends constantly to re-establish itself, exhibit then precisely the course which we have recognised as a peculiarity of the trajectories of cyclones, whilst the surface-trades have no relation to these same curves showing the courses of cyclones. This agreement is a further proof that cyclones must have their origin in the upper

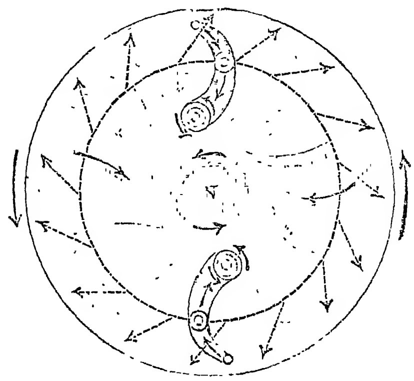

FIG. 14.

regions of the atmosphere, and thence descend even to the ground, and in doing so traverse strata of air either calm or in motion, in such a way as to be totally independent of the cyclone—a state of things incomprehensible on any other hypothesis that has yet been advanced. As to the direction of rotation of cyclones, it results from it that, in these currents strongly recurved, the velocity goes on diminishing transversely from the concave side to the convex side. The zone of calms would then no longer accord with the phenomena of an ascending updraught, but with a maximum of dilatation to the right and to the left of the place where the movement toward the poles commences. Lastly, the mean velocity of these currents, feeble at first in the neighbourhood of the equator, would go on accelerating just as the velocity of translation of our cyclones.

Segmentation of Cyclones.—Whatever may be thought of these opinions regarding the march of the upper trades, of which the surface-trades are the counterpart, it is impossible to doubt that cyclones take their origin from these currents. Let us then look more closely at these gyratory movements. If the maximum height of these trades be from 33,000 to 40,000 feet, and the lower diameter of the gyratory movements, or cyclones, where they meet the ground, from 120 to 180 nautical miles, it will be seen that cyclones must have a figure very different from waterspouts and tornadoes, whose proportions are altogether different, since the height of these last is enormously disproportioned to their lower diameter. Piddington was therefore right in comparing cyclones to mere whirling discs. It would however be more correct to regard them as waterspouts reduced to their upper funnel-shaped portion, or deprived of their slightly conical column, which descends even to the ground. As it advances, the generating current is lowered a little; the vertical height of the cyclone is thereby as much diminished, its section enlarges by contact with the ground, and the disc becomes even more flattened out.

This being granted, if any whirling movement encounters resistances, or if the general current exhibits differences of velocity in different places, it is in the upper regions of the atmosphere especially that these disturbing causes will act most powerfully on the phenomenon, because the velocities are there less, and the distances traversed by the currents enormous. Below, on the other

hand, where the column is narrowed to a very great extent, and where the velocity of the gyrations is excessive, the obstacles met with exercising little influence, are instantly reversed or overcome. Waterspouts acting by the lower extremity, at a distance from their funnel-shaped top (*embouchure*), undergo no change; but cyclones will not withstand the forces brought into play so easily.

Let the modifications thus induced by external causes be what they may, the preceding theory shows that they are possible, and that the rigorously circular movement enunciated by the authors of the "Laws of Storms" allows of perturbations more or less local, and more or less marked, for the simple reason that the whirling movements, which in the case of cyclones are reduced to their upper portions and are therefore little more than mere discs, are very easily modified. It is this, moreover, which explains the deviations from the rule that are found in even the earliest writings of the authors of the "Laws of Storms," as, for example, in Fig. 1 (vol. xii. p. 401), representing the Cuba hurricane, where, notwithstanding the general agreement of the arrows showing the wind with the purely circular theory of storms, there also occur several local deviations.

What can these perturbations be? How can a gyratory movement be changed under the influence of a given external cause? What happens if the velocities of the generating current undergo local changes? It would be as difficult to answer these inquiries *à priori* as it would have been to foresee, before the development of the mechanical theory of solid bodies, the astonishing results of an external force brought to bear on them; but the study of other whirling movements more within the reach of observation, and directed to the sun, has shown that a cyclone is not arbitrarily deformed in any manner whatever. Segmentation, or breaking up of the cyclone, is the last term of the alterations which it can undergo. Then the fragments into which it is broken up tend to assume the form of cyclones, each as perfect as the one from which they were formed, and they follow routes differing but little from each other and describing nearly the same trajectory, but at a distance from each other. This segmentation of cyclones occasionally occurs in the case of the thunderstorms which advance on France from the Bay of Biscay, of which the thunderstorm of the 9th of March, 1865, so well described by M. Marié-Davy, may be cited as an example. A like process of segmentation cannot take effect unless the primitive cyclone in some part and for some time deviate from its rigorously circular form. The tendency to keep this form maintains the ascendency sometimes, but if it begins to give way in a large cyclone, the result is a breaking up of the cyclone itself into segments.

It would be easy to adduce numerous cases in which whirlwinds, tornadoes, and cyclones appear in groups about a given point, or at least follow each other with rapidity. The evidence all goes to show that they are most frequently the result of the phenomenon of *segmentation*, so called from the term used in natural history to designate the process by which some of the lower animals are divided into segments each of which soon becomes a complete animal of itself. But it is in solar cyclones where this mysterious operation can be best followed step by step. Thus a circular sunspot may be seen gradually undergoing the process of deformation, then breaking up into parts, and ending by giving birth to other spots, which precede the original one in a row and at some distance, proceeding at the same pace and reproducing on a small scale the features and behaviour of the primitive type.

Conclusion.

The laws of storms, the statement of which in absolute terms ignores the modifications we have indicated, are therefore in reality only an approximate enunciation, just as are Kepler's laws, to which we have more than once compared them. Kepler's laws would be rigorously exact if we could leave out of account the action of the planets on each other and on the sun; but this being impossible, these laws are not an adequate expression of the truth. The same holds good with respect to the laws of storms. They would also be exact if the currents of the atmosphere never exerted any disturbing action, and as the laws take no account of these disturbing actions, and do not give the means of foreseeing them, or at least of measuring their effects, it would be a mistake to apply them blindly in practical affairs.

It was not by substituting the *cassinoïde* for Kepler's ellipse that science made progress; in like manner it will not be by the substitution of centripetal diagrams of storms for circular diagrams that navigation will be rendered safer. If we have succeeded in giving the true theoretical interpretation of these laws, it must be granted that the time has not come to abandon them, but rather to make them more complete.

To sum up, there are no centripetal waterspouts, whirlwinds, typhoons, or cyclones. The *moveable* forces of aspiration formed, as is said, over the heated ground of the tropics, do not transport themselves with their accompanying updraught to a distance of 700 or 800 leagues over the cold soil of high latitudes, and they have never determined the whirling movements of our atmosphere. The Laws of Storms are in general accord with the mechanical theory of these movements. The rules of navigation which are deduced from them, merit in ordinary cases the confidence sailors have had in them for the past thirty years. The exceptions should be only regarded as mechanical disturbances of the gyratory movement, the further study of which seems destined to complete a first and happy approximation to the truth. The discovery of the approximate laws of storms is one of the finest scientific conquests of this century, and if a closer approximation is to be made, it will be by a more careful study of solar cyclones.

Formerly whirling movements played an important part in our general conceptions of the universe. Fallen into disrepute by a very natural reaction from a false idea, they have been too much forgotten; therefore when at a later period a gyratory character was recognised in the great movements of the atmosphere, an effort was made with one consent to connect them with totally different causes. Geometricians seemed to class them among those irregular movements of which nothing could be made. We see, however, that movements of the cyclonic order constitute in truth a vast series of regular and stable phenomena, of which their perturbations even exhibit a behaviour in accordance with geometric principles. This series which begins with simple eddies in our streams of water, embrace the most singular as well as the most dreaded phenomena of the atmosphere, together with the vast movements which observation reveals in the sun, and extends even to the nebulæ, the structure of which Rosse's telescope has proved to be characterised by whirling movements. It is therefore most desirable that the theory of these movements should be again included in the domain of applied mechanics. The first step to this end is an empirical investigation of their laws, and this work the eminent authors of the "Laws of Storms" accomplished thirty years ago.

NOTES

Two members of the British Ornithologists' Union, Messrs. Harvie-Brown and Henry Seebohm, have recently returned from a most successful expedition into Northern Siberia. Leaving this country early in the spring of this year, they arrived at Ust Zylma, on the Petschora River, in the middle of April, after travelling overland from Archangel. They remained there

until the breaking up of the ice in the beginning of June, when they took boat to Alexievska, and made this their head-quarters for some time. Of the most important ornithological acquisitions amongst more than 1,000 skins, are the young in down together with the eggs of the Little Stint and Grey Plover, the eggs (for the first time) of Bewick's Swan, the eggs of *Sylvia middendorfii* and *S. borealis*, the eggs of *Motacilla citreola*, the eggs of the Smew, and a new species of Pipit. These specimens will be exhibited by Mr. Seebohm at the next meeting of the Zoological Society on the 16th instant.

THERE are three professorships in Trinity College, Dublin, which, by the School of Physic Act (40 Geo. III., chap. 84), become vacant at the end of every seventh year from the date of election; but it is also provided that every professor should be capable of re-election. The three professorships are those of Anatomy, of Chemistry, and of Botany. Pursuant to notice in the London and Dublin *Gazettes*, we learn that the latter of these will be vacant on the 23rd of January, 1876, and that on Saturday, the 29th of January, 1876, the Provost and Senior Fellows will proceed to the election. All candidates are required to send their names, with the places of their education, the universities where they have taken their degrees, to the Registrar of Trinity College, Dublin, before the 22nd January, 1876, and for further information are to apply to the Rev. Dr. Haughton, F.R.S., Medical Registrar of the School of Physic. The emoluments of the professor consist of 300*l.* a year, for which he is required to deliver, first, a course of lectures on Botany in the Arts School during each of the three college terms. Michaelmas Term commences early in October, and Trinity Term sometimes lingers on until the month of July. Secondly, a course of not less than forty lectures on Botany in the Medical School, commencing on the 1st of April and ending on the 1st of July in each year. As Curator of the College Herbarium, there is an additional salary of 50*l.* per annum. The professor being his own assistant, the whole work of arranging and sorting this well-known collection, as well as the correspondence incidental to such a charge, falls on the Curator. The fees average, we are informed, a sum of about nine guineas a year, as the lectures are free to all students of the University. The present Professor, Dr. E. Perceval Wright, being eligible, is a candidate for reappointment.

HIS Excellency the Lord Lieutenant of Ireland has been pleased to appoint Dr. John James Charles to the chair of Anatomy in the Queen's College, Cork, vacant by the resignation of Dr. Corbett. Dr. Charles was a pupil in the Queen's College, Belfast, and is a graduate with high honours of the Queen's University in Ireland. For some time he was assistant lecturer to Prof. Wyville Thomson, and for many years he was Prof. Redfern's assistant and demonstrator. Well taught himself, and already a contributor of numerous essays to the medical journals, we anticipate for Dr. Charles every success as a teacher. With Redfern and Cleland as his colleagues, anatomy appears to be well represented in the Queen's Colleges in Ireland.

THE Vienna Academy of Sciences, says *La Nature*, is occupied with a question which concerns all Europe—the decrease of the quantity of water in springs, rivers, and watercourses. A circular, accompanied by a very instructive report, has been addressed to the scientific societies of other countries, inviting them to undertake observations which, in time, may yield useful results. The Academy calls attention to the fact that during a certain number of years there has been observed a diminution in the waters of the Danube and other large rivers, especially since the practice of felling forests has become common. The Austrian Engineers' and Architects' Union are also occupied with this question, and have appointed a Hydrostatic Commission to collect facts and prepare a report. The Danube, the Elbe, and the Rhine have each been assigned to two members, while two others will be occupied with the meteorology relating to the same subject and with the influence that glaciers and Alpine torrents may exercise on the general result. The Commission considers the question urgent, and recommends the immediate adoption of measures to remedy the evil. According to the *Revue des Eaux et Forêts*, it is unanimous in declaring that the prime cause of the disastrous decrease of the water is the devastation of the forests.

WE are informed that Mr. Gould will shortly issue the first and second part of an important work on the "Birds of New Guinea," which will at the same time form a second supplement to the "Birds of Australia," and will contain illustrations and descriptions of several new species not included in the latter work.

AT a congregation held at Cambridge on Oct. 28, it was resolved to establish a Professorship of Mechanism and Applied Mechanics, with a stipend of 300*l.* a year. There are already three candidates, viz.—Mr. James Stuart, M.A., Fellow of Trinity College; Mr. E. J. Routh, M.A., F.R.S., of St. Peter's College; and the Rev. J. C. Williams-Ellis, of Sidney.

THE Board for superintending non-collegiate students at Cambridge give notice that there will be an examination in certain selected branches of physical science for the award of an exhibition granted by the Worshipful Company of Clothworkers, commencing on Thursday, Jan. 13, 1876, 9 A.M. The exhibition will be one of 50*l.* per annum, tenable for three years by a non-collegiate student of the University of Cambridge. Full information may be obtained from the Censor, Rev. R. B. Somerset.

AN interesting paper on "The Influence of the Sunspot Period upon the Price of Corn" formed the subject of a paper by Prof. W. Stanley Jevons, F.R.S., at the recent meeting of the British Association. After alluding to the attempts made by Mr. Carrington to trace a connection between the price of corn and the variations in the sunspots during portions of the last and present centuries, the Professor said that Mr. Schuster has pointed out that the years of good vintage in Western Europe have occurred at intervals approximating to eleven years, the average length of the principal sunspot period. The elaborate collection of the prices of commodities in all parts of England between the years 1259 and 1400, published in Prof. J. E. T. Rogers's "History of Agriculture and Prices in England," appears to afford the best data for deciding whether the sunspot period influences the price of corn. For this purpose, tables of the average prices per quarter of wheat and other grain, expressed in grains of pure silver, were used. Each series of prices was divided into intervals of eleven years, which were ranged under each other and averaged, so as to give the average of the first, of the second, of the third, &c., years, the commencement of the period being arbitrarily assumed. It is found that the price of each kind of produce examined rises in the first four years, but afterwards falls. It is further shown that the *maxima* prices are found to fall into the tenth, eleventh, first, second, and third years of the assumed eleven-year period. These results are to be looked upon as only preliminary, and need further investigation. It is also pointed out that commercial panics have tended to recur during the last fifty-four years in a distinctly periodic manner. The average length of interval between the principal panics is about 10·8 years, nearly coinciding with 11·11, the length of the solar-spot period. If Prof. Balfour Stewart be right in holding that the sunspot variation depends on the configurations of the planets, it would appear that these configurations are the remote cause of the greatest commercial disasters.

THE death is announced, at the age of seventy-eight years, of Sir John Gardner Wilkinson, F.R.S. He was well known for his successful explorations in Egypt, and his archæological and geographical publications. In 1852 he was created hon. D.C.L. of Oxford, was corresponding member of the R.I.A. of Vienna and of the Royal Academy of Turin.

DR. LORRAIN, one of the most popular professors of the Paris Medical Faculty, died from apoplexy a few days ago. The Minister of Public Instruction and all the professors of the faculty were present at his funeral. Dr. Lorrain wrote many excellent works on professional subjects, amongst which we may notice "Diagnostic by Pulsation."

THE resignation of M. Wurtz has been tendered once more and accepted by the French Minister of Public Instruction, and M. Vulpian has been appointed to succeed him as Dean of the School of Medicine of Paris.

THE Observatory of Toulouse has purchased a telescope of eighty-five centimetres diameter, and five metres focal distance, at a cost of 1,200*l.* M. Tisserand is head of the Toulouse Observatory.

PETERMANN'S *Mittheilungen* for November contains the following papers:—On Soleillet's and Largeau's travels in the Sahara and to Soudan, by Dr. Gerhard Rohlfs. The continuation of Weyprecht's "Pictures from the High North," in which he describes the formation of the pack-ice, and gives some forcible illustrations of ice-pressure. Under the head of "Most Recent Travels in Australia," accounts are given of Forrest's journey through W. Australia (1874), Lewis's explorations in the north and east of Lake Eyre, with a map (1874–5), Ross's journey in the S.W. of South Australia (1874), and Giles's journey from Fowler Bay to Torrens Lake. A paper, with map, by E. Behm, on the extension of the Egyptian power on the Upper Nile, treats of the results obtained by Baker, Long, Kemp, and Marno.

IN the *Bulletin* of the French Geographical Society for October is an itinerary of a journey by the energetic Abbé Desgodins in 1873, from Yerkalo to Tse-Kou, both on the river Lan-Tsang-Kang, in Eastern Tibet. It is accompanied by a map of part of Eastern Tibet to the north of Burmah and Yunan, containing the courses of many rivers, and the positions of a large number of towns. There is also a paper, with map, by Colonel Long, describing his journey in 1874–5 to the Victoria Nyanza, and the Niam-Niam country. M. E. Boisse describes a visit which he paid in 1874 to Samoa and a few other Pacific islands.

PROFESSORS Nordenskjöld, Lundström, and Stuxberg, who took leave of the Swedish Arctic Expedition at the mouth of the Yenesei River on the 19th of August last, with the intention of returning to Sweden *viâ* Siberia, arrived at Ekaterinburg on October 29, and were to remain for four days.

THE report of the meeting of the Eastbourne Natural History Society for October 15 contains a paper by Mr. F. C. S. Roper, F.L.S., on the additions to the Fauna and Flora of Eastbourne during 1875.

THE Eighth Annual Exhibition of the Haggerston Entomological Society will take place at the Society's Rooms, 10, Brownlow Street, Dalston, on Thursday and Friday, Nov. 11 and 12, 1875, between the hours of 6 and 11 P.M.

FROM the "Proceedings of the Liverpool Naturalists' Field Club" for 1874-5, we find that the Society continues to do a creditable amount of useful work. Ten field meetings were held last summer, and from the way in which these are conducted, the members are likely to derive much benefit from them. The "Proceedings" contain an admirable address by the President, the Rev. H. H. Higgins, well calculated to stimulate those who heard it to an earnest study of science. Mr. Higgins has been presented by the Society with a handsome testimonial in acknowledgment of his long and valuable services as president.

FROM the Tenth Report of the Quekett Microscopical Club we learn that the number of members is 530, and that the Club is in all respects in a prosperous condition.

ANOTHER part of "Figures of Characteristic British Fossils with Descriptive Remarks" has been issued. It will be recollected that Part I. appeared in 1867, II. in 1869, and III. in 1871. These three parts included from the Cambrian to the Devonian forming thirty plates. This new part (IV.) contains plates 31 to 42, and includes "Devonian, Old Red Sandstone, Carboniferous and Permian," completing the Palæozoic division. In addition to the plates giving figures of fossils and the letter-press description, there are descriptive remarks on groups of fossils with woodcuts of recent and fossil forms for comparison.

WE have just received a copy of the report on deep-sea dredging operations in the Gulf of St. Lawrence, by J. F. Whiteaves, dated Montreal, 1874. The ship used was the Government schooner *J. H. Nickerson*, of seventy tons. Four cruises were made. In the first 14 casts of the dredge were made in 110 to 220 fathoms, in the second 16 hauls in 20 to 70 fathoms, in the third 18 hauls, and the fourth 16, in neither of which is the depth stated. A summary of the zoological results is given, the determinations being mostly by Professors A. E. Verrill and S. J. Smith.

WE would recommend to the notice of those of our readers who are interested in the antiquities of our country, a third revised edition of Mr. Thomas Wright's well-known work, "The Celt, the Roman, and the Saxon" (Trübner). It contains a vast amount of information on the pre-Christian condition of England.

AMONG the subjects on which the Council of the Institute of Civil Engineers invite communications and offer premiums is "The Flow of Fluids, liquid and gaseous."

FROM the "Report" for 1874 of the Cardiff Naturalists' Society, established in 1867, we learn that it is increasing rapidly in numbers and prosperity. During 1874 the Committee tried the experiment of introducing scientific and other lectures, and although monetarily they were a failure, in other respects they were so satisfactory that the Committee recommended their continuance for another year. A large proportion of lectures on important scientific subjects were given, and two field meetings were held. The "Report" contains a Meteorological Report for each month of the year, by Mr. F. G. Evans, F.M.S., and also a table of rainfall observations in the Society's field.

THE following papers by Mr. T. Mellard Reade, C.E., F.G.S., have been reprinted from the Proceedings of the Liverpool Geological Society:—"The Glacial and Post-glacial Deposits of Garston and the surrounding District, with Remarks on the Structure of the Boulder Clay;" and "Speculations on the probable Distribution of Land and Sea during the Deposition of the Marine Boulder Clays and Sands."

WE have received an address by Prof. R. H. Thurston, C.E., delivered to the graduating class of the Stevens Institute of Technology (U.S.) It is entitled "The Mechanical Engineer, his Preparation and his Work," and contains some excellent advice, useful not only to young engineers, but to all who have been trained to other mechanical professions. The Stevens Institute, though what we would call a technical college, affords a good general scientific training, with a fair admixture of literary culture, and the object of Prof. Thurston's address is to show that the more complete is the culture of an engineer, the greater is likely to be his professional success.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. R. Roberts; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Gibbs; two Lesser White-throats (*Sylvia sylviella*), two Yellow Wagtails (*Motacilla flava*), European, presented by Mr. Augustus E. Field; two Central American Agoutis (*Dasyprocta punctata*) from Central America, presented by Mr. W. G. Davis; a Polar Bear (*Ursus maritimus*), Arctic Regions; a Smooth-headed Capuchin (*Cebus monachus*) from S.E. Brazil; a White-throated Capuchin (*Cebus hypoleucus*) from Central America; a Golden Eagle (*Aquila chrysaetus*) from Hudson's Bay; two Maximilion's Aracaris (*Pteroglossus wiedi*) from Brazil, deposited; two Golden Agoutis (*Dasyprocta aguti*), born in the Gardens.

ELEVENTH REPORT OF THE COMMITTEE FOR EXPLORING KENT'S CAVERN, DEVONSHIRE*

THE Committee have again the melancholy duty of reporting that death has deprived them of one of their members. As long ago as 1859, as soon as he became aware of the importance of the discoveries made in the Windmill Hill Cavern at Brixham, Sir Charles Lyell expressed a strong desire that Kent's Cavern should also be systematically and thoroughly explored; and it was with his full concurrence that the proposal to do so was laid before the Committee of the Geological Section of the British Association at Bath in 1864, the day after he delivered his Presidential Address, whilst his ardent advocacy, together with that of the late Prof. Phillips, secured its ready acceptance by the Committee of Recommendations and the General Committee. At the first meeting of the Cavern Committee, appointed in the year just mentioned, he was unanimously elected chairman, and he continued to occupy that post until his lamented decease on Feb. 27, 1875. Though the state of his health prevented him from taking any active part in the exploration, his interest in the work never abated; he always carefully studied the Monthly Reports of Progress sent him by the superintendents, and he made careful arrangements for their preservation.

The Tenth Report, read to the Geological Section of the Association at the Belfast meeting, and printed in the annual volume for last year, brought up the work to the end of July 1874. The exploration has been carried on without interruption from that date to the present time; the mode of excavation adopted at the beginning has been uniformly followed; the superintendents have visited the cavern daily; the progress of the work has been carefully recorded in the cavern diary; the workmen have, as heretofore, given complete satisfaction; and Monthly Reports have been regularly sent to Sir Charles Lyell until his decease, and subsequently to Mr. John Evans.

The cavern continues to be much visited by persons desirous of studying on the spot its characters and phenomena; and during the last twelve months the superintendents have had the pleasure of taking a large number of visitors through those branches which have been explored, and of explaining to them the mode of operation. Probably a still larger number have been conducted by the "guide," who, though under the control of the committee, is not permitted to take parties to those branches of the cavern in which the exploration is in progress, or has not been begun.

As in former years, rats have frequently been seen running about in various parts of the cavern, including those in which the men have been at work, though hundreds of feet from any glimmering of daylight; and they have displayed their usual boldness as well as their skill in carrying off candles. In other branches, almost as far from the entrances, where all researches have ceased for some years, their footprints are to be seen in great numbers, especially on the silt left, here and there, where the drip is copious in wet weather.

On Jan. 29, 1875, a "buzzing fly" was seen and heard about 300 feet from daylight.

Clinnick's Gallery:—The Tenth Report (1874) stated that the exploration of Clinnick's Gallery was in progress, and had been completed for about 34 feet; that below the least ancient, or the Granular, Stalagmitic Floor, for a distance of 18 feet from its entrance, a small quantity of "cave earth" uniformly presented itself, beneath which lay the Breccia, occasionally separated from it by remnants of the more ancient, or Crystalline, Stalagmitic Floor *in situ*; but that from the point just named, up to that reached when the Tenth Report was drawn, there was no cave earth, so that the two Stalagmites lay the one immediately on the other, with the Breccia, that is, so far as is known, the oldest of the cavern deposits, beneath the whole.

At the commencement of the exploration of this gallery, the deposits so very nearly reached the roof as to induce the belief that a very few feet at most was all that the workmen had before them. As the work advanced, however, the unoccupied interspace between the roof and floor became gradually larger, until on Aug. 6, 1875, John Clinnick, one of the workmen, forced himself through, and, after proceeding about 50 feet by estimation, entered a large chamber, into which he was followed by one of the superintendents. The chamber, probably one of the largest in the cavern, is beautifully hung with Stalactites, and has numerous Stalagmitic "paps," some of them four feet high, and of almost cylindrical form, rising from a floor of the same material.

Clinnick's Gallery, on being excavated, was found to be a somewhat tortuous passage, varying from four to eight feet in width, and from seven to ten feet in height. That it was once a watercourse there can be little doubt, as the roof bears the marks of the long-continued action of a running stream. The walls vary considerably, being in some places smooth, in others much fretted or corroded, and in others more or less angular.

The objects of interest found in this branch of the cavern during the last twelve months have been by no means numerous; nevertheless, they are not without considerable interest.

Attached to the upper surface of the Granular Stalagmitic Floor portions of three land-shells were found, and about twenty bones of mammals were met with lying together loose on the floor. Their characters imply a recent introduction into the cavern.

Incorporated in the Granular Stalagmitic Floor itself were a few bones, including a humerus, a tibia, and an ulna, each nearly entire, and a portion of a large humerus, all of which had been gnawed.

Though no cave-earth was met with beyond the point already specified, there seems no doubt that to the era of that deposit may be referred a considerable portion of a radius and of an ulna, both gnawed and found under loose pieces of stalagmite.

The remains found in the Breccia were four teeth of bear, a few bones and fragments of bone, and three teeth of lion in three portions of, no doubt, one and the same lower jaw. The latter "find" (No. 6,482) is of considerable interest, as being the first known instance of remains of any animal besides bear met with in the Breccia. Though the superintendents had no doubt of the feline character of the teeth, they forwarded one of them to Mr. G. Busk, F.R.S., a member of the committee, remarking that they believed it to be the last lower left molar of *Felis spelæa*, and requesting his opinion on it. In his reply, he remarks: "There is no doubt that the tooth is the left lower carnassial of *Felis leo*, but it is of very unusual size, being, I should estimate, one-twelfth bigger than the average dimensions of that tooth in the lion. It is usually longer, but not so thick, in the tiger than in the lion, but the thickness of the present one is proportionate to its length. Another peculiarity, as it seems to me, is the great wear that the tooth has undergone. I fancy existing lions are not allowed to live long enough to wear their teeth so much. At any rate the Kent's Hole tooth appears to be more worn than any other I have as yet met with. Can it belong to Machairodus?" Having succeeded in removing some part of the matrix encrusting the other portions of the jaw, they were also forwarded to Mr. Busk, with the observation that the superintendents had carefully considered the question before submitting the first tooth, and had come to the conclusion that the jaw was not that of Machairodus, for, waiving the fact that none of the teeth were serrated, the fang of the canine still remaining in the jaw was much too large for a lower canine of any known species of Machairodus; and it was suggested that it might be worth considering whether the specimen belonged to any of the species of *Felis* found in the forest-bed of Cromer. To this Mr. Busk replied: "The jaw does not appear to present anything unusual. It is, however, a good example to show that the cave lion lived to a good old age."

The Breccia in Clinnick's Gallery also yielded seven specimens of flint and chert, none of which need detailed description.

The comparative paucity of specimens induced the superintendents to suspend operations in that direction for at least a time. The labour of seven months had been expended on it,

* Abstract read at the Bristol meeting of the British Association.

during which the exploration of the gallery had reached seventy-five feet from the entrance, where the great chamber discovered by Clinnick may be said to begin.

The following is a complete list of the objects of interest found in this gallery from first to last:—Three shells of Helix and about twenty bones of mammals lying on the upper surface of the Granular Stalagmite; a few gnawed bones incorporated within this stalagmite itself; eight teeth of hyæna and two of fox, a tolerable number of bones and fragments of bone, one large chert implement, and one small flint flake, in the cave earth; and ninety teeth of bear and three of lion in portions of a left lower jaw, a large part of a skull, numerous bones and portions of bone, a flint pebble, and eleven specimens of flint and chert implements, flakes, and chips, including the very fine tool, No. $\frac{1}{6411}$, in the Breccia.

The Cave of Inscriptions.—The chamber in which the Long Arcade terminates has been called "The Cave of Inscriptions," from the number of names, initials, and dates graved on the stalagmite in various parts of it. Besides those on the "Inscribed Boss of Stalagmite" at the entrance of the cave, described in the Tenth Report, inscriptions occur on what is known as the "Hedges Boss" and on the walls of the chamber. There are also a large number of names, &c., smoked on various parts of the roof, as there are, indeed, in almost every branch of the cavern, some of which appear to be of very considerable antiquity. The oldest of the inscribed dates is 1609, and the most modern 1792, but the most conspicuous and most famous of the inscriptions is "Robert Hedges, of Ireland, Feb. 20, 1688."

It was stated in the Tenth Report that the exploration of this cave had been completed up to sixteen feet from its entrance, when it was suspended in order to proceed with Clinnick's Gallery; that the Granular, or less ancient, Stalagmitic Floor was found to be everywhere intact and continuous, and that the Crystalline, or more ancient, Stalagmite lay beneath it; that the latter had been broken by some natural agency, and though in some cases the severed portions remained *in situ*, in others they had been removed and were not always traceable; that adjacent to the left wall of the cave a wedge-like layer of cave earth lay in its proper place between the stalagmites, and was six inches thick at the wall, but thinned out about a yard from it, beyond which the one floor lay immediately on the other. On resuming the exploration of the cave it was found that the state of the deposits continued to be the same up to thirty-four feet from the entrance, with the single exception that the broken blocks of crystalline stalagmite were never dislodged beyond being faulted to the extent of two or three inches. At and beyond the point just specified, traces of the earlier explorers were again met with in almost every part of the cave, but were found to be limited to the breaking up of the stalagmites and the subjacent deposit to the depth of twelve inches at most. A thin layer of typical cave earth extended throughout the entire chamber, and it was obvious that at the time when the deposition of the cave earth commenced the crystalline stalagmite did not exist as a continuous sheet, for in considerable spaces the cave-earth lay immediately on the breccia without any stalagmite between them, and it was not always easy to determine the exact junction of the two deposits. On the discovery of objects of interest at or near this doubtful junction, care was taken to record them as belonging to the "cave earth and breccia," even though, from their own characters, it was usually easy to refer them to their proper deposits and eras respectively.

The Cave of Inscriptions was found to extend upwards of sixty feet from north-east to south-west, forty-five feet from south-east to north-west, and to be upwards of twenty feet high.

Two "finds" only were met with in the Granular Stalagmitic Floor; one consisting of a few bones, including a portion of a large humerus, whilst the other was a very small bone, probably of bat, with bits of charcoal and of coprolite, all lodged in the same hand specimen.

The cave earth yielded four teeth of hyæna, a few gnawed bones, coprolites on several occasions, and one flint flake.

At and near the junction of the cave earth and breccia, where they were not separated by stalagmite, two right lower jaws and four loose teeth of hyæna, thirty-eight teeth of bear, part of a jaw of fox, one incisor tooth of a small rodent, numerous bones and fragments of bone, a somewhat large number of coprolites, and one flint flake were met with. At least most of the ursine remains may be safely referred to the breccia, whilst all those of hyæna undoubtedly belong to the cave earth. One of the hyæna jaws just mentioned contains all its teeth except the inner incisor, but, as is commonly the case with lower jaws of the era of the cave earth, it has lost its lower border and condyles, and is much gnawed. The other jaw of hyæna has lost the two inner incisor teeth and the condyles, and is slightly gnawed, but is otherwise entire.

There were found in the Breccia eighty-two teeth of bear—some of them in jaws or parts of jaws—two of lion, in a portion of right upper jaw, numerous bones and pieces of bone, including part of a skull and several other good specimens, and thirteen implements, flakes, and chips of flint and chert. The lion's teeth (No. 6,518) are the last two molars. The sockets of the canine tooth and of the small tooth immediately behind it still exist, and everything betokens an animal of great size. The specimen, to which a considerable quantity of the breccia still adheres, is peculiarly interesting as being found in a deposit in which careful methodical research, continued for years, had failed to detect any other osseous remains than those of bear, with but one exception, and that, as already stated, being also the lower jaw of a lion, found less than two months before. This interesting relic was met with on 31st December, with two teeth of bear, bones and fragments of bone, in the second foot-level of Breccia. No feline remains have been detected since that date.

A few only of the flint and chert specimens require description:—

No. 6,550 is an implement made out of a well-rolled chert nodule. It is somewhat semilunar in form, but broader at one end than the other, and measures about 4·4 inches in length, 2·3 inches in greatest breadth, and 2·5 inches in greatest thickness, which it attains near the broader or butt-end. It has undergone a considerable amount of chipping, has been reduced to an irregular edge along the greater part of its perimeter, and is comparatively thin near the pointed end. It is very, but unequally, convex on both faces, each of which has a central ridge, and retains the original surface of the nodule over the whole of the butt-end, whence a trace of it extends along the central ridge of the less convex face to about an inch from the point. The portion of the surface which has been chipped is of a yellowish hue, derived, no doubt, from the matrix in which the specimen lay. This, however, is but a superficial stain, as there are indications of an almost white colour within. This fine implement was found 15th February, 1875, between the Hedges Boss and the left wall of the cave, thirty-six feet from its entrance, in the second foot-level below the surface, that is, in the uppermost foot-level of the Breccia, and having no other object of interest near it.

No. 6,565 is a chert implement 3·7 inches long, 2·7 inches in greatest breadth, and 1·7 inches in greatest thickness, which it attains not far from its centre. It has unfortunately lost one of its extremities—apparently broken off whilst the tool was being made. It is very, perhaps equally, convex on each face, but the centres of convexity are not situated opposite one another; and, though made from a nodule, not a flake, no part of the original surface remains. A considerable amount of work has been expended on it, and it has been reduced to an edge all round the perimeter except at the broken end. The marginal edge is neither keen nor regular, nor in the same continuous plane. There can be little doubt that it was intended to be a somewhat pointed ovoid tool, and that had it been perfected its form would have been more symmetrical than the breccia tools are usually, and its colour is whiter than that of most of the implements found in the same deposit. It was met with on 13th April, 1875, in the second foot-level of the Breccia, without any other object of interest near it, forty-seven feet from the entrance of the Cave of Inscriptions.

The earlier explorers had but imperfectly examined the material they dug up in this branch of the cavern. On taking it to the daylight, the committee found in it nineteen teeth of bear, twelve of fox, nine of hyæna, two of horse, and one of rhinoceros; a large number of bones, numerous coprolites, a fragment of a marine shell, and six flakes and chips of flint.

The exploration of this cave was completed on 14th June, 1875, having occupied the labour of between eight and nine months.

The following is a list of the specimens found in it in undisturbed ground, inclusive of those mentioned in the Tenth Report:—One bone of bat, a few other bones, a few patches of coprolite, and a bit of charcoal, in the Granular Stalagmite; twenty-seven teeth of hyæna, several of them in jaws or parts of jaws,

eleven of bear, one of a small rodent, one jaw of fox, numerous bones and fragments of bone, of which six had been charred and a greater number gnawed, a large number of coprolites, and seven tools, flakes, and chips of flint, in the Cave Earth; 213 teeth of bear, some of them in jaws or pieces of jaws, two of lion, in parts of upper jaw, and twenty implements and flakes of flint and chert.

The Recess.—On completing the exploration of the Cave of Inscriptions, operations were at once commenced in a "Recess" occupying its north-western corner, and which was expected to lead to a new external entrance to the cavern. It extends in a north-westerly direction for fully sixty feet, and is of sufficient width for a man to pass easily; beyond this its extent is considerable, but at present it is too narrow for examination. Its floor is a thick sheet of the crystalline or more ancient stalagmite, and is abruptly truncated at the junction of the Recess with the Cave of Inscriptions. It rested on a thick mechanical accumulation, which is unmistakeable breccia, and reaches a higher level than elsewhere in the cavern, so far as is at present known. It was decided to leave intact the Stalagmitic Floor, and in fact to burrow under it; but when the excavation had reached a distance of ten feet, the two walls were found to be so very nearly together as to render it necessary to abandon the work, or to break up the floor and proceed at a higher level. The former course was, though reluctantly, decided on. The only specimens found here were two teeth of bear, a few bones, and an unimportant piece of flint.

The Alcove.—A recess in the eastern wall of the Cave of Inscriptions, near the Hedges Boss, and which received the name of the "Alcove," was next explored. When emptied it proved to be scarcely lofty enough for a man to stand erect, and ten feet in length and breadth, but divided into two compartments by a limestone partition extending nearly across it. Its exploration, which occupied three weeks, was rewarded with thirty-nine "finds" of remains of mammals, including fifty-nine teeth of bear, several of them in portions of jaws; sixteen of fox, all of them in portions of three lower jaws; four of hyæna; numerous bones, including several good specimens, though all of them more or less fragmentary; and one coprolite. The teeth of hyæna, two of the jaws of fox, and the coprolite were met with in cave earth; but the remaining jaw of fox (No. 6,619) was found in the breccia. It was broken into two pieces, which were lying together and contained five teeth, and is the only known relic of the genus in this old deposit. The Alcove contained no trace of flint or chert.

The Great Oven.—A very long, narrow, and low tunnel opening out of the south-western corner of the Cave of Inscriptions has been termed the "Great Oven." Its exploration was begun July 27, 1875, or but four days before the period at which this report closes. It contains a thin layer of cave earth, and a deposit of breccia of unknown depth. The former has already yielded a few traces of hyæna, and the latter a greater number of ursine remains.

On studying the osseous remains found in the Breccia in the branches of the cavern explored during the last twelve months, the following prominent facts arrest attention:—Some of the teeth of bear are those of very old animals and worn almost to the fang. The jaws, though frequently broken, have never lost their lower borders, as is almost uniformly the case with the cave-earth specimens; and none of the bones appear to have been gnawed. In no instance were the bones found lying in their anatomical relations, but different parts of the skeleton were often huddled confusedly together; thus, in No. 6,613, found in the Alcove, a canine tooth adheres to one side of the proximal end of a tibia, and a piece of jaw to another side. Some of the specimens have fretted surfaces, and appear to have been rolled by running water. Many of the bones were broken where they were finally lodged, and the parts, with little or no displacement, reunited with stalagmitic infiltration. Others appear to have been flattened, or more or less crushed, where they lay. Occasionally, in the same rock-like mass of breccia were found bones of very different colours, showing that mere colour is no test of age.

Nor are the remains from the cave earth void of instruction. Up to the present time, wherever the cave earth has been met with, there also have traces of the hyæna been found, either in the form of parts of his skeleton, or his coprolites, or bones scored with his teeth-marks, or jaws divested of their lower borders, or long bones broken after his well-known fashion. But though everywhere present in greater or lesser numbers, these traces became less and less plentiful with increased distance from the external entrances of the cavern, and were very "few and far between" in the chamber most remote from the entrances. Whilst remains of the hyæna were thus met with wherever the cave earth occurred, they were accompanied in the interior by very few of his contemporaries Thus, whilst the chambers adjacent to the entrances contained teeth and bones of horse, rhinoceros, deer (several species), bear, fox, elephant, ox, lion, wolf, and hare, as well as hyæna—the last being by far the most prevalent—remains of the hyæna alone have been found during the last twelve months. Nor is it without interest to note the branches of the cavern in which remains of the different forms just enumerated were last detected on the way to the Cave of Inscriptions. The hare was not found anywhere in the western division of the cavern—that of which the Cave of Inscriptions is the innermost chamber; the badger, wolf, and ox were represented in the "Charcoal Cave," but not beyond it; and relics of horse, rhinoceros, deer, bear, fox, elephant, and lion did not appear beyond the Long Arcade. Finally, no traces of Machairodus have been met with since the incisor tooth, found July 29, 1872, and described in the Eighth Report, presented at Brighton.

SCIENTIFIC SERIALS

Proceedings of the Berwickshire Naturalists' Field Club, vol. vii. No. ii.—This earliest of Field Clubs continues to sustain the high reputation it has had from the beginning; the present part of the Proceedings shows that the members continue to investigate diligently and to good purpose the natural history and antiquities of the interesting district which forms their field. Most of the papers are of real value, and the best service we can render the club and our readers is to give a list of them:—"On supposed lake or river-terraces near Kelso," by Mr. T. Craig; "On Jedburgh Pears," by Mr. James Tate; "On the antiquity and history of some Border Pears," by Mr. Jas. Hardy; "On evidences of ice-action in Berwickshire," by Mr. W. Stevenson; "Ornithological notes," by Mr. H. Gibb; "On the value of the horse-chestnut (*Æsculus hippocastanum*) as a timber-tree in plantations," by Mr. R. Carr-Ellison; "On Lepidoptera, taken mostly in 1874," a list of captures by various members; "On the signification of some names of places in South Northumberland," by Mr. R. Carr-Ellison; "On the occurrence of the Wild Cat in the border district," by Mr. James Hardy; "A list of local plants and their localities," by Mr. A. Brotherston; "Ornithological notes," by Mr. R. Gray; "On iron and iron slag found at Worm Law and Yeavering," by Mr. Jas. Hardy; "On some flint implements of prehistoric people in Berwickshire,' by Mr. James Hardy, with some beautifully executed illustrations; "A note on a specimen of *Arabis turrita*, discovered at Haining," by Mr. A. H. Borthwick; "On ancient stone cysts and human remains discovered at Aycliffe House, near Ayton," by Mr. J. Hardy, with an illustration; "On a bronze celt found at Linden," by Mr. R. G. Balam, with an illustration; "Some notes on the movements of migratory birds," by Dr. Scott and Mr. Hardy; "Zoological notes," by Messrs. Ferguson and Brotherston; various information on local natural history, by Mr. Hardy; "On some of the birds of Lauderdale," by Mr. A. Kelly; "List of *Araneidea* and *Phalangidea*, collected from Oct. 1871 to Dec. 1874, in Berwickshire and Northumberland, by Mr. James Hardy," by the Rev. O. P. Cambridge; "On Berwickshire insects," by Mr. Hardy, who also has "Contributions to the entomology of the Cheviot Hills."

Third Report of the Winchester College Natural History Society.—This report is altogether very encouraging; it has, as the preface justly states, "a real amount of active and intelligent life" to record during the year. The members as a body seem to be really interested in the work of the Society, and the tendency of that work is evidently to train the members to be accurate observers and independent thinkers. In the preface considerable importance is rightly attached to the collection and exhibition of specimens at the meetings for examination and comment, especially with the view of encouraging the younger members to become intelligent collectors. The report contains a considerable number of papers, nearly all by present or past members, and these papers give evidence of real intelligence, honest study, and in some cases of original observation. The first paper especially, that by W. A. Forbes, is highly creditable to its author; G. L. Hawker's, on Bio-geology, shows considerable knowledge and not a little originality of conception; the paper by N. M. Richardson also deserves mention. But indeed

the papers as a whole are above the average of those emanating from similar societies. The lists of specimens in the various sections appended show that the members continue to do much practical work; a botanical garden has also been opened in connection with the Society.

Proceedings of the Bath Natural History and Antiquarian Field Club, vol. iii. No. 2, 1875.—This part contains the following papers on scientific subjects:—Notes on some railway sections near Bath, by the Rev. H. H. Winwood, F.G.S., with an illustration.—Studies and problems for Somersetshire geologists, by M. H. B. Woodward, F.G.S.—There is an interesting address by the Rev. Preb. Scarth, on the results of modern archæological achievement, and a summary of Proceedings for the year 1874–75, by the Secretary.

Morphologisches Jahrbuch.—The first part of this new Journal of Anatomy and Embryology, issued by Prof. Gegenbaur (see vol. xii. p. 15) consists of about 200 pages, and has five double plates. Prof. Gegenbaur supplies an excellent introductory article on the position and signification of morphology. The succeeding sixty pages are occupied by an elaborate account, by Dr. Richard Hertwig, of *Podophrya gemmipara*, a new species of Acinetan, followed by an essay on the structure and systematic position of the Acinetæ. The author identifies his species with one figured, but not determined, by the late Mr. Alder in the "Annals of Natural History" for 1851, p. 426. Its nucleus is remarkable for having a number of irregular stellate branches, and its tentacles are differentiated into captorial and suctorial. After a review of the structure of Acinetæ generally, Dr. Hertwig comes to the conclusion that a unicellular organism, covered with cilia, is the original form from which Acinetæ and Infusorians have sprung, but that it cannot yet be determined whether it possessed a cytostome, and thus was a true ciliated Infusorian, or whether it was provided with tentacles, and was intermediate between Ciliata and Acinetæ.—The whole of the remainder (114 pages) of this part is occupied by a very notable paper by Dr. Emil Rosenberg, on the development of the vertebral column and of the os centrale carpi of man. He sets before himself the problem, little touched hitherto, of the discovery of the steps by which man may have developed from the nearest mammalian stock. Taking first the vertebral column, he sets forth the differences existing therein in the various Anthropomorphæ, and seeks to reconcile them with that of man. For instance, in two genera, Troglodytes and Hylobates, there are thirteen dorsal vertebræ, while in the Orang and in man there are only twelve. But Dr. Rosenberg has discovered in more than one human embryo an actual rib-rudiment on the 13th dorsal vertebra; so that the homology of the 13th dorsal in man and Troglodytes is established. Another result that Dr. Rosenberg claims to have demonstrated from examination of human embryos is that a process of transformation goes on in the growth of the sacrum, by which vertebræ at the proximal end, with their costal elements, are assumed into the sacrum, while a corresponding number at the distal end undergo reduction and are dismisssd into the caudal region. And this process, generalised, may be applied to each of the hinder regions of the vertebral columns. Thus in the history of development each lumbar vertebra in man is the result of a single transformation from the condition of a dorsal vertebra; each sacral vertebra has previously passed through the lumbar stage; while the caudal vertebræ have been successively dorsal, lumbar, and sacral, before becoming caudal. This is necessarily but a very imperfect sketch of the major subject of this paper, which is of very high interest.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, Oct. 26.—M. Frémy in the chair.—In opening, he referred in feeling terms to the death of Sir Chas. Wheatstone.—M. Milne-Edwards presented the second part of the eleventh vol. of his work on "The Comparative Physiology and Anatomy of Men and Animals." The following other communications were made:—On employment of means in experimental physiology, *àpropos* of the influence of stripping the leaves off the beet, upon the production of saccharine matter, by M. Cl. Bernard. M. Frémy made some remarks also on this subject.—On the carpellary theory, according to the Irideæ (third part), by M. Trécul.—On the dates of fall of meteorites, by M. Sainte-Claire Deville. He finds an excessive fall of bodies on the 12th, 13th, and 14th May; also something like a ten-days' period, corresponding to periodical inequalities of temperature.—On the practical value of steam-injectors, by M. Ledieu.—Progress realised, in the question of making land, by employment of the rational method, and in determination of the daily working of chronometers, by M. de Magnac. The new method (he shows) renders navigation much more exact.—Magnetic observations on the island of St. Paul, in November and December 1874, by M. Cazin.—On the mosses of St. Paul and Amsterdam Islands, by M. Bescherelle.—List of Lichens collected by M. de l'Isle, on St. Paul and Amsterdam, and description of new species, by M. Nylander.—New spectro-electric tube (modified fulgurator), by MM. Delachanal and Mermet. A small conical capillary tube is placed over the platinum electrode passing through the bottom of the larger tube; through this the liquid rises and is illuminated by the spark.—On the laws which govern reaction with direct addition (continued), by M. Markovnikoff.—The industry of nitrate of soda in South America, by M. L'Olivier.—Experimental researches on the mechanism of coagulation of blood in treatment of varices by simple isolation of veins, by M. Bergeron.—On the alterations produced in the vine by *Phylloxera vastatrix*, by M. Max. Cornu.—Conservation of food stuffs, by M. Reynoss.—M. de Carvalho presented a note on the properties of air subjected to passage of an induction current.—M. Delauney on a "solar concentrator," *àpropos* of M. Mouchot's paper.—M. Pertinset on a project of exploration of Terra del Fuego.—The Minister for the Navy and Colonies communicated part of a report from the Governor of Martinique on the earthquake there from 17th to 25th September, and magnetic phenomena accompanying it. M. Sainte-Claire Deville said M. Duvignan had written him from Guadeloupe that none of the Martinique shocks had been felt there.—Observations of the planet (149) discovered by M. Perrotin at Toulouse (sent by M. Leverrier).—Experiments made on Geissler tubes with the chloride of silver pile formerly described, by MM. Warren De la Rue and Müller.—On spiral nebulæ, by M. Planté. He shows how a cloud of metallic matter detached from the electrode by an electric current of high tension, in a liquid, assumes a gyratory movement when acted on by a magnet; and supposes the form of spiral nebulæ may thus be due to strongly magnetic celestial bodies in their neighbourhood.—On the hydrological map of the department of Seine-et-Marne, by M. Delesse.—M. Degantière presented a note on the noise which accompanies or precedes the fall of hail.

BOOKS AND PAMPHLETS RECEIVED

Colonial.—Report of the Agricultural Conditions, Capabilities, and Prospects of the Neilgherry District: W. R. Robertson, M.R.A.C. (Madras).

American.—The Mechanical Engineer; his Preparation and his Work. An Address by R. H. Thurston, A.M., C.E. (New York, Van Nostrand).—Monthly Report of the U S. Department of Agriculture, Aug. and Sept.—Memoirs of the Boston Society of Natural History. Vol. ii. Part 4, No. 2.—Report of Mount St. Elias: W. H. Dall, W.S.C.S.—Bulletin of the Buffalo Society of Natural Sciences.

Foreign.—Bulletin de la Fédération des Sociétés d'Horticulture de Belgique (Liége)—Liste des Jardines, des Chaires, et des Musées Botaniques du Monde (Liége).

CONTENTS

Erratum.—Vol. xii. p. 559, col. 2, line 17 from bottom; for "sixty years" read "ten years."

THURSDAY, NOVEMBER 11, 1875

SEVENTH REPORT OF THE SCIENCE COMMISSION

THE present Report deals with the University of London, the Universities of Scotland, the University of Dublin and Trinity College, and the Queen's University in Ireland. With regard to the University of London the Commission has few suggestions to make, though it is of opinion that the Matriculation Examination would have a still higher value than it has if a Practical Examination could be instituted in connection therewith. "The enforcement of a practical test would accelerate the introduction of practical work into school teaching, and would thus exert a very favourable influence on the Progress of Scientific Education."

The Commission is also of opinion that the University of London should follow the example of the University of Edinburgh, and award the degree of D.Sc. only to those who have given proofs of the desire and capacity to make some addition to scientific knowledge.

The greater portion of this Report refers to the Universities of Scotland. The Report begins by referring to the inquiry conducted by the Commissioners appointed under the Universities (Scotland) Act of 1858, and to the reforms instituted by them. The recommendations made by this Commission were, however, controlled by the fact that the sum to be provided by Parliament to carry them out would not exceed 10,000*l.* a year. The Universities Commission kept very much, therefore, to the old lines, making classical learning the foundation of a University course, and prescribing for graduation in arts, a course extending over four winter sessions, and including "attendance on the Classes of Humanity, Greek, Mathematics, Logic, Moral Philosophy, and Natural Philosophy:" and, in addition to these, "attendance on a course of English Literature," which previously had not been required in any Scottish University except that of Edinburgh.

The Commission observes with satisfaction that in the Scotch Graduation Examination it is clearly recognised that a fair training both in literature and in science is the best basis for further advances in either the one direction or the other. They suggest, however, that the student should be allowed to show the required proficiency, whether in science or literature, by passing an examination at such a period in his University career as will enable him, in the latter part of his academical course, to devote his attention systematically to a particular group of subjects.

In referring to the examinations for the degrees of Bachelor and Doctor of Science, the Report states that recently a regulation has been made at Edinburgh that each candidate for the degree of D.Sc. must submit a thesis containing "some original researches on the subject of his intended examination, and such thesis must be approved before the candidate is allowed to proceed in his examination." It seems quite astonishing that this, which has for generations been the rule on the Continent, has not been done in all our Universities long ago. Degrees of an essentially similar kind have been instituted in Glasgow.

The most important part of the Report on the Scottish Universities is concerned with the deficiencies in respect to assistants and apparatus. In some cases the rooms are not at all adapted to the kind of teaching that must be carried on in them. The laboratory accommodation is throughout glaringly deficient, and ill-adapted for practical work. Indeed, if we except Glasgow, where new buildings have recently been erected, practical teaching can scarcely be said to exist, and now that it has come to occupy so large a space in the higher education, it is not to be wondered at that the scientific professors feel completely hampered in carrying on their work. Happily, in the case of Edinburgh this state of matters is likely soon to be remedied; 80,000*l.* have been already subscribed to build a new medical school, so as to leave the present buildings for the other departments of the University.

With regard to assistants, all the Universities are also miserably deficient, the deficiencies being attributable to the inadequacy of their resources. There are certain funds available for assistants to the scientific as well as to the other professors, but these are so scanty that in some cases the science professors have to provide additional assistants out of their by no means munificent incomes. The apparatus also, in connection with the scientific chairs, is discreditable to the Universities and quite inadequate to the modern requirements of scientific teaching.

In the case of the Universities of Edinburgh, Glasgow, and St. Andrews, the Commissioners recommend that Government augment their grant sufficiently to enable the Universities to increase the number, and, in some cases, the emoluments of assistants; to make more ample provision of apparatus for teaching; and to revise the salaries of the scientific professors.

In the case of Edinburgh it is recommended that such assistance be given, both in the form of a capital sum in aid of a scheme of extension, and of an annual grant.

The Report also deals shortly with the Andersonian Institute, or "Anderson University" of Glasgow, founded under the will of John Anderson, Professor of Natural Philosophy in Glasgow University towards the close of last century. There is no doubt it does good work among those who cannot afford a regular University education; many students in Arts and Medicine get their education here. It has been suggested that this Institute receive a charter, but the Commissioners wisely decline to support such a suggestion.

A movement was set on foot some time ago to establish a Science School at Dundee, about twelve miles from St. Andrews, across the Firth of Tay, which is being bridged for a railway. The Commissioners, however, cannot recommend any scheme which would involve the St. Andrews professors travelling to and from Dundee to teach, or which would remove the scientific chair to that town.

For some reason the University of Aberdeen has declined to avail itself of the opportunities afforded it of tendering evidence before the Commission.

With regard to the two Irish Universities, that of Dublin and the Queen's University, the Commissioners report very favourably on the portion allotted to science in these two institutions.

In the Dublin University there are thirty-three fellowships, which are tenable for life, irrespective of the restriction of celibacy, and are now open to all without distinction of creed. The Commissioners think that it would be very desirable that in the election to Fellowships important original research should be regarded as a substantial element of merit.

The nature of the constitution of the Queen's University, Ireland, and its three colleges at Belfast, Cork, and Galway, is well known. The education to be obtained at these colleges is fairly complete, both on the scientific and literary side, and the examinations imposed by the University are such as to make its degrees of real value.

The evidence shows that the appliances for teaching are in some respects insufficient, and that there is a serious deficiency of funds for maintaining the efficiency of the Queen's Colleges in this respect. The Report concludes and recommends as follows with regard to the Queen's University in Ireland:—

"In founding the Queen's Colleges, the State did not adopt the principle of assisting and stimulating local efforts, and if we except the exhibitions and prizes, to which reference has been already made, as having been provided by public subscription, and a few other exhibitions which have been founded at Belfast, no voluntary contributions have been received by them. They are institutions for which the State has made itself responsible, and in which, as part of a University system, a complete scientific training is implied.

"As we think it of great importance that the sanction of the State should not be given to the teaching of science on a scale inadequate to ensure its efficiency, we recommend (1) That an increased annual grant be made to the Queen's Colleges for the purpose of providing assistants, apparatus, and the other necessary appliances of practical scientific teaching. We further recommend (2) that the Professorship of Natural History in the Queen's College, Belfast, be separated from that of Geology and Mineralogy."

The general conclusion reached, then, in this Seventh Report is that it would take very little to make London University nearly perfect as an examining and degree-granting body; that Dublin University is in a healthy condition, and by a little amendment in the subjects of examination for her Scholarships and Fellowships, she might be an example to her sister Universities in England; that the Queen's University, Ireland, and the four Scottish Universities are all working in the right lines, and that what they mainly require in order that they may develop into perfectly efficient teaching bodies, so far as science is concerned, are funds to provide the necessary men, buildings, and apparatus. No doubt the recommendations of the Commissioners in reference to these and other matters will receive serious attention in the proper quarter.

HERMANN'S "ELEMENTS OF HUMAN PHYSIOLOGY"

Elements of Human Physiology. By D. L. Hermann, Professor of Physiology at the University of Zurich. Translated by Arthur Gamgee, M.D., F.R.S. (London: Smith, Elder, and Co., 1875.)

FOR a considerable time a first-class work on the Elements of Physiology in our own language has been a desideratum. The bulky Handbook by Carpenter was framed in a nearly bygone era of the science; Kirkes' smaller volume is under a similar disadvantage; Huxley's excellent little book does not appeal to others than beginners, and the "Handbook to the Physiological Laboratory," by Drs. Sanderson, Foster, Brunton, and Klein, was never intended to fill the place of a manual. Dr. Gamgee steps forward to fill the gap with a carefully conducted and excellent translation of the fifth edition of Prof. Hermann's deservedly esteemed "Elements of Physiology," a work unequalled in the care which has been bestowed on the collecting and balancing of the investigations of authors from all quarters, as well as in its general construction and inherent unity of design.

Dr. Gamgee tells us, "After much hesitation and many doubts I decided not to annotate the text, for had explanatory notes, of the nature of commentaries with illustrations, been added to it, as I once intended, its appearance would have been still further delayed, and the work would have been materially altered in character—it would have ceased to have been Hermann's Physiology." We have a sufficiently high estimation of Dr. Gamgee's ability to think that the English-reading public are the sufferers from his change of determination. The work being Hermann's therefore, and not in any way Gamgee's, except as far as the translation is concerned, our remarks apply only to the former.

The subject is treated in four sections, or parts. The first is entitled "The Exchanges of the Matter of the Organism"; the second, "The Activities or Energies of the Body"; the third, "The Liberating Apparatus; the Nervous System"; and the last, "Origin, Development, and Death of the Organism." As in most works on general subjects written by authors with any special predilections, the space devoted to the different functions is not quite that which would suggest itself to the unbiassed reader. As an instance of this in the present case we may refer to the fact that the account of the organ of sight alone occupies more than one-eighth of the volume, and nearly three times as much space as that devoted to the circulation of the blood.

The first part treats of the chemical constituents of the human body, the blood, and the circulation. The most advanced method of notation is adopted, and Baeyer's observations on the relations of uric acid are incorporated.

In the chapter on the blood we find one section devoted to the death of that fluid, the expression being employed to indicate those effects which follow its withdrawal from the influence of the walls of the living vessels. With reference to the movement of the blood in the circulatory system, we cannot help feeling that there is considerably more that might have been said about it with advantage, and that it might have been treated in a more connected and precise manner. Too much stress is laid on the aspiratory power of the thorax, which is assumed to be so continuous that "an ordinary expiration merely removes the inspiratory increase of the negative pressure." The duration of the systole of the ventricles of the heart is said not to vary with differences in the pulse-rate, according to the observations of Donders, which have been since shown to be incorrect. We are also led, incorrectly, to infer that the blood-pressure in the ventricles at the end of the diastole is a negative one; that the

force of gravity is one of those which aids the circulation; that "all those vessels which carry blood *to* a capillary system are called arteries;" that in "scaly amphibia"—by which we assume reptiles are meant—the two ventricles always communicate, which is not true as far as the crocodiles and alligators are concerned; and that the heart of a warm-blooded animal, removed from the body, will continue to beat "so long as a supply of oxygenated blood is provided."

The term "secretion" in its widest sense is said to denote "all those processes in which substances quit the blood in an altered or unaltered condition." This involves the inclusion of that simple nutritive diffusion into tissues which results in the origin and growth of bone, cartilage, &c.; an unnecessary complication, we cannot help thinking, and one apt to mislead. When it is stated that "nothing is known about the formation and regeneration of bone-tissue, except the morphological appearances presented in the various stages," justice is not done to Dr. Beale's most ingenious and highly probable explanation of the process by which it comes into existence.

The second portion of the work discusses the energetic relations of the body. Parts give indications of having been evolved from the author's inner consciousness, when he might have appealed to sound fact. On the whole we prefer the way in which the subject is treated in Dr. Pavy's excellent work on "Food." Prof. Hermann's theory of muscular contractility, based entirely on slender analogies, does not impress itself on our attention more than does the not less satisfactory one of Dr. Radcliffe.

The "liberating" or "discharging" apparatus, in other words the nervous system, occupies the third section of the work. As our knowledge of the nerves is very superficial, remarks the author, it must suffice to establish empirically the conditions which increase, diminish, or destroy irritability. This is done in a most exhaustive and excellent manner. Prof. Hermann regards the phenomenon of electrotonus as an effect of contact, the contents of nerve-tubes which are dying or in activity being negative to the contents of nerve-tubes which are living and at rest. The chapters on special sense will be read with particular interest, from the masterly manner in which they are written. Why so much space is devoted to the horopter, a surface the physical relations of which are as much connected with stereoscopic photograph cameras and double magic lanterns as with eyes, we do not know. With regard to the author's ideas on the recent views promulgated by Hitzig, Fritsch, Nothnagel, and Ferrier, we will quote his own words. "The movements which have recently been induced by electrical stimulation, since they do not occur after mechanical or chemical stimulation, may very well be set down to the irritation of more deeply seated regions, for the latter are unavoidably exposed to the diffusion of currents. . . . . No results as to the nature and distribution of the functions of the cortex, even of the value of approximations, can be deduced from these experiments."

In the fourth section of the work a short account is given of the development of the embryo, not detailed enough to be of much service, except to the initiated.

This rapid glance at the contents of Prof. Hermann's work indicates that it adopts a method of treatment that is more modern than most. In perusing it in detail the incorporation of the results arrived at in all directions by physiologists during the last twenty years, makes its value still further apparent. The many conflicting statements which have sometimes to be made, without any explanation being given, leave several questions without any definite answer. Such must for some time be the case in a science so young as physiology. The authorities for the different statements introduced are given in every case where there might be any doubt, and the book would have been still further serviceable if references had been introduced to the publications in which the results are described, as well as to the author's name. Many, in looking through the work, will feel that much of the method and many of the phenomena there explained, which, although they have not made their way into our text-books, have been current in the oral tradition of physiological circles; they must remember that a considerable amount of capital has been made out of foreign investigations by those who have done little more than dole them out in a different language from that in which they originally appeared.

The arduous task of translation has been most conscientiously performed by Dr. Gamgee, who has evidently weighed, carefully and acutely, the unavoidably difficult forms of expression employed, many necessarily quite new on account of the novelty of the conceptions developed. Taking for example the word "Schwellenwerth," as employed with reference to Fechner's psycho-physical law which is shortly explained; at the suggestion of Dr. Sanderson it has been translated "liminal intensity," an expression which does not at first sight explain itself, as does "initial intensity," the rendering which first occurred to Dr. Gamgee. In physics "initial" is employed of velocities, and we are not sure that any other term was necessary.

In conclusion, there is no doubt that the appearance of this work has greatly reduced the need, at the present time, for any other treatise on the Elements of Physiology.

WHITE CONQUEST

White Conquest. By William Hepworth Dixon. Two vols. (London: Chatto and Windus, 1876.)

MR. DIXON has been again in America, this time to collect evidences of the struggle between the races that is being waged on that wide battle-field. Although his method of treating the subject is not such as quite to bring his work within the critical sphere of NATURE, and although the author makes no attempt to treat his subject scientifically, still even the scientific reader, the student of ethnology or of the characteristics of the various races of men, and he who takes an interest in the struggle for existence wherever it is being carried on, will find much in Mr. Dixon's striking pictures well fitted both to interest and instruct. It is not in our province to criticise the quality of the artistic element in the work, but about its fascination there can be no doubt. Of course the work is one-sided. We do not use the term by way of depreciation, but in its literal sense. Mr. Dixon's aim is to represent, by means of a

In the Dublin University there are thirty-three fellowships, which are tenable for life, irrespective of the restriction of celibacy, and are now open to all without distinction of creed. The Commissioners think that it would be very desirable that in the election to Fellowships important original research should be regarded as a substantial element of merit.

The nature of the constitution of the Queen's University, Ireland, and its three colleges at Belfast, Cork, and Galway, is well known. The education to be obtained at these colleges is fairly complete, both on the scientific and literary side, and the examinations imposed by the University are such as to make its degrees of real value.

The evidence shows that the appliances for teaching are in some respects insufficient, and that there is a serious deficiency of funds for maintaining the efficiency of the Queen's Colleges in this respect. The Report concludes and recommends as follows with regard to the Queen's University in Ireland:—

"In founding the Queen's Colleges, the State did not adopt the principle of assisting and stimulating local efforts, and if we except the exhibitions and prizes, to which reference has been already made, as having been provided by public subscription, and a few other exhibitions which have been founded at Belfast, no voluntary contributions have been received by them. They are institutions for which the State has made itself responsible, and in which, as part of a University system, a complete scientific training is implied.

"As we think it of great importance that the sanction of the State should not be given to the teaching of science on a scale inadequate to ensure its efficiency, we recommend (1) That an increased annual grant be made to the Queen's Colleges for the purpose of providing assistants, apparatus, and the other necessary appliances of practical scientific teaching. We further recommend (2) that the Professorship of Natural History in the Queen's College, Belfast, be separated from that of Geology and Mineralogy."

The general conclusion reached, then, in this Seventh Report is that it would take very little to make London University nearly perfect as an examining and degree-granting body; that Dublin University is in a healthy condition, and by a little amendment in the subjects of examination for her Scholarships and Fellowships, she might be an example to her sister Universities in England; that the Queen's University, Ireland, and the four Scottish Universities are all working in the right lines, and that what they mainly require in order that they may develop into perfectly efficient teaching bodies, so far as science is concerned, are funds to provide the necessary men, buildings, and apparatus. No doubt the recommendations of the Commissioners in reference to these and other matters will receive serious attention in the proper quarter.

HERMANN'S "ELEMENTS OF HUMAN PHYSIOLOGY"

Elements of Human Physiology. By D. L. Hermann, Professor of Physiology at the University of Zurich. Translated by Arthur Gamgee, M.D., F.R.S. (London: Smith, Elder, and Co., 1875.)

FOR a considerable time a first-class work on the Elements of Physiology in our own language has been a desideratum. The bulky Handbook by Carpenter was framed in a nearly bygone era of the science; Kirkes' smaller volume is under a similar disadvantage; Huxley's excellent little book does not appeal to others than beginners, and the "Handbook to the Physiological Laboratory," by Drs. Sanderson, Foster, Brunton, and Klein, was never intended to fill the place of a manual. Dr. Gamgee steps forward to fill the gap with a carefully conducted and excellent translation of the fifth edition of Prof. Hermann's deservedly esteemed "Elements of Physiology," a work unequalled in the care which has been bestowed on the collecting and balancing of the investigations of authors from all quarters, as well as in its general construction and inherent unity of design.

Dr. Gamgee tells us, "After much hesitation and many doubts I decided not to annotate the text, for had explanatory notes, of the nature of commentaries with illustrations, been added to it, as I once intended, its appearance would have been still further delayed, and the work would have been materially altered in character—it would have ceased to have been Hermann's Physiology." We have a sufficiently high estimation of Dr. Gamgee's ability to think that the English-reading public are the sufferers from his change of determination. The work being Hermann's therefore, and not in any way Gamgee's, except as far as the translation is concerned, our remarks apply only to the former.

The subject is treated in four sections, or parts. The first is entitled "The Exchanges of the Matter of the Organism"; the second, "The Activities or Energies of the Body"; the third, "The Liberating Apparatus; the Nervous System"; and the last, "Origin, Development, and Death of the Organism." As in most works on general subjects written by authors with any special predilections, the space devoted to the different functions is not quite that which would suggest itself to the unbiassed reader. As an instance of this in the present case we may refer to the fact that the account of the organ of sight alone occupies more than one-eighth of the volume, and nearly three times as much space as that devoted to the circulation of the blood.

The first part treats of the chemical constituents of the human body, the blood, and the circulation. The most advanced method of notation is adopted, and Baeyer's observations on the relations of uric acid are incorporated.

In the chapter on the blood we find one section devoted to the death of that fluid, the expression being employed to indicate those effects which follow its withdrawal from the influence of the walls of the living vessels. With reference to the movement of the blood in the circulatory system, we cannot help feeling that there is considerably more that might have been said about it with advantage, and that it might have been treated in a more connected and precise manner. Too much stress is laid on the aspiratory power of the thorax, which is assumed to be so continuous that "an ordinary expiration merely removes the inspiratory increase of the negative pressure." The duration of the systole of the ventricles of the heart is said not to vary with differences in the pulse-rate according to the observations of Donders, which have been since shown to be incorrect. We are also led, incorrectly, to infer that the blood-pressure in the ventricles at the end of the diastole is a negative one; that the

force of gravity is one of those which aids the circulation; that "all those vessels which carry blood *to* a capillary system are called arteries;" that in "scaly amphibia"—by which we assume reptiles are meant—the two ventricles always communicate, which is not true as far as the crocodiles and alligators are concerned; and that the heart of a warm-blooded animal, removed from the body, will continue to beat "so long as a supply of oxygenated blood is provided."

The term "secretion" in its widest sense is said to denote "all those processes in which substances quit the blood in an altered or unaltered condition." This involves the inclusion of that simple nutritive diffusion into tissues which results in the origin and growth of bone, cartilage, &c.; an unnecessary complication, we cannot help thinking, and one apt to mislead. When it is stated that "nothing is known about the formation and regeneration of bone-tissue, except the morphological appearances presented in the various stages," justice is not done to Dr. Beale's most ingenious and highly probable explanation of the process by which it comes into existence.

The second portion of the work discusses the energetic relations of the body. Parts give indications of having been evolved from the author's inner consciousness, when he might have appealed to sound fact. On the whole we prefer the way in which the subject is treated in Dr. Pavy's excellent work on "Food." Prof. Hermann's theory of muscular contractility, based entirely on slender analogies, does not impress itself on our attention more than does the not less satisfactory one of Dr. Radcliffe.

The "liberating" or "discharging" apparatus, in other words the nervous system, occupies the third section of the work. As our knowledge of the nerves is very superficial, remarks the author, it must suffice to establish empirically the conditions which increase, diminish, or destroy irritability. This is done in a most exhaustive and excellent manner. Prof. Hermann regards the phenomenon of electrotonus as an effect of contact, the contents of nerve-tubes which are dying or in activity being negative to the contents of nerve-tubes which are living and at rest. The chapters on special sense will be read with particular interest, from the masterly manner in which they are written. Why so much space is devoted to the horopter, a surface the physical relations of which are as much connected with stereoscopic photograph cameras and double magic lanterns as with eyes, we do not know. With regard to the author's ideas on the recent views promulgated by Hitzig, Fritsch, Nothnagel, and Ferrier, we will quote his own words. "The movements which have recently been induced by electrical stimulation, since they do not occur after mechanical or chemical stimulation, may very well be set down to the irritation of more deeply seated regions, for the latter are unavoidably exposed to the diffusion of currents. . . . . No results as to the nature and distribution of the functions of the cortex, even of the value of approximations, can be deduced from these experiments."

In the fourth section of the work a short account is given of the development of the embryo, not detailed enough to be of much service, except to the initiated.

This rapid glance at the contents of Prof. Hermann's work indicates that it adopts a method of treatment that is more modern than most. In perusing it in detail the incorporation of the results arrived at in all directions by physiologists during the last twenty years, makes its value still further apparent. The many conflicting statements which have sometimes to be made, without any explanation being given, leave several questions without any definite answer. Such must for some time be the case in a science so young as physiology. The authorities for the different statements introduced are given in every case where there might be any doubt, and the book would have been still further serviceable if references had been introduced to the publications in which the results are described, as well as to the author's name. Many, in looking through the work, will feel that much of the method and many of the phenomena there explained, which, although they have not made their way into our text-books, have been current in the oral tradition of physiological circles; they must remember that a considerable amount of capital has been made out of foreign investigations by those who have done little more than dole them out in a different language from that in which they originally appeared.

The arduous task of translation has been most conscientiously performed by Dr. Gamgee, who has evidently weighed, carefully and acutely, the unavoidably difficult forms of expression employed, many necessarily quite new on account of the novelty of the conceptions developed. Taking for example the word "Schwellenwerth," as employed with reference to Fechner's psycho-physical law which is shortly explained; at the suggestion of Dr. Sanderson it has been translated "liminal intensity," an expression which does not at first sight explain itself, as does "initial intensity," the rendering which first occurred to Dr. Gamgee. In physics "initial" is employed of velocities, and we are not sure that any other term was necessary.

In conclusion, there is no doubt that the appearance of this work has greatly reduced the need, at the present time, for any other treatise on the Elements of Physiology.

WHITE CONQUEST

White Conquest. By William Hepworth Dixon. Two vols. (London: Chatto and Windus, 1876.)

MR. DIXON has been again in America, this time to collect evidences of the struggle between the races that is being waged on that wide battle-field. Although his method of treating the subject is not such as quite to bring his work within the critical sphere of NATURE, and although the author makes no attempt to treat his subject scientifically, still even the scientific reader, the student of ethnology or of the characteristics of the various races of men, and he who takes an interest in the struggle for existence wherever it is being carried on, will find much in Mr. Dixon's striking pictures well fitted both to interest and instruct. It is not in our province to criticise the quality of the artistic element in the work, but about its fascination there can be no doubt. Of course the work is one-sided. We do not use the term by way of depreciation, but in its literal sense. Mr. Dixon's aim is to represent, by means of a

series of sharply outlined and brilliant pictures, the most prominent and often the most unpleasant features of the great struggle out of which it is evident the white race must come victorious.

The regions with which the work is mainly concerned are the Pacific States, especially California, and also the States on the Gulf. In the West, especially, the fight is a regular *mêlée* between white men, red men, black men, and yellow men. Very striking indeed is Mr. Dixon's account of the means by which the Chinese are rapidly asserting for themselves a place of the first importance in and around San Francisco, notwithstanding the disgusting and degrading habits of the majority of them.

When the heat of the struggle is over, when the country is again sufficiently populated, and the people have settled down to a life of steady progress, what will be their characteristics, physical, intellectual, and moral? It is an interesting question, an intricate problem, which we fear it would be difficult to work out beforehand. In a recent number we referred to the valuable paper by Prof. Wilson, of Toronto, detailing his observations on the relations between the whites and the Indians, especially in Canada. His conclusion is, that in accounting for the disappearance of the American Indian, too much prominence has been given to extermination and too little to absorption. He produces data to show that a very considerable amount of red blood has been absorbed by the white intruders, and that aboriginal traces are to be found widespread among all classes of society. Moreover, that it is difficult to find a pure Indian, and that the half-breeds who now mainly represent the old proprietors of the soil have excellent stuff in them, and are being constrained gradually to settle down to a civilised life. The conclusion is, that in the end a homogeneous race will result, having no doubt large white characteristics, but at the same time showing unmistakeable marks of a red ancestry.

Where one race intrudes itself forcibly into a country already populated, and has to fight its way to find a place for itself, this mixture is inevitable; the men who do this rough work cannot as a rule take their own women with them. Some of the most impressive pictures in Mr. Dixon's work are connected with this subject, and show how inevitable it is that under the circumstances alluded to, a large half-breed population must arise. We are sorry to see, however, that Mr. Dixon does not speak so well of the half-breeds as Prof. Wilson does, though this may arise from the fact that those of Canada have as a rule more white blood than red in their veins. In the end, which approaches with accelerating speed, when homogeneity is attained, the United States will be populated by a race of very mixed blood indeed, though it is evident to everyone but a pessimist, that the brain and sinew and muscle which dominate in the Old World will, both in quality and quantity, in intension and extension, to use logical terms, bear the sway on the other side of the water. The great stumbling-block in this, as in other respects, in America, is the Negro, the "culled gemm'n," as he now calls himself. Extermination does not appear likely to be his fate, and "absorption" in his case seems a mighty long way off.

Two of the most interesting chapters in Mr. Dixon's works refer to education in America, and will somewhat surprise those who fancy that America has a system of education as thorough and uncompromising as that of Germany. While Mr. Dixon has evidently presented here almost exclusively the dark side of the education question in America, there is no withstanding his statistics. Still, all things considered, especially looking at the heterogeneous population, ever largely increasing from the outside, with which American educationists have to deal, both the extent and the quality of education in the United States do the citizens infinite credit.

While, we repeat, Mr. Dixon's work makes no pretensions to be scientific, still we are grateful to him for bringing before us so brilliant and attractive a series of pictures of a struggle which is indeed only the continuation, further westwards, of that which was begun far back in prehistoric times by the ancestors of those whites who at present seem likely to be victors and lords all the world over. We fear that after all, however much we may plume ourselves on our superior culture and advanced civilisation, might is still with us, as with our predecessors, right; and perhaps after all, both on scientific and humanitarian grounds, it is only right that it should be so.

OUR BOOK SHELF

Elementary Analytical Geometry. By the Rev. T. G Vyvyan. (London: George Bell and Sons, 1875.)

Conic Sections treated Geometrically. By W. H. Besant, F.R.S. (Same publishers.)

THERE is little calling for special notice in Mr. Vyvyan's work. The fact of its having reached a third edition is a clear indication that it has met with acceptance. New chapters have been added on focal properties of conics and on abridged notation and trilinear co-ordinates; the central conics are discussed together; and the chapter on the general equation has been enlarged. There is a good selection of exercises. The work is reduced in price, and now forms one of the publishers' series of Cambridge School and College Text Books.

The new matter in this second edition of Mr. Besant's "Conics" is confined to little more than two articles. The errata of the first edition have been carefully removed, and we have detected only some half-dozen simple typographical mistakes. Between thirty and forty new examples have been added. We notice that in consequence of a few slight alterations, in some four or five cases, the same figures come on to opposite pages, a fact easily accounted for when we know that the work is now in its second edition.

We presume that though Mr. Besant in his Introduction still states that "a knowledge of Euclid's Geometry is all that is necessary," he does not thereby mean us to infer that a like knowledge of geometry obtained from other and more modern text-books would not answer as well. It is not necessary to say anything in praise of a work so well known and prized as this as a text-book of Geometrical Conics.

Die Periodischen Bewegüngen der Blattorgane. Von Dr. W. Pfeffer, A.O. Professor in Bonn. Mit 4 lithographirten Tafeln und 9 Holzschnitten. (Leipzig: verlag von Wilhelm Engelmann, 1875. 8vo., 176 pp.) (The Periodic Movements of Leaf-organs. By Dr. W. Pfeffer, Extraordinary Professor in Bonn. With 4 lithographed plates and 9 woodcuts. Leipzig: W. Engelmann.)

THE essential character of periodic movements as defined by Pfeffer is their being recurrent. All "repeated" movements, whatever their cause and mechanism may be, are periodic. Recurrent or periodic movements are of diffe-

rent kinds, and it is necessary carefully to distinguish between them. Thus certain periodic movements occur only during the growth of the part, and cease entirely when the structure has become full-grown; and the term "nutation" is restricted by Pfeffer to these recurrent movements during growth. In other cases periodic movements occur which are not determined by the growth of the part, but are due exclusively to the elongation and contraction of certain portions of tissue; and these latter are called by Pfeffer "movements of variation." These movements of variation which occur so commonly in the Leguminosæ are due to the action of more or less joint or hinge-like portions of the leaf. Nutations on the other hand which occur in very many leaves or petioles are due to unequal growth of the tissues, and not to the presence of a joint. As the movements of nutation are dependent on the growth of the part, they cease when growth ceases; and as the zone of maximum growth of the part changes its position, so also the seat of the nutation will vary. The movements of variation have a very different character, as they continue when the leaf is full-grown, and naturally, as they depend on a definite structure having a fixed position, they do not change their place during growth. The two forms of movement are very closely related, and jointed parts during growth often exhibit movements of nutation, thus showing the close relationship that exists between the two.

Periodic movements, whether movements of nutation or of variation, are either entirely independent of external stimuli, or are conditioned by them. The former class are the "autonomous" or "spontaneous" movements, the latter are the "paratonic" or "induced" movements—"Receptionsbewegungen," and depend on the paratonic action of external agents, as, for example, light and heat. As a consequence of the paratonic action, the leaf makes, in addition to the simple to-and-fro pendulum-like movement, certain further oscillations with decreasing amplitude, which Pfeffer calls "Nachwirkungsbewegungen," but which for want of any better word we may call simply secondary movements. It is by the help of these "secondary" movements that Pfeffer explains the peculiarities of the daily periodic movements of plants. The first chapter of the work now before us is devoted to these general remarks on the movements.

The second chapter treats of the mechanism of the induced movements evoked by alternation in illumination, the so-called sleeping and waking of plants. These movements are either movements of variation, as in the *Phaseolus vulgaris*, or they are movements of nutation, as seen in the leaves of *Impatiens noli-me-tangere* and the flowers of *Leontodon hastilis*. The measurements of the movements are made by an instrument described and figured by Pfeffer as the Lever Dynamometer.

The third chapter treats of the daily periodic movements. The subsequent chapters treat of such subjects as the mechanism of the daily movements, the intensity and internal causes of the movements, the influence of temperature and gravity, autonomous movements, and the like. A short chapter is devoted to the distribution of periodic movements. From it we learn that movements of variation are common in plants belonging to the Leguminosæ and Oxalidaceæ. All the plants of an order do not necessarily show movements of variation. Thus in the Euphorbiaceæ they occur in Phyllanthus; while in Euphorbia we have movements of nutation. A short historical review and *résumé* of results concludes this most interesting volume. W. R. M'NAB.

Jahresbericht der Meteorologischen Centralstation Carlsruhe über die Ergebnisse der an den Meteorologischen Stationen des Grossherzogthums Baden im Jahre, 1874, angestellten Beobachtungen. (Bearbeitet von Oscar Ruppell.)

THIS report gives a very satisfactory discussion, by copious tables and accompanying remarks, of the meteorological observations made at sixteen stations in the Grand Duchy of Baden during 1874. In addition to the tables usually printed in such reports, the temperature is given for the five-day means at all the stations. The monthly means of temperature, humidity, pressure, &c., include also the means of the separate hours of observation,—a feature of the report which deserves, from the important practical questions it throws light upon, to be more generally followed. The tabulation of thunderstorms shows each day on which these phenomena occurred at each of the stations. This method is greatly to be preferred to giving only the gross number for the separate months, since the data so published will be available in determining the periodicity of thunderstorms through the year,—an inquiry with which many interesting inquiries are intimately bound up. It is unnecessary to remark that 16 stations are miserably inadequate as a representation of the rainfall over the diversified surface of the Grand Duchy. Future reports will doubtless show a large increase to the staff of rain-observers. The daily pressure is given for two stations, Carlsruhe (404 ft.), and Höchenschwand (3,322 ft.), but unfortunately only the mean of the three daily observations is given, instead of one, or, better still, the whole three observations, it being only observations at particular hours which can be turned to account in charting the weather.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Dr. Richardson's Hygeia

THE eloquent address in which Dr. Richardson has sketched the possible Health City of the future might furnish matter for much discussion—among other points, the probable statistics of the community. The author contemplates the possible reduction of the death-rate to 8 per 1,000 in the first generation, and to 5 or less in the next, as suggested by Mr. Chadwick. It sounds simple enough to talk of knocking 1 or 2 per 1,000 from a death-rate, and, so long as the rate is tolerably high, such as 20 or more, the effect is not so startling, but when we come to such low figures as 8 and 5 the difference becomes enormous. Thus, whereas a diminution from 21 to 20 raises the expectation of life by only $1\frac{1}{2}$ years, a fall from 9 to 8 raises it by 9, from 6 to 5 by 21 years, and from 5 to 4 by 40 years. We should thus have at 8 per 1,000 death-rate an expectation of life of 86 years, and probable mean duration of 120, whilst there would be cases of old people living to 160. Again, at 5 per 1,000 the ages would be respectively 137 years for expectation at birth, and old people living on to 250; at 4 per 1,000 the expectation would be 177, and old people would live to beyond 330. Compare these figures with Dr. Richardson's closing address, where he claims a modest 90 years as the proper length of human life.

Another aspect of the case is the probable increase of population, which we may thus calculate:—The mean birth-rate of England for the last 35 years is 33·8; if the death-rate be 5 the net increase would be 28·8 per 1,000. At this rate the population of Great Britain and Ireland would reach 66,000,000 by the year 1900, and, by the year 2000, no less than 1,120,000,000, or about the present population of the inhabited globe. At the same time the model City of Hygeia would more than double itself by the end of the present century, whilst, by the end of the next, its population would be 3,450,000, or as nearly as possible that of our overgrown metropolis. What check does Dr. Richardson contemplate to this inordinate hypertrophy?

F. DE CHAUMONT

Photography in the "Challenger"

WHEN the *Challenger* was fitted out, I was asked to prepare certain special dry photographic plates to go with her. I wished to give them the sensitiveness of wet collodion and unlimited keeping qualities, and the following letter from the chief photographer on board is very satisfactory. The stains alluded to on

some occur from the shifting of the packing papers, and the faces of two plates then coming in contact:—

"H.M.S. *Challenger*, Yokohama, 15th June, 1875.

"Sir,—It gives me great pleasure to acquaint you that the dry plates supplied to this ship three years ago are working well, being *fully* sensitive, notwithstanding the great trial that they have been subjected to—extreme cold and heat. On some plates I found damp spots on the film, which stain the picture, and hence I discard them; but, on selecting plates, I travelled up 2,500 feet (where the wet process seemed impossible) and obtained *perfect* negatives. I would suggest that more substance be placed between the plates, as I have found them sticking together, and hence the same spots on each plate. I am using your new developer, which works well.

"I remain, yours obediently,
(Signed) "JESSE LAY, Photographer.

"To Col. Stuart Wortley."

If at any time any scientific worker may be contemplating an expedition where highly sensitive dry photographic films might be of use, I shall be glad to place my experience at his disposal, and give him formulæ on which he can thoroughly and implicitly rely. H. STUART WORTLEY

Patent Office Museum, South Kensington, Nov. 8

Bees and Clover

IN NATURE, vol. xii. p. 527, it is stated that two nests of English humble-bees have been sent out to New Zealand, and that they are specially desired there for the purpose of fertilising the common clover. I suppose the red clover is meant, as the white is fertilised by the hive-bee, and the wonderful rapidity with which it has spread over the Australian colonies proves that it does not require any further assistance.

The species of *Bombus* sent out is not mentioned in the paragraph, and it is not likely that Mr. Frank Buckland would send the wrong one; but it is worth pointing out, as not being generally known, that the commonest of the humble-bees (*Bombus terrestris*) does much more harm than good to many of our flowers. I have for several years watched the humble-bees, and I never saw this species go to the mouth of the corolla of the red clover. As far as my experience goes, it invariably bites a hole at the base of the flower and extracts the nectar from that opening, so that it is of no use in carrying the pollen from one flower to another. All the other species of humble-bees that I have noticed go to the mouth of the flowers, and they alone are useful in their fertilisation.

The common scarlet-runner or pole-bean is entirely dependent on the visits of bees for the fertilisation of its flowers, and I have lately seen an instance where the attentions of *Bombus terrestris* were mischievous and hurtful. A friend of mine, living near Finchley, had a late sowing of scarlet-runners rendered barren by their operations. The smaller humble-bees did not visit his garden, and *Bombus terrestris* cut holes at the base of both the expanded flowers and the unopened buds. The hive-bee with some trouble, by pushing between the petals, can get at the nectar and sometimes fertilises the flowers, but as soon as the humble-bee commences to cut holes at the base it seeks for these perforations as a readier means of access.

At the beginning of the season some of the *Bombus terrestris* will be seen visiting the flowers of the scarlet-runner in a legitimate manner, but they soon learn that it is easier for them to get at the nectary by cutting holes at the base, and later on their acquired experience teaches them to attack the buds in the same manner. Large gaping flowers such as the Nasturtium and the Fox-glove are fertilised by this species, but to most of the narrow tubular ones its visits are injurious.

I hope therefore that it is not *Bombus terrestris* (the common large yellow-banded kind) but some other species of the genus that has been sent to New Zealand, and if so it will be a most valuable addition to the fauna of the country should it be successfully acclimatised.

In sending humble-bees to a distant country I believe the best plan would be to dig up the fertilised queens, in winter, out of the ground where they hybernate, and forward them in their dormant state packed in earth kept cool by ice.

Cornwall House, Ealing THOMAS BELT

Cherry Blossoms destroyed by Squirrels

THE very general interest exhibited in your columns some time since in regard to the destruction of flowers by birds, leads me to report the following observation.

I have noticed repeatedly here in New England that the common red squirrel (*Sciurus Hudsonius*, Pall.) is extremely fond of flowers, and I am inclined to believe that in this immediate vicinity he destroys far more flowers than any bird. The squirrel in question, though smaller than the common squirrel of Europe (*S. vulgaris*, Linn.), bears a close resemblance to the latter. We have field-mice also whose habits so closely resemble those of the squirrel that it seems highly probable that mice as well as squirrels often aid in the destruction of flowers. For cherry blossoms in particular our squirrel has a well-nigh insatiable appetite.

Having lived for several years upon the edge of a considerable belt of woodland, I have been surprised to witness the extent of the devastations of the squirrel in this particular, and have watched their operations with no little interest. The flower is bitten from its stalk precisely as a nut would be, and held between the paws of the animal while the little ovary at the base of the blossom is eaten. All this is the work of but a moment, since the edible morsel is exceedingly minute. The flower is then dropped to the ground, seemingly in a perfect state, since the petals are untouched, and remain adhering to the calyx. I have noticed that one squirrel working by himself will destroy in this way two hundred blossoms or more in the early morning of a single day. On examining the discarded flowers it appeared that they were in no wise mutilated excepting that the ovary had been bitten from the pedicel in every instance. Freshly opened flowers seem to be preferred. At all events the very first blossoms of the spring are eaten, and the destruction of flowers is largest in the early days of the blossoming. As soon as the flowers have become somewhat mature, the squirrels leave them, and they neglect the immature cherries also until near the time of ripening, when they again attack them, both for the sake of the fleshy part of the fruit and of the kernel. With respect to the fruit, however, the squirrels are far less harmful than birds, since the latter descend upon it in overwhelming force. The red squirrel has long been detested by American gardeners because of his destruction of pears, the choicest of which he gnaws in two, for the sake of their seeds merely, but I am ignorant whether anyone has hitherto called attention to his fondness for the blossoms of fruit-trees.

I have occasionally noticed the rose-breasted grosbeak (*Guiraca Ludoviciana*, Linn.) plucking cherry blossoms, or perhaps the unopened flower-buds, at the same time with the squirrels, but the birds ate leaf-buds from an adjacent ash tree as often as they ate the cherry flowers, and the number of blossoms destroyed by the birds was insignificant in comparison with the work of the squirrels.

Bussey Institution of Harvard University, Oct. 20

Plagiarism

A FRIEND has just called my attention to the letter of Mr. Boyd Dawkins in last week's NATURE under the head of "Plagiarism." Mr. Dawkins may have found out by this time that he has made a mistake to my detriment, but I am bound to reply to his letter.

The map accompanying the article "The Early Geography of the British Isles" (*Leisure Hour*, July 1874), which Mr. Boyd Dawkins says is a reproduction of one he published in 1871, is in reality the well-known map first issued by Sir Henry de la Beche more than forty years ago, with the addition of hypothetical river-courses (indicated in the first instance by Mr. Godwin-Austen) and submerged forests, the said river-courses having since been more completely and strikingly pourtrayed by Mr. Dawkins, whilst I have added to the submerged forests.

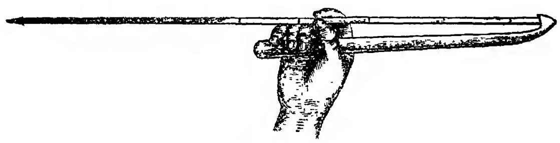
The *Leisure Hour* map is thus a composite production. Beneath it, so far from there being no reference to its various authors, are the words: "After Sir Henry de la Beche and Mr. Godwin-Austen, F.R.S." (I regret to find Mr. Dawkins's name is not placed on the map as well); whilst in the text of the article are the words: "See a paper by Mr. Boyd Dawkins, F.R.S., in 'Hardwicke's Popular Science Review' for October 1871."

I can only suppose Mr. Dawkins had not given due attention to the *Leisure Hour* map and its accompanying article when he wrote his letter off San Francisco. If he had, I disallow his exclusive claim to the one hundred fathom line of the British seas, the submerged forests, and (with the modification above mentioned) the hypothetical river-courses.

8, Walterton Road, W., Nov. 8 HENRY WALKER

Curious Australian Implement

In NATURE, vol. xii. p. 544, a correspondent points out the resemblance existing between an implement used by the Ute Indians and one belonging to the Australian natives, which he calls a vermin hook. May I venture to suggest that he may possibly have mistaken the use of the latter? It appears to me to be identical with the instrument used by all the Australian "river" blacks to throw their light reed spears with, which consist of a heavy miall wood point and a shaft of reed. The bone hook is inserted in the head of the reed, the spear resting between the forefinger and thumb of the hand that holds the thrower and lying parallel to it, thus :—



the spear being propelled from the hooked end of the thrower, which is rapidly brought forward into a vertical position, thus propelling the spear before it. During several years on the different Australian rivers, I saw the weapon universally used as above, but neither there nor elsewhere in the colonies for any other purpose.

Derby, Oct. 29

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—The following are the Greenwich mean times of geocentric minima of Algol, occurring before 14h., to the end of the present year, according to the elements employed by Schönfeld for his later ephemerides :—

	h. m.		h. m.		h. m.
Nov. 14 ...	11 42	Dec. 4 ...	13 24	Dec. 27 ...	11 57
,, 17 ...	8 30	,, 7 ...	10 13	,, 30 ...	8 46
,, 20 ...	5 19	,, 10 ...	7 2		

The first heliocentric minimum in 1876, with the epoch and period of Schönfeld's second catalogue of variable stars (1875), occurs on January 2, at 5h. 34·5m. G.M.T., or January 2·23226; the minima throughout the year will be obtained by the successive addition of $2^{d}\ 86729$. For times of geocentric minima, corrections must be applied to the times so calculated, which may be found from

$$\text{Corr. to heliocentric minimum} = 7{\cdot}67\text{m. R. sin. } (S + 35^{\circ}{\cdot}69),$$

where R is the earth's radius-vector at the date, and S the sun's longitude.

The period of Algol, which had diminished since 1782, at first slowly, but afterwards more rapidly, after remaining constant or nearly so for a time, appears to be again slowly diminishing.

According to Schmidt, of Athens, the brightness of Algol is equal to that of δ Persei about 47 minutes before and after minimum, to that of ϵ Persei about 62 minutes before and after the same, and to that of β Trianguli 95 minutes before and after. The fluctuations extend over about $9\frac{1}{4}$ hours.

There is a suspicion of variability about the light of the small companion of this star, first remarked by Schroeter. Smyth measured it in 1835. During the last two years it has sometimes been readily visible and at others discernible with difficulty with the same instrument; but a systematic course of observations is required to decide if there be a real variation.

According to Schönfeld, S Cancri will be at a minimum on Nov. 14 at 16h. 50m., Dec. 3 at 16h. 3m., and Dec. 22 at 15h. 17m. G.M.T.

For U Geminorum it appears very difficult to make a prediction likely to be of any service, so that very frequent examination is necessary for the determination of the times of maximum. Mr. Otto Struve states that this object does not usually disappear in the Pulkova refractor. Schönfeld thinks the period varies between 70 and 150 days. A secondary minimum has been remarked on several occasions about the time of greatest light. In most periods the star has not continued visible in ordinary telescopes more than a fortnight, and occasionally less. Winnecke has given a list of the small stars in the vicinity of U Geminorum, which will be useful in its identification (See *Astron. Nach.*, No. 1,120). At maximum this star is a little brighter than an average ninth magnitude in Bessel's scale.

THE MINOR PLANETS.—There are this week three additional discoveries to record. No. 151, by Palisa, at the Observatory of Pola on the Adriatic on Nov. 1, place at 13h. 24m. local mean time in R.A. 3h. 2m. 17s., and N.P.D. 71° 40'; No. 152, by Paul Henry, at Paris on Nov. 2, place at 11h. in R.A. 2h. 38m. 17s., N.P.D. 74° 35'; and No. 153 by Palisa, on Nov. 2, place at 12h. 40m. in R.A. 3h. 1m. 28s., N.P.D. 72° 25'; all three are of the twelfth magnitude, or somewhat fainter. In Prof. Tietjen's Berlin Circular he transposes the above numbers for the planets discovered on Nov. 2, but upon what ground does not appear; according to the times of observation given in the first announcement of discovery, the Paris planet should precede that detected at Pola. No. 150, which was found by Watson at Ann Arbor on Oct. 19, soon after his return from Europe, has been observed at Berlin, Düsseldorf, Leipsic, and Pola, and No. 151 on the night after discovery, at Berlin.

Though in certain cases it may be necessary to use caution in announcing the discovery of a new small planet, the actual positions of several of those already observed being very imperfectly known, there appears every probability that the three just brought to light are really new. No. 138 (Tolosa) is probably near the ecliptic in 3h. R.A., but some thirteen or fourteen degrees to the east of Palisa's objects, as will be found from the elements of Gruber, calculated upon the six weeks' observations in June and July 1874. The rough approximations to the orbits of Dike and Camilla at present obtained, place the former in the 5th hour of R.A., and upwards of 34° N. of the equator, and the latter at the beginning of the 4th hour, but at a considerable distance from the ecliptic, or with a N. declination of 8° or 9°. The position of No. 137 (Melibœa) is open to great uncertainty, the observations so far published extending over sixteen days only, and an orbit founded upon them would be of little service so long after the date of observation. A circular orbit appears to have been computed by Dr. Becker at the time, as he published a short ephemeris in the *Astronomische Nachrichten*—but the elements were not appended. Even with the shortest period yet assigned to any member of this group of planets, Melibœa would hardly be so far advanced in R.A. at the present time.

No. 97 (Clotho), in opposition on Nov. 9, is now very little below an eighth magnitude in Argelander's scale. The calculated places for Berlin midnight are –

BESSEL'S WORKS.—With No. 2,061 of the *Astronomische Nachrichten*, Dr. Engelmann, formerly attached to the Observatory of Leipsic, issues a prospectus of an important astronomical publication, entitled "Abhandlungen von Friedrich Wilhelm Bessel," in which it is intended to reprint a selection of upwards of 130 of the more important papers, &c., of the great Königsberg astronomer. Many of these are now scattered in works which are often costly and difficult to procure, and the proposed collective edition of the principal memoirs cannot fail to be of vast service to the astronomical student. The selection which has been made will be contained in three

volumes, the first of which is to appear in the present month, the second in the spring, and the third during the summer of 1876, and will be arranged under the following divisions:—(1) Motions of the Bodies of the Solar System; (2) Spherical Astronomy; (3) Theory of Instruments; (4) Stellar Astronomy; (5) Mathematics; (6) Geodesy; (7) Physics, and (8) Various. A portrait and short life of Bessel is to be attached to the first volume. Dr. Busch's complete list of Bessel's works, inclusive of astronomical notes in various scientific periodicals, as the *Monatliche Correspondenz* of Zach, the *Berliner Jahrbuch*, &c., which is appended to vol. xxiv. of the Königsberg Observations, contains 385 titles; but many of the shorter contributions being of minor or ephemeral interest, it is probable that the selection proposed will include all the writings of the illustrious astronomer which can now possess value.

AMONG THE CYCLOMETERS AND SOME OTHER PARADOXERS*

II.

MR. H. HARBORD, who hails from Hull, has put forth three letters, with which we have been favoured. "The Circle Squared" (in November 1867) has, we guess, been noticed by Prof. De Morgan. There is a nicely drawn diagram, two concentric circles, two squares, said to be their respective equivalents, all in black; an equilateral triangle and its circumscribing circle in red ink; the former is described on a side of the smaller square, and the red circle passes through the extremities of the same side. A statement is made, which appears to be a statement and nothing more, for it proves nothing. From "Squaring the Circle" (April 15, 1874) we learn that the writer has leisure (*fons et origo mali!*), and so has ventured to amuse himself by considering the relation of the equilateral triangle, the square, and the circle. He obtains the positive altitude of an equilateral triangle on a side of the square to be 7·75448559771125, and requires the exact side of the square and the proportion of the triangle to the square and the equivalent circle. He winds up, like many of his race, with the following reflections:—"I think if the learned in geometry, mathematics, and trigonometry, abandoned approximating theories, and would take the trouble to elucidate the above-stated propositions, they would undoubtedly be able to subvert all anomalous and vague theorems, free the study of geometry, &c., from ambiguity, enable tutors to explain correctly, remove burthens imposed on the mind of the pupil, and establish a system of teaching which shall be correct and intelligible, for it is evident the result of minute calculations proves there is no mystery in geometry, mathematics, or trigonometry; they are uniform, and may be more easily taught and comprehended with perfect truthfulness without approximation." To prevent trouble, this man of leisure appends the rule; it is: Add one-seventh to the altitude, and we get the base; and so on. Not satisfied with the above remarks, we have a note to the "learned" (see above); and it is the following curious sentence:—"It is worthy of remark, and more especially to those who are interested in the forthcoming 'Transit of Venus,' when the true distance of the earth from the sun is to be determined, and a difference of about three millions of miles accounted for, to be in a position to prove the fact. Now all this can be accomplished by anxious, minute observation and correct calculation!" He then appends (we don't see the connection): "Length of an arc of one degree, ·017 . . . to twenty-seven places final." We got the last communication a few days ago; it is, "Construction of the Perfect Ellipse" (Dec. 22, 1874). This is a fine large figure on a sheet of paper some eighteen inches by fourteen. He finds that the true ellipse is only to be described on the perpendicular of the equilateral triangle. Mr. Harbord has evidently an idea, and that is, that the equilateral triangle is the key to unlock many geometrical mysteries.

* Concluded from vol. xii. p. 560.

Mr. Michael Callanan, of Cork (September 1874), "is in a position to demonstrate before any appointed number of scientific gentlemen, the perfect quadrature of the circle, rendering it as clear as the most simple, plain (*sic*) rectilineal figure. The Circle, that colossal mystery, to prove the area of which has been looked upon as the climax of geometrical science; and, although the object of search by the mathematicians of all nations, their greatest efforts have failed; every attempt, as yet, to square the circle being undemonstrable, and offering no reward to the anxious investigator beyond mechanical or approximate measurement—a manipulation of the great problem. My solution will be found original and thoroughly demonstrative in all its details, without having anything whatever to do with the given or polygonal rules for approximation. Entirely new ground is opened up in the path of science which I have chosen, guided only by positive mathematical laws, combined in the most strict logical arrangement, and thus *proved to demonstration*. I now proclaim the absolute fact of being able to set aside for ever any further doubt as to the complete quadrature of the circle, and thereby confound those scientific prophets who pronounced it an impossibility." Local circumstances offer many impediments in bringing the matter before the scientific world, and "being a geometrical secret, the law of Patent cannot be applied." He then puts himself in the same position with other inventors and discoverers, but he asks for an accredited tribunal "from which I would ask an impartial hearing, so as to verify these statements, and also to be identified and protected as the discoverer." For this end he is willing to attend at any selected place in England, Ireland, or Scotland. He then glances at some of the immediate results in the realisation of this problem. "At the proper time will be published a comprehensive work, including all the new diagrams necessary to carry out and complete the demonstration." And this is all we know of Mr. Callanan's "Secret of 'the Circle' solved."

Our next claimant for notice is not a Circle-squarer, but he would certainly have got a warm corner in the "Budget." Middleton's "new process of measuring the height of the sun," an observation for latitude demonstrated by geometry, proving the sun's height less than the latitude of observer. On this leaflet our paradoxer says, "the sun's height is under 3,000 miles." The principles of this discovery are published in the *West Londoner*. Mr. Empson E. Middleton, *Poet* (Naval and Military Club), sends us a further document (May 5th, 1873): "£100 Reward to the first who disproves the following Diagram—Middleton's Geometrical Proof that the Earth is Flat." Proof is said to turn upon the SPHINX SOLUTION,—"a globe demands six cardinal points." Having disposed of this point to his satisfaction, he "challenges all the mathematicians to support their statement that a perpendicular line and a line at right angles are the same; one is *flat*, the other *upright*. I undertake to prove that the perpendicular line is *not* the same as a line at right angles, though the two are utterly confused in every school-book of the day. I undertake to meet in public and to confute any of our mathematical professors who may have the manliness to come forward and discuss this question of the perpendicular, a question which forms the fundamental basis of the whole science of geometry, and is of the very first importance. I remain faithfully, to the Majesty of Truth." Mr. Middleton has published a translation of "the first two books of the Æneid of Virgil" to supersede Mr. Connington's (*sic*): he has a work "On Space" unpublished, and one "On Man" awaiting demand.

Naturally, after this we should turn to Parallax, or to

Mr. John Hampden, but we have preserved nothing from either of these paradoxers. The former has gained notice in the *Budget* (we are sorry to record the recent death of another able opponent of these views, Mr. T. T. Wilkinson, F.R.A.S.); the latter has figured before the public in the daily papers. A consequence of Mr. Wallace's acceptance of Mr. Hampden's wager is that the former gentleman has for nearly five years been the subject of continuous libels (see letters in *Daily News*, March 11, also March 9). It is to be hoped that an enforced retirement of a twelvemonth will result in Mr. Hampden's learning wisdom and the keeping of the peace towards Mr. Wallace and all others.

In De Morgan's account of Taylor the Platonist (*B* of *P*. pp. 182, &c.) there is nothing said of an early work of his, "The Elements of a new method of Reasoning in Geometry applied to the rectification of the Circle" (1780), "a juvenile performance lost or suppressed" (biographer in *Penny Cyclopædia*). We have examined this work, but it is impossible to give an account of it here; the solution is approximative.

The malady (*Malus cyclometricus*) is not confined to the Old World; our concluding instances will be drawn from a Geometry published at New York, and from a treatise specially devoted to the subject and printed at Montreal. We have not a copy of Mr. Lawrence S. Benson's "The Elements of Euclid and Legendre, with Elements of Plane and Spherical Trigonometry," but he has sent us "A Reply to Criticisms on Benson's Geometry." This will answer our purpose better, for the defence shows that the malady is confirmed. The symptoms are even more exaggerated than in Mr. J. Smith's case, for whereas his circumference ("Budget," p. 318) shrank into exactly $3\frac{1}{8}$ times his diameter, Mr. Benson's has shrunk to only 3 times! Where all this will end if the malady increases it is hard to say; perhaps the unfortunate circle will shrink up into its own centre! Opponents had pointed out "that when the areas of polygons inscribed in the circle are computed by means of plane triangles, a result is obtained for the inscribed polygons greater than $3R^2$," and they reasoned (it seems to us irresistibly) "that it is impossible for a circle to be less than a figure inscribed in the circle." Mr. Benson trusts, however, that after fourteen years' application to mathematics he will not be thought to have committed so egregious a blunder as to bring himself into direct contradiction of the self-evident proposition, "A part is less than the whole." He commences his defence with the statement that Torelli contends that the circle will be proved to be the square on its diameter exactly as 3 to 4. He then goes on to instance that Playfair ("Euclid," p. 307) demonstrates that Torelli's proposition is true on *two conditions*. Is it credible that Mr. Benson should proceed to say: "The fact that the proposition is true 'on two conditions' prevents the proposition from being *false*, for a false proposition can be true on *no* condition." The conclusion of the whole matter is that he replies to the inquiry, "How is it that reasoning from plane triangles for the computation of the areas of polygons, and reasoning from the ratios of rectangles, when they are all rectilinear magnitudes, that different and conflicting results are obtained?" that "the reasoning on the *ratios* and *rotation* of surfaces involves their *relation* to each other; whereas the computation of the plane triangles involves their *boundaries*: and since for the QUADRATURE OF THE CIRCLE *the relation between the circle and a certain rectangular space is required*, it is evident that the proper mode of reasoning is by means of the relation of the ratios of the small rectangles inscribed in the circular spaces to the ratios of the sums of those rectangles, or of the whole rectilinear figures; or by means of the rotation of rectilinear and curvilinear surfaces around a common axis—and not by the process of continually doubling the number of sides of the polygons described about the circle; since the sides do not reach the circumference, this process gives an approximate result only, which is inconsistent with the strictness of geometrical reasoning." We do not profess to follow the writer's reasoning, but hold fast by the *terra firma* which he appears to discard.

"The Circle and Straight Line" is a work got up in an elaborate and elegant dress: it consists of Parts I., II., III., and a supplement in brown binding, and a duplicate of the supplement in green (there is a portion of a flyleaf additional in the former supplement, or else the two copies appear to be identical). Further, there is with each a book of plates, all most clearly drawn, and the diagrams protected by slips of tissue paper. Evidently the author, John Harris, or Kuklos, is not a needy man. Let us gather from Mr. Harris's preface the object he has in view. Deeming the solution of the geometrical problem which demonstrates the relation of the circle to the straight line to be peculiarly of public importance, he gives a statement of what he has done in the matter. "The discovery of the solution was communicated by letter, dated 29th of December, 1870, accompanied with demonstration, &c., to the Astronomer Royal." There was, the author admits, imperfection and error in the case as then presented. The Astronomer Royal declined to examine the case. In January 1873 the papers were presented to the President of the Royal Society (still Sir G. B. Airy), "with a request (claim) in writing to have the case judicially examined by that Society." The documents were returned; they met with a similar fate at the hands of the Professors of M'Gill College. The subject is to describe a circle (or circumference) equal in length to a given straight line, and to draw a straight line equal in length to the arc of a circle, "accompanied with demonstration that the conditions of the requisition have been mathematically fulfilled. We publish our solution with the distinct statement that it is essentially in strict accordance with that scientific system known as Euclid's. We claim to have our demonstration admitted or disproved, and we challenge objection or adverse argument on that system." We shall first convince our mathematical readers, on Kuklos's own summing up ("Corollary," p. 34), that he is wrong, and then, on the charitable supposition that he is willing to be convinced, point out where we consider he has failed. We shall take the last sentence of the Corollary cited above: "Wherefore, if a square be inscribed in a circle, the ratio of the inscribed square to the circle is the ratio of nine to ten." It will be seen that this gives for the value of π, $\frac{20\sqrt{2}}{9}$, that is 3·142696; not a very close approximation to the accepted value. But, of course, in arguing with Mr. Harris we must go over his work and point out, if possible, where he has tripped. We commence with enunciating his Theorem A.: "If an arc containing one-eighth of a circle be applied upon a straight line, and from the terminal extremity of the arc a perpendicular be drawn intercepting the straight line, and if from the arc one-tenth thereof be cut off, then, if the remaining arc (to wit, the arc containing nine-tenths of the whole arc) be rolled upon the straight line, the point of contact shall be the same point on the straight line intercepted by the perpendicular drawn from the terminal extremity of the whole arc." $B\,M$, $B\,n$ are taken to be the two arcs, and O, d are taken to be the corresponding points to M, n, on the tangent at B, also D is the foot of the perpendicular from M on the same tangent. Mr. Harris's object is to show that $D\,d$ coincide: *if* they did, then we would admit that he has proved his point; but on p. 22, line 13 (all his previous working having been sound, though somewhat tediously put), he has "$c\,d$" instead of $C\,D$ (his $c\,d$ is a misprint, we presume, for $C\,d$), and then easily gets to his desired conclusion. We would ask him *how* he gets "$C\,d$." Again, on p. 24, third line from bottom of page, we tell him that "$D\,O$ is one-tenth of $B\,O$" is a cool

assumption, and we also ask him how he gets the last line on p. 27. These crucial points occur in "independent proofs" of the same theorem; they are pure "beggings of the question," we believe. This is all we have to say on Part I. Part II. opens with an admirable motto (reminding us herein of Mr. James Smith), "Prove *all* things; hold fast *that* which is *good*." Having *proved* then the previous theorem, he *holds* fast to *that*, and proceeds to the "construction of the circle;" his object being "to make manifest the great importance of the circle as one of the fundamental facts belonging to the Plan of Creation." As we consider the foundation wrong, until Prop. A is proved, we shall not follow the writer through the twenty-four pages of rather obscure mathematics devoted to this subject. We come next to "Mathematics and the Art of Computation." Starting from what he has (as he thinks, we will say) just proved, viz., that "the difference of the quadrant and the chord of the quadrant is an aliquot part of the quadrant and of the chord, and that the number of those equal parts contained in the chord being nine—the quadrant contains ten": because he finds in this "conclusive evidence that the (so-called) Arabic system of notation is is not an artificial human contrivance, but a great natural fact of a primary character, a fundamental part of the Science of Creation." Further down he speaks of many persons preferring "with a strange, and, as it would seem, with an increasing perversity, to cultivate the *thorns and thistles*, leaving the *good seed* as not worth utilising." He is then careful to state that by "thorns and thistles" he does not mean the modern methods of mathematical analysis. Still, "is it, or is it not, true that the language of mathematics is fast becoming an unknown tongue to ordinarily educated men, and that those to whom it is known can scarcely hold converse with their fellows (on any scientific subject) in ordinary language without a feeling of condescension, and scarcely without a feeling of impropriety? . . . . Is it true that the mathematician does now, *in some degree*, regard his fellow-worker who is unpractised in the calculus and non-conversant with differential methods as but little better than a publican and heathen?" We will not undertake to answer this question, but perhaps our author's ground for this opinion is the reputed division of the human species by the "Cambridge Wrangler" into those who understand the differential calculus and those who do not. He himself goes on to say, "If it be true that such a result does manifest itself in any considerable degree, it may be pronounced decidedly unwholesome and bad—bad for science and bad for civilisation—because mathematical knowledge is a necessity to science and a necessity to civilisation." This we admit. He then reiterates the statement that he knows that examination will show his demonstration of the quantitive (*sic*) ratio of the perimeters of the circle to the diameters is "mathematically incontestable." He then goes into an examination of Prop. XIII., Book V., of Brewster's Legendre: "The surface of a regular inscribed polygon and that of a similar polygon circumscribed, being given, to find the surface of the regular inscribed and circumscribed polygons having double the number of sides." Among other objections, he objects to the italicised statement (Prop. XIV., "Legendre"), "We shall infer that the last result expresses the area of the circle, which, *since it must always lie between the inscribed and circumscribed polygon*, and since these polygons agree as far as a certain place of decimals, must also agree with both as far as the same place." His objection to the whole method is "in the omission to observe that comparison has to be made between a continuous curved line (the circle) and a continuous straight line (the diameter)." And then, as elsewhere, he indulges in metaphysics. Part III. begins with Curvature and ends with Theology. "A human science which does not distinctly recognise the primary truths of theology as its ultimate basis, is not based on reality; it has not and cannot have any actual and secure foundation. If the science of England is not so based, no matter what seeming progress may for a time be made, whenever the trial comes it will be as the house built on the shifting sand, and, if not destroyed by sudden catastrophe, will eventually become a ruin, together with the civilisation which rests upon it." Our safety then, we presume, Kuklos would have us believe, is to believe in $\pi = \frac{20\sqrt{2}}{9}$. The supplement has "Supplementary Illustrations" and Tables. The work is printed at Montreal.

The conclusion of the matter is, that there are Cyclometers and Cyclometers. We have endeavoured to give a fair presentment of the several kinds by giving as far as possible their views in their own words. The majority of their writings evidence great waste of ingenuity, which, had it been otherwise directed, might have resulted in works of utility instead of in such utterly trivial work as it has done.

To any who may be thinking of taking up this "curiosity of literature," not having done so hitherto, we say emphatically, "Don't."

SCIENCE IN GERMANY

(*From our own Correspondent.*)

In Wiedersheim's recently published book, "*Salamandrina perspicillata* und *Geotriton fuscus*," two very little-known tailed amphibians (Urodela) are described and compared anatomically, which, by their entire organisation, stand at the two opposite limits of the Salamandrinæ that are known to us, representing the highest and the lowest form of these. *Salamandrina perspicillata*, which is rather a land than a water animal, seems to be found only in the western half of Italy; it is a prettily coloured, small, and slender animal, which lives on insects, and during the dry summer months continues in a kind of summer sleep, but in winter it is found in full vital activity. In its skull are almost entirely wanting the cartilaginous parts denoted as the "primordial cranium," so that in this it rises above all other Salamandrinæ, and comes near the Reptiles. In accordance with this, also, is the existence of a cavity in the base of the skull (sella turcica), the prolongation of the frontal bone (frontale) into the eye cavity, and a roofing-over of the latter; lastly, the absence of a special nose-partition (which, again, quite characterises the Reptiles). On account also of the course of development of its vertebræ, and the numerous bones of its carpus and tarsus, *Salamandrina perspicillata* must stand at the top of the Salamandrinæ; its divided kidneys, again, suggest the reptile, so that we must look on this animal as a form rendering

Tongue of *Geotriton fuscus*.

possible the transition from the Amphibia to the Reptilia, and which, on account of its peculiarities, might represent a separate family. *Geotriton fuscus*, on the other hand, holds quite a different position. If, in view of the numerous anatomical relations adduced, we are able, commencing with *Salamandrina perspicillata*, and passing through the various water salamanders (Tritons), to the land salamander (*Salamandra maculata*), to form a descending series of ever less-developed forms, *Geotriton fuscus* comes at the lower end of the series, for in many respects it ranks with the lowest Amphibia generally, the Perennibranchiata. Indications of this appear in the fewness of bones in the skull and the tarsus, the extended double cone form of the soft-cartilaged vertebræ;

then, too, the joint processes are wanting, &c. On the other hand, *Geotriton* is distinguished in the most peculiar way, by one organ, from all other Amphibia, viz., by the tongue. This is a pedicelled disc, like a mushroom, on the bottom of the mouth cavity, where it is connected with the tongue-bone apparatus; the latter, however, does not merely consist of the same parts as in other Amphibia, but at its two hinder ends there is attached on either side a long thin cartilage, which reaches, free between the neck muscles and the skin, as far as the back, and is enclosed in an envelope of special muscles, which are only attached at its hinder end and in front to the rest of the tongue-bone. If, now, this muscle be contracted, it thrusts out the cartilage rod, and with it the tongue, in a way similar to that observed in Chameleons, Woodpeckers, and Ant-eaters. Compare the annexed drawing. Thus Nature connects in the most remarkable manner a complicated organ of the higher Vertebrates with the organisation of amphibians that evidently stand very low.

EVIDENCES OF ANCIENT GLACIERS IN CENTRAL FRANCE

WHEN visiting the Mont Dore district, in Central France, with Prof. Huxley in the summer of 1873, my attention was accidentally directed to some magnificent transported boulders occupying the floor of an elevated valley due south of the highest ridge of the Pic de Sancy.

These, though gigantic, and occupying a very conspicuous position, in every respect similar to positions occupied by deposits from ancient glaciers in Switzerland and in all other Alpine regions, are not alluded to in Le Coq's exhaustive work on Central France, or his geolo-

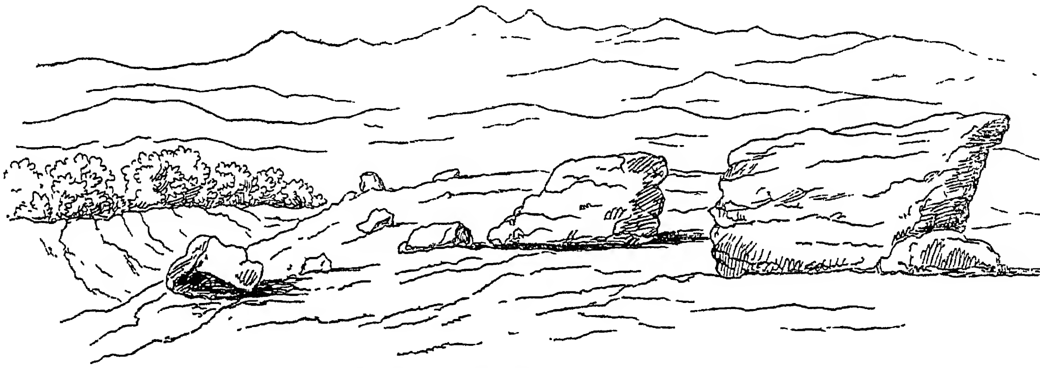

FIG 1.—Transported blocks in the Tranteine Valley, Mont Dore. Mountains of Cantal in the distance.

gical map appended thereto; nor are they in either of Mr. Scrope's works on the Volcanoes of Central France; nor can I obtain any information regarding them from those of my geological friends who are most versed in glacial phenomena.

Under these circumstances, though still of opinion that they cannot have escaped the notice of French observers, if not writers, on the geology of France, I may assume that they are of sufficient novelty and interest to render the accompanying notes and sketches acceptable to the readers of NATURE.

The well-known lofty range of Mont Dore is described

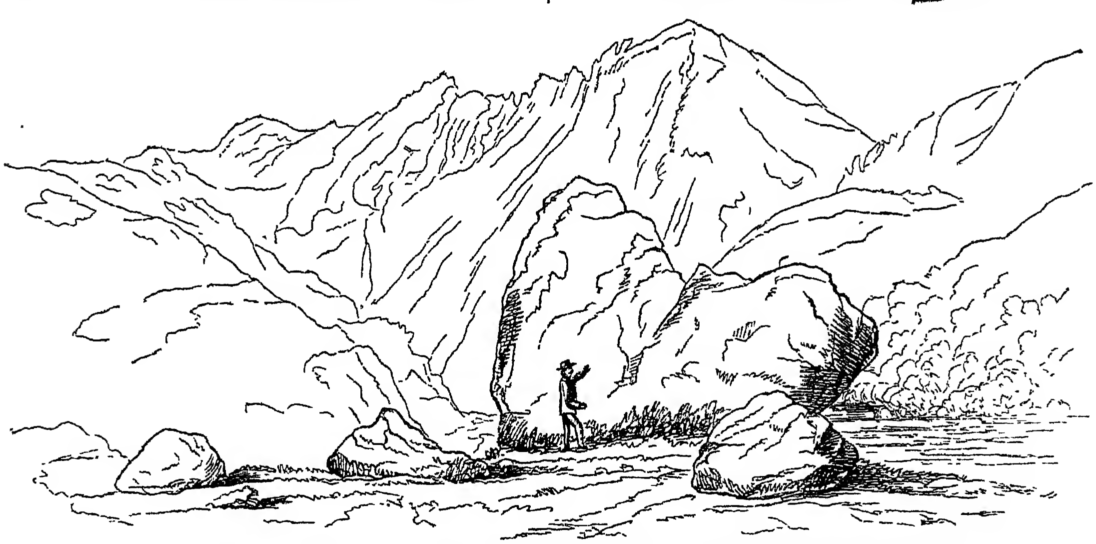

FIG. 2.—Transported block in the Tranteine Valley, Mont Dore (estimated length 36 feet). Pic de Sancy (N.) in the distance.

by Scrope ("Volcanoes," ed. ii., p. 362) as a mountain mass rising in its highest peaks more than 6,200 feet above the sea-level, composed of beds of trachytic and basaltic lavas, alternating with their respective conglomerates. And again, in his "Volcanoes of Central France" (ed. ii., p. 124), the same author says of the figure of the mass, that it is best understood by supposing seven or eight rocky summits grouped together within a circuit of about a mile in diameter, from which, as from the apex of a flattened and somewhat irregular cone, all

the sides slope more or less rapidly, the mass being deeply and widely eaten into on opposite sides by two principal valleys, those of the Dordogne and the Chambon.

It is with the southern valley, or that of the source of the Dordogne river, that we are concerned, the head of which occupies a noble amphitheatre facing the south, immediately under the highest summit of Mont Dore. My companion and myself were on our way to the summit of the Pic de Sancy, from the village of Latour about seven miles to the westward; we were skirting the rocky and very steep sides of the amphitheatre at an elevation of some 5,000 feet, and were enjoying the view of the snow-streaked mountains of the Cantal which bounded the horizon to the southwards at nearly forty miles' distance, when my attention was arrested by some large objects on the broad and level (as seen from a height) floor of the valley at our feet. They were presumedly huts, haystacks, or glacially transported blocks, and their position in reference to the head of the valley and amphitheatre so strongly inclined me to the latter view, that I determined on visiting them before leaving the neighbourhood. Accordingly, on the following day, I took the high road to Latour, south-eastward to the village of Chastail. Then leaving the road, I descended and crossed a small stream to the eastward. The ascent of its steep opposite bank led through beechwoods to a broad flat ridge with some cheese-makers' huts upon it, from which, still proceeding eastward, I descended by a gentle slope immediately upon the floor of the valley, and found myself amongst a group of magnificent boulders that had evidently been deposited by an ancient glacier which had flowed from the rocky amphitheatre at the head of the valley.

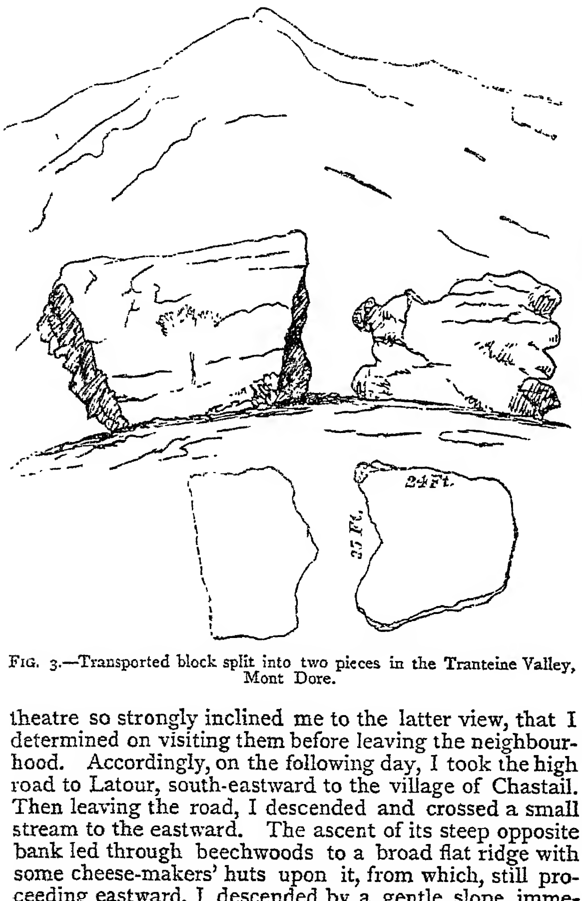

FIG. 3.—Transported block split into two pieces in the Tranteine Valley, Mont Dore.

The blocks were of trachyte, and what I took to be domite, of the same nature as the rocks towards the top of the pic; they were scattered over an undulating surface, which I guessed to be about half a mile long by a quarter of a mile broad, and occupied both the floor and the very gentle slopes of this part of the valley, up to perhaps 200 feet above the stream. Others were seen further down the valley, which however soon contracted; its stream, which meandered in the position of the greatest number of blocks, becoming, beyond it, a torrent. For about a mile above this there were no blocks; that is, between my position and the base of the steep cliffs forming the amphitheatre where the glaciers had descended. The largest blocks were those furthest down the valley; at least twenty of them appeared to me to be upwards of as many feet in length, and one of greater length was also of greater height. Several were split in two, like blocks that had been fractured by falling through the crevasse of a glacier. All were weather-worn and covered with lichens, ling, and grass.

Returning I took a north-westerly direction, ascending the spur I had crossed in coming, passing close under a magnificently mountainous mass of basalt to the east of the Puy de Pouge. Still further eastward and south of this Puy are meadows where brood mares and foals are grazed, upon which were a few large blocks of trachyte or basalt artificially shaped into very odd forms, some like skittles, others like a truncated cone with the earth heaped up round its base; they may be worthy of further investigation, but I had no time to examine them and no opportunity of making inquiry. Thence my direction lay under the Puy de Compaine, and so by a steep descent to the Ruisseau de la Chambasse, which I followed to the village of Sarsenae, and thence ascended to Latour.

J. D. HOOKER

ASSOCIATION OF GERMAN NATURAL PHILOSOPHERS AND PHYSICIANS

THE forty-eighth meeting of this Association was held from the 18th to the 25th of September at Gratz, the chief town of Styria, in one of the most beautiful valleys of the Austrian Alps.

The Association is the oldest of its kind; founded in 1822, and preceding, therefore, by several years, the birth of its British sister. In times of political disturbances and wars, such as the years 1848, 1866, and 1870, it held no meetings; in several previous years the German Governments, who in days gone by regarded every public meeting with suspicious eyes, prohibited them, and thus forty-eight meetings only were held during the fifty-four years of its existence. The German "Naturforscher-Versammlung" owes its formation to one of the founders of comparative anatomy, the celebrated Oken, late Professor of Zoology at Jena, and it cannot be denied that politics entered into the intentions of its founder as well as of many of its original members. When German unity was nothing but a treasonable aim of persecuted patriots, every meeting of Germans from different States served to spread and to give fresh vigour to this aim, and was in itself a protest against the division into small States of the common country, and against persecutions such as Oken himself has had to suffer. Aye, even now, when the old wishes have been fulfilled and no division separates Government and nation, remains of the old political undercurrent can still be traced in some of these meetings.

Gratz has an entirely German population, whose sympathies with the new German realm are increased by their proximity to Slavian provinces. It has taken a prominent part in the Reformation, and although brought back to the old religion by threats of fire and sword, by the establishment of Jesuit colleges and the suppression of the Protestant University once graced by Kepler, it still glories in its old recollections and carries high the banners of freedom and of its German nationality. In 1842, the "Naturforscher-Versammlung" was invited to Gratz and gave to that town a foretaste of the right of association then proscribed in Austria, and in 1875 the town opened her gates once more to her non-Austrian brethren, principally to assert her intellectual unity with Germany. This idea, and their enthusiasm for the freedom of thought, formed the

chief contents of the opening address delivered by Prof. Rollett, and of the welcome tendered by Dr. Kienzel, the chief magistrate of the town. The Government was represented by the lord-lieutenant of the province and by an under-secretary of the Board of Agriculture, while the Minister of Public Instruction welcomed the meeting in a letter excusing his absence. The Emperor Francis Joseph had contributed largely to the costs of the meeting. But this did not prevent his Government from interfering with the hoisting of the flags of Germany, which were destined to greet the visitors on their entrance into the town. It would naturally be supposed that the sympathy evinced by the town of Gratz would have been responded to by large numbers of German visitors. In this respect, however, the meeting was destined to be a disappointment, without any very prominent reason to account for it. Most likely a good many reasons contributed to this result: such as the distance of the place of meeting from the centre of Germany, the bad aspect of monetary matters, the day chosen for the assembly, which, lying in the middle of the summer vacation, prevents visitors from taking journeys into distant countries. Again, some of the branches represented in the Association have commenced to hold separate meetings: the geologists, the astronomers, the societies for the improvement of public health, for ophthalmotology, psychiatrics, and surgery, hold separate annual meetings independent of the Association of Natural Philosophers and Physicians. Lastly, certain events that have lately taken place in Austria seem to have deterred German members of the Association from visiting the Austrian Empire. It will be remembered that some of the most prominent German professors of the University of Prag have been all but forced to leave their posts, and that the vacillating policy of the Austrian Government wishes at present to reconcile the Slavian population by excluding as much as possible German influence from Austrian Universities.

The number of visitors at the meeting of Gratz was 715 members, 1,567 associates, and 1,700 lady associates. Of the 2,282 male visitors, 1,705 belonged to Austria (1,141 being residents of Gratz), and 546 to the German Empire; 114 of the latter being residents of Silesia, the nearest German province. Seventeen Russians, four Swiss, three Turks, two Swedes, two Roumanians, and one visitor from England, one from Italy, and one from America make up the total. It will be seen that this number corresponds very nearly with the average number of attendants at the British Association.

This, of course, is a merely fortuitous resemblance. But many other points indicate that the British Association has been modelled from the German pattern. Both Associations are convened for the same number of days; both hold the same number of general and sectional meetings; they resemble each other in the nature of the recreations offered to visitors: excursions, dinners, concerts, to which in Germany (and Austria) are added balls and theatrical performances, while England has the private hospitality of its nobles and rich manufacturers and merchants to offer, which do not enter into the German programme or certainly do not appear in it to the same extent. A festivity of a peculiar character in addition to those named was offered by the municipality of Gratz: an illumination by bonfires of the mountains surrounding the town, a sight of most impressive beauty.

Generally speaking there are no evening meetings in Germany, and the festivals being of a public nature (not depending upon private hospitality), the connection between the visitors is greater than it is at the British meetings. A peculiarity of the German meetings is the absence of a president; two chargés d'affaires (*Geschäftsführer*) being nominated to conduct the business of the Association, one a natural philosopher, one a physician. Professors Rollet and L. von Pebal occupied these positions in Gratz. The sections nominate new presidents for each of their daily meetings. A consequence of this arrangement is a certain want of formality. No retrospective introductions are offered at the opening of the sectional meetings, no criticisms of the work of fellow-workers by more or less competent critics, no sweeping remarks on the state of science in general, which happen to be the more disparaging the less the critic himself is actually engaged in contributing to the advancement of the branch of science he is discussing.

In two respects the British Association has an indisputable advantage over the German meetings. Those splendidly illustrated evening lectures addressed to the general public, which form one of the attractions of the meetings in the United Kingdom, are not offered in Germany.

Again, the funds of the German Association are small; they are spent for the purposes of each meeting, and no money can be given in grants for scientific purposes as is done in Great Britain. There are therefore no general and no sectional committees in Germany. On the other hand, the German Association offers the advantage of a speedy publication of its transactions. Instead of publishing an annual volume long after the close of the meetings, the German Association offers a daily paper (*Tageblatt*) giving the proceedings in a more or less condensed form according to the notes given by members to the general or the sectional secretaries. Generally some supplementary numbers are issued, completing the report within one month after the conclusion of the meeting.

The papers read at the general meetings are mostly given in full. At the first general meeting at Gratz, after the opening ceremony already alluded to, the Arctic explorer, Lieut. Weyprecht, gave a most interesting review of Arctic explorations, and at the same time a curious and stirring piece of self-criticism.* Amongst the most characteristic passages are the following:—

"Originally it was the wish for material gain, in the shape of fur and fish-oil, that prompted Arctic exploration. Later on this cause was replaced by the ambition of geographical discoveries such as are easily understood by the general public. The running after this sort of fame gradually assumed such proportions that Arctic exploration became a sort of international steeplechase towards the North Pole, a system opposed to true scientific discoveries. Topographical geography must be subordinated in Arctic regions to physical geography. Geographical discovery derives its value only from scientific discoveries connected with it. The exploration of the great and unknown latitudes near the poles of our globe must be continued without regard to the expenditure of money and of life which it demands. But its ulterior aim must lie higher than the mere sketching and christening in different languages of islands, bays, and promontories buried in ice, and the mere reaching of higher latitudes than those reached by our predecessors. One reason of the indifferent results of previous expeditions is that they have been unconnected with each other. The progress of meteorology consists in comparison, and every success it has obtained, such as the laws of storms, the theory of winds, &c., is the result of simultaneous observations. The aim of future Arctic explorers must be to make simultaneous observations, extending over the period of a whole year, with identical instruments and according to identical rules. In the first place, they will have to consider natural philosophy and meteorology, botany, zoology, and geology, and only in the second place the discovery of geographical details. I do not intend in what I said to depreciate the merits of my Arctic predecessors, whose sacrifices few can appreciate better than I do. In giving utterance for the first time to these opinions, which I have taken time in forming, I complain against myself, and I condemn the greater part of the results of my own arduous

* Some of the chief points in this address we gave in NATURE, vol. xii. p. 539.

labours. I will conclude by announcing that the future participation of Austria in such an enterprise has been secured by the generosity of a man who has already made several sacrifices in the interest of Arctic voyages."

The Mæcenas of the new expedition alluded to but not named in this announcement is understood to be Count Hans Wilczek.

Weyprecht's manly speech was followed by great applause, and has already produced the effect of inducing the Commission appointed by the German Government to examine the question of expediency of a new expedition to the North Pole, *not* to recommend the despatch of a new expedition, but the establishment of stations of observation in northern latitudes.

The second general meeting selected Hamburg for its place of assembly in 1876, and appointed the chief magistrate of the town, Burgomaster Kirchenpauer, and Dr. Dantzel, to manage affairs. Prof. Behn brought before the meeting the plan of a society for the assistance of scientific men in reduced circumstances.

Dr. Günther then gave a very interesting lecture, to which, unfortunately, no abridgment could do justice, on the aims and results of the history of mathematics; followed by Prof. Benedict on the history of crime with regard to ethnology and anthropology. He touched upon delicate ground, asserting that every action is based less on liberty than on compulsion; that our acts are governed by natural laws and not by theological opinions, and that punishment may act as a corrective of perverted human nature, but is chiefly the outflow of the desire of society to avenge wrongs inflicted upon it. The best prevention of crime depends upon the increase of our knowledge of those circumstances that necessarily engender it. In England a speech like this would no doubt have raised a storm of theological indignation. In Germany the clergy is distinguished by its absence from scientific meetings. The separation of natural science and orthodoxy is complete, and no opposition was therefore offered to these remarks.

In the third and last general meeting two popular medical lectures were given, one by Dr. Ravoth, on nursing the sick; the other by Dr. Lender, on ozone (the latter gentleman having made some doubtful efforts of introducing infinitesimally small doses of ozone into medicine). Then Prof. von Pebal rose, and declaring the order of the day exhausted, thanked the members for their attendance at Gratz, and proposed a vote of thanks to the sovereign in whose realm they had assembled. This proposal having been cheerfully responded to, Dr. Stilling proposed and carried a cordial vote of thanks to the town of Gratz, and Dr. Rollet, who presided at the meeting, declared the assembly closed.

Of minor incidents may be mentioned the invitation of a society in Offenburg (Black Forest) to contribute for a monument to be erected to Oken in this his native town; and the distribution of several works written for the occasion, amongst others a guide to Gratz, and a commemorative volume published by the Medical Society of that town.

Reverting at last to a short review of the proper business of the Association, its sectional meetings, the reader will remark the absence at the German assembly of one of the most popular sections of the British Association, viz., that of engineering, while several other sections appear in the German programme that are omitted in the British society, notably those devoted to medicine. This review will form the subject of a second article. A. OPPENHEIM

THE GERMAN COMMISSION ON ARCTIC EXPLORATION

THE German Commission on Arctic Exploration, appointed by the Reichskanzler, and to which we have before referred, consists of Professors Dove and Neumayer, Doctors v. Richthofen and Siemens from Berlin, Prof. Karsten from Kiel, Prof. Grisebach from Gottingen, Prof. Zittel from Munich, Prof. Bruhns from Leipzig, Prof. Quenstedt from Tubingen, Director Rümker from Hamburg, Professors Schimper and Winnecke from Strassburg. The Commissioners have held meetings at Berlin from October 4 to 13; and the result of their deliberations—a long memoir on the value of the different branches of science—has been delivered to the Bundesrath for further consideration. The *résumé* of that report is contained in the following unanimously adopted conclusions:—

"1. The exploration of the Arctic regions is of great importance for all branches of science. The Commission recommends for such exploration the establishment of fixed observing stations. From the principal station, and supported by it, are to be made exploring expeditions by sea and by land.

"2. The Commission is of opinion that the region which should be explored by organised German Arctic explorers, is the great inlet to the higher Arctic regions situated between the eastern shore of Greenland and the western shore of Spitzbergen.

"Considering the results of the second German Arctic expedition, a principal station should be established on the eastern shore of Greenland, and, at least, *two* secondary stations, fitted out for *permanent* investigation of different scientific questions, at Jan Mayen and on the western shore of Spitzbergen. For certain scientific researches the principal station should establish temporary stations.

"3. It appears very desirable, and, so far as scientific preparations are concerned, possible, to commence these Arctic explorations in the year 1877.

"4. The Commission is convinced that an exploration of the Arctic regions, based on such principles, will furnish valuable results, even if limited to the region between Greenland and Spitzbergen; but it is also of opinion that an exhaustive solution of the problems to be solved can only be expected when the exploration is extended over the whole Arctic zone, and when other countries take their share in the undertaking.

"The Commission recommends, therefore, that the principles adopted for the German undertaking should be communicated to the Governments of the States which take interest in Arctic inquiry, in order to establish, if possible, a complete circle of observing stations in the Arctic zones."

NOTES

WE take the following from the *Times*:—

The award of the medals in the gift of the Royal Society for the present year, by the Council, is as follows:—The Copley Medal to Prof. A. W. Hofmann, F.R.S., for his numerous contributions to the science of chemistry, and especially for his researches on the derivatives of ammonia; a Royal medal to Mr. William Crookes, F.R.S., for his various chemical and physical researches, more especially for his discovery of thallium, his investigation of its compounds, and determination of its atomic weight, and for his discovery of the repulsion referable to radiation; a Royal medal to Dr. Thomas Oldham, F.R.S., for his long and important services in the science of geology, first as Professor of Geology, Trinity College, Dublin, and Director of the Geological Survey of Ireland, and chiefly for the great work which he has long conducted as Superintendent of the Geological Survey of India, in which so much progress has been made that in a few years it will be possible to produce a geological map of India comparable to the geological map of England executed by the late Mr. Greenough—also for the series of volumes of Geological Reports and Memoirs, including the "Palæontologia

Indica," published under his direction. It is hoped that Dr. Hofmann may be spared from Berlin for a few days so as to receive the medal in person. The medals will be presented at the anniversary meeting of the Society on the 30th inst.

The following are the names to be proposed for election as Council and officers of the Royal Society for the ensuing year at the anniversary meeting of the Society, to be held on the 30th inst., St. Andrew's Day:—President, Joseph Dalton Hooker, C.B. Treasurer, William Spottiswoode, M.A., LL.D. Secretaries, Prof. George Gabriel Stokes, M.A., D.C.L., LL.D., and Prof. Thomas Henry Huxley, LL.D. Foreign Secretary, Prof. Alexander William Williamson, Ph.D. Other members of the Council:—Prof. J. C. Adams, LL.D., Major-General John T. Boileau, Edward Viscount Cardwell, F.G.S., Warren De la Rue, D.C.L., Capt. Frederick J. O. Evans, R.N., C.B., Edward Frankland, D.C.L., Albert C. L. G. Günther, M.D., Prof. T. Wharton Jones, F.R.C.S., Joseph Norman Lockyer, F.R.A.S., the Rev. Robert Main, M.A., Prof. Daniel Oliver, F.L.S., Prof. Edmund A. Parkes, M.D., Right Hon. Lyon Playfair, C.B., LL.D., William Pole, C.E., the Rev. Bartholomew Price, M.A., Warrington W. Smyth, M.A.

AT last Friday's lecture by Dr. Carpenter, in connection with the St. Thomas Charterhouse School Teachers' Science Association, Dr. Lyon Playfair presided. In proposing a vote of thanks to Dr. Carpenter, Dr. Playfair referred to the subject of compulsory education, which is gradually becoming universal in this country, but which, he said, would be pure tyrrany unless the education in our schools was increased and its quality raised. Quantity is all very good, but unless there is quality along with it, there is not much gained. "If it was to be said that children of thirteen or fourteen years of age were merely to receive the same education as children of eight years of age, compulsory education would be but tyranny. Therefore compulsory education involved higher education." Dr. Playfair expressed his gratification that the teachers composing the Association had banded themselves together in order to qualify themselves by attending such lectures as those of the Gilchrist fund and by other means, to undertake this higher education, which, we believe with Dr. Playfair, will be forced upon us even in elementary schools by the spread of compulsory education.

THE conferring of the Freedom of the City of London on Sir George B. Airy, the Astronomer Royal, and late President of the Royal Society, which took place on Thursday last, is, we believe, the first instance in which that honour has been bestowed for scientific services unconnected with military or engineering science. In the civic speeches which accompanied the ceremony, great stress was laid on Sir G. B. Airy's services in connection with the Metric Standard.

IN the Quarterly Return of Marriages, Births, and Deaths, just issued by the Registrar-General, we are glad to see that attention is pointedly drawn in the remarks to the annual epidemic of infantile diarrhœa, and the opinion expressed that it rests with the health officers of the diarrhœa-stricken towns to discover the nature of the sanitary shortcomings which lead to this waste of infant life. Perhaps equal stress might have been laid on a correct knowledge of the modes of nursing infants prevailing in the separate towns as on their merely sanitary conditions, as likely to lead to the true causes of the observed variations in the diarrhœa death-rate.

AT the Meteorological Congress to be held under M. Le Verrier's presidency at Poitiers on the 19th, 20th, and 21st inst., as already stated in NATURE, steps will be taken to inaugurate, for the west of France overlooking the Bay of Biscay, a system of daily weather telegrams by the Observatory of Paris. Since this system of warnings is more specially designed to further the interests of agriculture, subscriptions are solicited from proprietors and others more specially interested in the success of the proposed scheme, particularly in view of the considerable expense which will be incurred in founding a sufficient number of stations with the necessary equipment of instruments. Weather warnings for agriculturists, if they are to be of practical utility, must do more than forecast high winds, they must also, and more particularly, aim at giving warning of the approach of frost, rain, snow, and thunder-storms; and this requires for its successful accomplishment more numerous stations and more frequent observations than are necessary in issuing warnings for the benefit of the shipping interest.

WE have received the Transactions of the Michigan State Medical Society for 1875, containing among other matters a discussion by Professor Kedzie, the president, of the observations on ozone made by him during 1872-75; and a form for meteorological observations made thrice a day, adopted by the State Board of Health, Michigan, which appears to be well adapted for medico-meteorological purposes, except that the directions given for the position of the thermometer are vague as well as faulty to secure comparability among the observations.

AT the last meeting of the General Council of the Yorkshire College of Science, under the presidency of Dr. Heaton, it was unanimously resolved to found a scholarship of the annual value of 25*l.*, to be called the Cavendish Scholarship, in recognition of the obligations conferred upon the college by the Duke of Devonshire and Lord F. C. Cavendish, M.P. From a statistical return presented by Mr. Henry H. Sales, secretary, it appears that 200 students are in attendance at the college, of whom more than forty are availing themselves of the day classes.

THE Report of the Scotch Herring Fishery Board states that already certain facts have been discovered in the course of the experiments which have been instituted for the purpose of discovering how far the temperature of the sea and other meteorological conditions might be concerned in determining the migration of the herring. Arrangements were made during the season of 1874 for regular observations, and twenty of the fisheries were supplied, through the liberality of the Marquis of Tweeddale, with deep-sea thermometers for ascertaining the temperature of the sea at the times and places when fishing was going on. The records of these observations, taken in conjunction with the returns of the daily catch, and with particulars collected from other sources, were referred to Mr. Buchan, Secretary to the Meteorological Society, who analysed them. Although the returns are not sufficiently full to afford any accurate rule, owing to the lateness of the period before the sea-thermometers were ready to be sent to the fishermen, they prove that "during the periods when good or heavy catches were taken the barometer was, in the great majority of cases, high and steady, the winds light or moderate, and electrical phenomena wanting; and on the other hand, when catches were low, the observations often indicated a low barometer, strong winds, unsettled weather, and thunder and lightning." From the complete returns of the daily catch of the fish, and of the meteorological conditions, inclusive of the temperature of the sea, now obtained, it is anticipated that materials will be collected in three or four years from which most valuable conclusions will be arrived at.

A NEW edition of Dr. Lardner's "Handbook of Astronomy," revised and completed to 1875 by Mr. Edwin Dunkin, F.R.A.S., is nearly ready for publication by Messrs. Lockwood and Co. It will contain a large number of plates and woodcuts.

THE *Daily Telegraph* announces that the letters from Mr. Stanley, committed to the charge of M. Linants de Bellefonds, have safely arrived, notwithstanding the assassination of Colonel Gordon's representative. They contain a full description of the south-eastern, eastern, and northern shores of Lake Nyanza.

The letters are said to contain valuable geographical data in illustration of the map already forwarded, including soundings of the Victoria Nyanza and an exploration of the White Nile above Ripon Falls.

IN reference to the Reuter's telegram (vol. xii., p. 562) relative to the mission to Italy of Major Festing and Mr. Lockyer, we should state that the instruments which it was sought to collect for the forthcoming Government Exhibition of Scientific Instruments at South Kensington Museum are not instruments used in *recent astronomical* observations, but rather such as will be historically interesting as illustrating those sciences in the early development of which Italian philosophers such as Galileo, Toricelli, Volta, and Galvani took such a large share.

ON Saturday evening, Captain Adams, of the whaler *Arctic*, arrived in Dundee from the Davies Straits fishing. From the condition of the wind and sea at Carey Island, Captain Adams believes that there must have been a vast extent of open water towards the north, and he is convinced that the Government ships must have reached a higher latitude than they possibly could have attained for many years past. Captain Adams has an intimate knowledge of the Polar regions, and has already made several valuable contributions to Arctic discoveries.

A SERIES of Popular Scientific Lectures was commenced at the Town Hall, West Bromwich, on Tuesday week, when Prof. Williamson, F.R.S., lectured on "Coal and Coal Plants." The following remain to be given:—On Nov. 16, "The Age of Ice in Britain," by Rev. H. W. Crosskey, F.G.S. On Nov. 30, "Coal Gas," by F. Jones, F.R.S.E., F.C.S. On Dec. 14, "Nerve Cells and Nerve Fibres," by Prof. A. Gamgee, M.D., F.R.S. On Jan. 10, "The Mariner's Compass," by J. Hopkinson, D.Sc., M.A.

WE have received the Report of the "Botanical Locality Record Club" for 1874. It forms a valuable addition to our topographical knowledge of British plants; and in the list of "New County Records," care seems to have been taken not to give those of the rarer plants so precisely that the publication will be likely to result in their extinction. A suggestion has been made to extend the area of the records to Cellular Cryptogams (Vascular Cryptogams being already included). This might probably be done with advantage as far as Mosses, Lichens, and Hepaticæ, and possibly also Fungi, are concerned; but with regard to Algæ, it is more doubtful whether much would be gained by a record of their geographical distribution.

MM. REESS and WILL, of Erlangen, record in the *Botanische Zeitung* No. 44 for the current year, a series of observations on the carnivorous habits of *Dionæa* and *Drosera*. Made quite independently of Mr. Darwin's researches, and partly before their publication, they abundantly confirm his conclusions as to the power possessed by the sundew of absorbing and digesting nitrogenous substances. Similar experiments on other plants with glandular hairs produced, like Mr. Darwin's, negative results.

THE *Argonaut* is to be doubled in size at the commencement of a new volume in January. A new feature will be a monthly report, suited for general readers, on the progress of science, specially prepared for the magazine "by professional gentlemen of acknowledged standing in their respectives spheres of study."

IT is gratifying to see that the value of experimental observation is coming to be more and more recognised in Medicine. We would draw attention, in reference to this, to a summary of an excellent address on the subject, by Dr. McKendrick, of Edinburgh, which appears in last Saturday's *British Medical Journal*.

PROF. W. R. M'NAB reprints from the *Quarterly Journal of Microscopical Science* his translation of Brefeld's most important researches on the life-history of one of the common blue moulds, *Penicillium glaucum*. A very close research succeeded in detecting the hitherto unknown sexual mode of reproduction of this fungus. Brefeld terms the second generation a sclerotium or sporocarp, from which are developed—as the result of the union of the true sexual organs, the carpogonium and antheridium—asci and ascospores, the formation of which shows that *Penicillium* must be placed in the group of Ascomycetes; and he considers that, from the striking resemblance of the minute structure of the sclerotia to those of the truffle, a position must be assigned it close to the Tuberaceæ.

THE second part of Bentley and Trimen's "Medicinal Plants" fully maintains the character of the first. It contains seven plates: *Theobroma Cacao* (the cocoa-plant), *Rhamnus catharticus*, *Prunus Amygdalus* (the almond), *Pyrus Cydonia* (the quince), *Lobelia inflata*, *Gaultheria procumbens*, and *Cinnamomum zeylanicum* (the cinnamon). The letter-press is amply descriptive of the various species and their officinal preparations. The work will be completed in about forty parts.

MM. Wiegandt, Hempel, and Parey, of Berlin, are publishing a large number of wall-maps or diagrams for instruction in natural history, with especial reference to agriculture. Five series have been issued up to the present time; the first relating to the breeding of stock; the second to the production of wool; the third to the minute structure of plants; the fourth to the cultivation of root and other crops; and the fifth to physical geography.

MR. J. J. HARRIS TEALL, B.A., First Class in the Natural Sciences Tripos 1872 and Sedgwick Prizeman 1873, has been elected a Fellow of St. John's College, Cambridge. Mr. Teall is at present one of the lecturers engaged on behalf of the University in the larger towns.

THE unfortunate explosion of the *Magenta* at Toulouse has involved a loss of some consequence to science. Eighteen Phœnician inscriptions, recently discovered and on their way to the Louvre Museum, were on board the ill-fated steamer. Great efforts will be made to raise the hull, and the inscriptions may possibly be recovered by divers.

THE Crystal Palace Company's School of Practical Engineering is to be further developed this season by the addition of a Colonial Section. This section is designed particularly for gentlemen who intend to proceed to the colonies or abroad, as explorers or settlers. The object proposed is to afford them so much practical knowledge of scientific and mechanical work and expedients as shall enable them best to utilise the means with which they may have to deal, especially when entirely dependent on their own resources. The Colonial Section will be opened on January 5, 1876.

A RETRIEVER DOG, whose owner was working in the garden of the Bath Institution, lately killed a favourite cat, a frequenter of the same grounds. Having committed this unprovoked murder, the dog deliberately took the cat in his mouth, carried it some distance, dug a deep hole behind some bushes, and after depositing the cat therein, carefully replaced the earth, and had he not been observed there would have been no evidence of the crime. Shortly after, the dog lost his life by poison, probably a penalty for the offence.

IN the neighbourhood of Bath a gentleman possesses a pair of carriage horses, one of which evinces more than ordinary intelligence when his own ends have to be served. If the horse hears, even in the distance, the very first movement of a mowing-machine, he connects the sound with fresh grass, and at once taps with his hoof at the boarding of the stall to summon the

coachman for a supply. At first this is done gently, but if time passes he imperatively demands attention, or it is doubtful if the stable would contain him. The coachman lives adjoining the stable, and, much to his discomfort, the horse sometimes has imaginary wants during the night, and repeats the same process; and at whatever hour this occurs, the coachman is under the necessity of getting up to attend to him.

ON the 23rd inst. there will be an election at Balliol College, Oxford, to a scholarship on the foundation of Miss Hannah Brakenbury, "for the encouragement of the study of Natural Science," worth 80*l*. a year, tenable during residence of four years; open to all such candidates as shall not exceed eight terms from matriculation. Candidates are requested to communicate their intention to the Master of Balliol by letter, on or before Tuesday, the 16th inst., enclosing testimonials.

THE formal opening of the Zoological Garden of Cincinnati took place on the 18th of September. It contains sixty-six acres, and is very well arranged for its purposes.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented by Mrs. Tipping; an Egyptian Goose (*Chenalopex ægyptiaca*) from Africa, presented by Dr. E. Swain; a Ring-necked Parrakeet (*Palæornis torquata*) from India, presented by Miss Thirlwall; a White-fronted Guan (*Penelope jacucaca*), a White Eye-browed Guan (*Penelope superciliaris*) from S.E. Brazil, a Vulpine Phalanger (*Phalangista vulpina*) from Australia, a Blue and Yellow Maccaw (*Ara ararauna*) from S. America, two Jambu Fruit Pigeons (*Ptilonopus jambu*) from the Indian Archipelago, deposited; two Upland Geese (*Chlœphaga magellanica*) from the Falkland Islands, received in exchange.

OBSERVATIONS ON BEES, WASPS, AND ANTS*

THIS is a continuation of my previous papers on the same subject. In them I recorded various experiments tending to show that in many cases Ants and Bees which have found a store of food or of larvæ certainly do not communicate the information to their friends. This unexpected observation was received with so much surprise, and indeed was so unexpected to myself, that I determined to repeat the experiments: which I have now done, with, however, the same result. To take one as an illustration: I placed an *F. Flava* (the small red ant) to a heap of larvæ, which, as is well known, are fleshy legless grubs incapable of motion. I placed them about two feet from the entrance to her nest. I then watched her from eleven in the morning till after seven in the evening, during which time she made eighty-six journeys from the nest to the heap of larvæ, carrying one off each time; but although she had so much work to do, and though the precious larvæ were lying for so long exposed to so many dangers and to the weather, she brought no other ant to assist her in carrying them off. One of the ants I observed in this way carried off one by one no less than 187 larvæ in a day. In other instances, on the contrary, the opposite result occurred. I was for some time uncertain, in the latter cases, whether the ants purposely brought friends to their assistance, or whether, as the ants are sociable insects, it merely happened that the one accompanied the other, as it were, by accident. To test this question, I took two ants, and placed them under similar circumstances, the one to a heap of larvæ, the other to a group of two or three, always, however, putting one in place of any that was carried off; and it was quite clear that the ants which were placed to the large group of larvæ brought far more friends to their assistance than those which had apparently only two or three larvæ to move. Of thirty ants which were observed, those placed to a large number of larvæ brought 250 friends, while those placed to two or three larvæ under similar circumstances only brought eighty.

One account, much relied on as showing the intelligence of ants, has been the following observation made by M. Lund in Brazil. Passing one day under a tree which stood almost by itself, he was surprised to hear the leaves falling like rain. On examining the cause of this, he found that a number of ants had climbed the tree, and were cutting off the leaves, which were then carried away by companions waiting for them below. Of course it might be said that the leaves which dropped fell by accident; in which case they would naturally be carried off by the ants below. It occurred to me, however, that this was an observation which might easily be repeated. I placed therefore a number of larvæ on a slip of glass, which I suspended by a tape, so that it hung one-third of an inch from the surface of one of my artificial nests; isolating it, however, in such a manner that for an ant to walk to the nest she would be obliged to go thirteen feet round. I then placed some black ants (*F. nigra*) on the glass with the larvæ. Each of them took a larva in the usual way, and then endeavoured to go by the quickest road home. They leaned over the glass and made every effort to reach down, but of course in vain, though the distance was so small that they could all but touch the nest with their antennæ, and even, in one or two cases, succeeded in getting down by stepping on to the back of an ant below. Those, however, which did not meet with any such assistance, gradually, though at first requiring some help from me, found their way round to the nest, and after a short time there was quite a string of ants passing to and fro from the nest to the larvæ, although it would have been so easy for them to throw the larvæ over the edge of the glass, or to go straight home, if they would have faced a drop of, say, one-tenth of an inch.

Moreover, I placed some fine mould within half an inch of the glass, so that it would have been easy for the ants, by literally one minute's labour, to have constructed for themselves a stepping stone up to the glass; yet they did not adopt any of these expedients, but for hours together, and by hundreds, continued to make the long journey round. I confess this experiment, which I repeated on several occasions, surprised me very much.

As my previous experiments, which showed that bees did not by any means in all cases bring their friends to share stores of food which they had discovered, have been much questioned by bee-keepers, I have repeated them again.

No doubt, if honey is put in an exposed place, so that it is found by one bee, it is most natural that others should also find their way to it; but this does not, according to my experience, happen if the honey is concealed. For instance, I put a bee to some honey in a flowerpot placed on its side, and so arranged, that the bee had only a small orifice through which to enter. Under these circumstances, from a quarter to seven in the morning till a quarter past seven in the evening, she made fifty-nine journeys, and during the whole of this time only one other bee found her way to the honey.

I found that bees soon accustomed themselves to look for honey on papers of particular colours. For instance, on Sept. 13 I placed a bee to some honey on a slip of glass on green paper, and after she had made twelve journeys to and from the hive I put red paper where the green had been, and placed another drop of honey on a green paper, at a distance of about a foot. The bee returned, however, to the honey on the green paper. I then gently moved the green paper, with the bee on it, back to the old place. When the bee had gone, I replaced the green paper by a yellow one, and put the green again a foot off. After the usual interval she returned again to the green. I repeated the same proceeding, but with orange paper instead of green. She returned again to the green. I now did the same with white paper: she returned again to the green. Again I tried her with blue: she again came to the green. I then reversed the position of the blue and green papers, but still she returned to the green. I repeated this experiment with other bees, and with the same result, though it seemed to me that in some cases they did not distinguish so clearly between green and blue as between green and other colours. In other respects they seemed to adhere equally closely to any colour to which they were made accustomed.

As regards wasps, my experiments fully confirm those previously made, and justify everything I have said with reference to their great industry. Indeed, they begin to work earlier in the morning and cease later in the evening than bees, continuing all day with the utmost assiduity. Thus, a wasp which I watched on the 10th of September, worked from seven in the morning until seven in the evening without a moment's intermission, during which time she made no less than ninety-four visits to the honey. As is the case with bees, if a wasp is put to exposed honey, others soon come. To determine this, if pos-

* A paper read by Sir John Lubbock, Bart., M.P., D.C.L., F.R.S., at the Linnean Society, Nov. 4. Communicated by the author.

sible, I trained a wasp to come to some honey which I placed in a box communicating with the outside by an india-rubber tube six inches in length and one-third of an inch in diameter. She came to this honey continuously for three days, during which time no other wasp found the honey. As regards colour, I satisfied myself, by experiments like those made with bees, that they are capable of seeing colour, though they appear to be less influenced by it than are bees.

OUR BOTANICAL COLUMN

IRISH HEPATICÆ.—S. O. Lindberg has just published a quarto memoir on the "Hepaticæ in Hibernia mense Julii 1873 lectæ." This memoir is a reprint from the tenth volume of the "Acta Societatis Scientiarum Fennicæ," and contains a list of eighty-nine species of Hepaticæ collected during a month's visit to Ireland. The author had the benefit of the great geographical knowledge of Dr. Moore—the author with A. G. More of the "Cybele Hibernica"—to enable him to visit, without delay, the most product. vt . ortions of Ireland; otherwise it may be doubted if his collections would have been so rich. Many of the species described are v ry rare; some of them are new. The synonymy of the species is worked out in a manner worthy of the greatest praise. Many of the smaller forms among Lejeunea and other genera are described from fresh specimens or from those preserved in alcohol. The collections were chiefly made in Killarney. Of the new species we may mention *Lejeunea patens, L. Moorei, Zygodon aristatus*. In an appendix we find a list of the genera of European Hepaticæ classified as follows:—

1. Marchantiaceæ.
2. Jungermaniaceæ.
3. Anthoceroteæ.

The group of Marchantiaceæ is divided into *A. Schizocarpæ* and *B. Cleistocarpæ* (this latter includes such genera as Tessellina and Riccia); that of Jungermaniaceæ into the same two subsections; and these are again much sub-divided.

The existence in Ireland of so large a number of interesting forms, of which so very much yet remains to be known as to their life-history, ought surely to act as a stimulant to the rising school of Irish botanists.

MARINE ALGÆ OF THE UNITED STATES.—Although nearly twenty years have elapsed since the third part of Harvey's "Nereis Boreali-Americana" was sent to the press, yet the contributions to a knowledge of the North American Algæ have been but few. W. G. Farlow, one of Prof. Asa Gray's assistants, ascribes this to the fact that but few American botanists reside on the western coast of America, where novelties might be expected; and he publishes a most welcome list of the marine species of the United States *proper*, not including Alaska, but in part enumerating those of Vancouver's Island. Those added since the publication of Harvey's "Nereis" are denoted by a star. The number of species enumerated is 430, a number that doubtless will be increased when the Algæ are investigated as recent forms either living or preserved in fluid, and not, as is now frequently the case, only examined when in a state of what is but little better than that of stains on white paper. Mr. Farlow's list will be found in vol. x. 2nd ser. of the Proceedings of the American Academy of Arts and Sciences.

COFFEE IN DOMINICA.—A good deal of attention has been directed of late to the island of Dominica as a coffee-producing country, a fact briefly referred to in NATURE, vol. xii. p. 173. At one time coffee was one of the staple products of the island, and was grown not only in large quantities, but also of excellent quality. At the present time little or none is exported to Europe, but the island still grows sufficient to supply its own demands, and we believe sends a little to the neighbouring islands. This falling off in the cultivation of the coffee-plant, in a soil and climate which experience showed was eminently suited to it in every respect, was due to the extensive destruction of the plants by what was then known as the coffee blight. This was soon found to be of insect origin, but no active or energetic measures were taken to rid the island of the pest, which continued its ravages, destroying many plantations, and even driving planters away in great numbers. Nothing seems to have been known regarding the insect itself until within the past few weeks, when specimens in their various stages, together with the injured leaves, have been received at the Kew Museum. Upon submitting these specimens to an entomologist, they were at once identified as the White Coffee-leaf Miner (*Cemiostoma coffeellum*, Mann.), an insect exceedingly destructive to the coffee-plants in Brazil, Rio Janeiro, Martinique, &c. The crops of coffee in Brazil are said to be lessened one-fifth in consequence of the ravages of this insect.

It is remarkable that little seems to have been known in Dominica about the classification or habits of the insect, though it made its first appearance there in 1833, some forty-two years back, and it seems to have been known in Brazil only within the last twenty or twenty-three years. An elaborate description of the insect and its ravages will be found in the *American Naturalist*, vol. vi. pp. 332, 596; 1872.

SCIENTIFIC SERIALS

Annual Report and Proceedings of the Belfast Naturalists' Field Club, 1873, 74.—This Report was written before the meeting of the British Association in Belfast last year, so that its issue must have been very much delayed. The Society, according to the Report, as to financial condition and number of members, is in a thoroughly satisfactory condition. The Society, as a Field Club, makes excursions during summer; an account of those for 1873 is contained in this part of the Proceedings. The papers read during the winter session are all interesting; we have space only for the titles:—"On the British Association, its aims and objects," by Mr. W. Gray; "On Progressive Development," by Mr. G. Langtry; "On the Surnames of the Inhabitants of the County Antrim, and their indications," by the Rev. E. M'Clure; "On Flints, and the Foraminifera, Entomostraca, &c., contained in them," by Mr. Joseph Wright, F.G.S.; "Irish Cranoges and their contents," by Mr. F. Wakeman; "Notes on the Aurora Borealis, taken in Belfast in the years 1870, 71, with suggestions as to its source and that of the earth's magnetism and magnetic currents," by Dr. T. H. Keown, R.N. The Appendix contains two valuable lists; first, of the Mosses of the North-east of Ireland, by Mr. S. A. Stewart; and second, of the Cretaceous Microzoa of the North of Ireland, by Mr. Joseph Wright, F.G.S., the latter illustrated by a large number of figures.

Poggendorff's Annalen der Physik und Chemie, No. 9, 1875.—This number commences with a long paper, in which M. Wilhelm Weber investigates mathematically the motion of electricity in bodies of molecular constitution. Among the points treated are, objections against the fundamental law of electric action; identity of the moveable parts (in all bodies) whose movement is heat, magnetism, or galvanism; identity of *vis viva* of the electromotive force in the current with the heat produced by the current in the conductor; movement and distribution of electricity in conductors; and Kohlrausch's theory of thermo-electricity.—In an article on formation of sound, Prof. Stern inquires why tuning forks without resonant supports give such a very weak sound. It cannot be due, as many physicists suppose, to their less surface of contact with the air, else high-pitched small forks could not sound louder than low and large ones, nor could overtones sound louder than ground tones when *e.g.* a large fork is struck with a hard body. Having shown reason for thinking that the amplitude of vibration and number of vibrations in unit of time have no direct influence on the strength of the sound, Prof. Stern groups together a number of interesting phenomena bearing on the subject: the difference in rate of decrease of sound, in high and low forks, on withdrawal from the ear; a like difference with regard to transverse vibrations and those produced longitudinally; the interference-effects where resonance-cases act on each other; the effects of bringing a resonator near an organ-pipe, &c. The paper is not yet concluded.—The action of the Holtz machine still requires some elucidation, and in a paper to the Berlin Academy (here reproduced) M. Poggendorff furnishes "further facts towards an adequate theory of electric machines of the second kind" (with two moveable discs). One of these facts is as follows:—The two discs turning in opposite directions, stop (say) the front one by holding it (the screw having previously been loosened); then, when the back disc is rotated, a current is obtained as before. Now turn the front disc round through 360°, and rotate the back disc as before. If this turning be done in the direction of the front disc's former rotation, the current in the back disc is unaltered; but if in the opposite direction, it is reversed. A turning of 180° or even of 90° has the same effect. These and similar facts, indicating an influence of *direction* (rather than extent) of dis-

placement, on the direction of the current, the author is unable to account for satisfactorily; they cannot, he thinks, be due to inductive action.—Some researches by Dr. Neesen on attraction and repulsion by rays of light and heat are noticed in our "Science in Germany."—M. Soret describes the diffraction phenomena obtained with circular gratings, consisting of opaque discs with a series of openings in the form of concentric rings; and a paper of "Optical Notes," by Dr. Wolcott Gibbs, of the American Academy, treats of a new optical constant, and a method of measuring indices of refraction without employment of graduated instruments.—M. Fuchs shows how the electrometer may be used for determining intensity of current, polarisation, and resistance; and M. Mach describes a polarisation apparatus with rotating analyser.

Bulletin de l'Academie Impériale des Sciences de St. Petersbourg. (t. xix. Nos. 4 and 5; t. xx. Nos. 1 and 2).—From these publications we notice the following more important papers:—On the double star Σ 634 = Camelopardali 19, Hev., by Dr. O. Struve. —On the salts of parabanic acid, by N. Mentchutkine; the author considers the potash, soda, ammonia, and silver salts of this acid.—On oxalurate of potash and on the determination of potassium in the salts of the acids of the uric group, by the same.—On the velocity of irritation in the spinal marrow, by E. Cyon.—Researches on blood, by Heinr. Struve.—On carbon tetraiodide, by M. G. Gustavson.—On a simple evaporimeter, alike useful in winter or summer, by H. Wild.—Continued observations of the companion of Procyon, by O. Struve.—On dimethylisobutylcarbinol and the new heptylene obtained by means of this alcohol, by M. D. Pawlow.—On iodide of ethylidene, by M. G. Gustavson.—On the chemical structure of pinacoline, by M. A. Boutlerow.—Preliminary note on the elasticity of rarefied air, by M. D. Mendeleeff and M. Kirpitschoff. —Diagnoses plantarum novarum Japoniæ et Mandshuriæ, by C. J. Maximowicz.—Report on a new iron meteorite from the shores of the Angara river, in the government of Jenisseisk, by M. A. Goebel.—Observations of the planets at the Academical Observatory of St. Petersburg; determination of the longitude of the ascending node in the orbit of Mars, by A. Savitsch.—Results of measurements made on crystals of arragonite, copper, pyrites, and skorodite, by N. von Kokscharow.—On the doubts recently raised on the cosmical origin of the Pallas iron, and a refutation of the same, by M. A. Goebel.—Hydrological researches, by Prof. C. Schmidt, of Dorpat. The author treats of the Caspian Sea, the Sea of Aral, the Dwina, and the White Sea.—On a method to obtain a uniform exposure in photographing the sun, by Dr. B. Hasselberg.—On the existence of a resisting medium in celestial space, by Dr. E. von Asten.—Researches on the theory of the determination of orbits, by Fr. W. Berg.—Barycentric theorem, which gives a means to express the duration of any movement of a point, by relation of two straight lines; by J. Somoff.—A note on perowskite crystals, by N. von Kokscharow; the author describes the determination of perowskite forms by approximate measurements made with the ordinary reflexion goniometer of Wollaston, the nature of the perowskite crystals from the Ural Mountains, and the angles measured.—Results of exact measurements of sulphur crystals, by the same. Analysis of the observations made in the Caucasus on terrestial refraction, by M. Sawitch.—A note on mechanisms which retard reflex actions, by J. Setschenow.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, Nov. 4.—Dr. G. J. Allman, F.R.S., president, in the chair.—The following papers were read:—Observations on Bees, Wasps, and Ants, Part III., by Sir John Lubbock, Bart., F.R.S. An abstract of this paper appears in another column.—On the rate of growth of the female flower-stalk of *Vallisneria spiralis*, by A. W. Bennett, F.L.S. The peduncle of the female flower of this plant is remarkable for the rapidity of its growth, attaining a length of from three to four feet, and increasing, at its period of greatest energy, at the rate of half an inch per hour. The observations were chiefly directed to determine which portion of the peduncle displayed the greatest part of this energy; and this was found to lie in a portion at but a short distance below the flower-bud; a marked zone of two inches increasing ultimately relatively to the remainder of the flower-stalk about in the proportion of three to two. This displays a greater analogy to what has been hitherto observed in the case of roots than in that of aërial stems. The coiling up of the peduncle so as to bring the flower beneath the surface does not take place when the flower has not been impregnated.—On plants collected by Lieut. Cameron about Lake Tanganyika, by Prof. Oliver, F.R.S.—On a collection of North Celebes plants made by M. Riedel, by Prof. Oliver, F.R.S.

Chemical Society, Nov. 4.—Prof. Abel, F.R.S., president, in the chair.—First paper, On the decomposition of stearic acid by distillation under pressure, by Mr. G. Johnston.—Dr. C. R. A. Wright read a paper, by himself and Mr. G. A. Beckett, On Isomeric Terpenes and their Derivatives, being Part V. of their researches on this subject; also one On the Alkaloids contained in the Aconites, Part I.; after which Mr. F. J. M. Page gave an account of a simple form of gas regulator for maintaining a constant temperature in air-baths, water-baths, incubators, &c.—Communications were also read from Mr. R. W. E. M'Ivor, on the fluorides of arsenic, phosphorus, and iodine; and on the iodide of antimony.—The last paper, On Tolylphenyl, a new hydrocarbon, was by Mr. T. Carnelly.

Zoological Society, Nov. 2.—Dr. E. Hamilton, V.P., in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the months of June, July, August, and September, 1875.—A letter was read from Signor L. M. D'Albertis, giving some account of several excursions he had made into Southern New Guinea from his present quarters in Yule Island.—A note was read from Mr. Walter J. Hoffman, describing a horn of an American Prong-horn (*Antilocapra americana*), with a double prong.—A letter was read from Capt. J. Moresby, R.N., giving the exact locality of the young *Casuarius uni-appendiculatus*, presented by him to the Society in August 1874.—A communication was read from Dr. P. von Bleeker, containing a description of a rare Central-Asiatic fish (*Elopichthys dahuricus*.—A communication was read from Mr. Edgar A. Smith, containing the description of a new species of *Carinifex* from California, which he proposed to name *Carinifex ponsonbii*.—A second communication from Mr. Smith contained remarks on the genus *Alaba*, with the description of a new species.—A communication was read from Mr. W. T. Blanford correcting certain errors in the figures of *Herpestes ferrugineus* and *Ovis polii*, in the Society's Proceedings.—Mr. P. L. Sclater, F.R.S., and Mr. O. Salvin, F.R.S., read a paper giving the descriptions of two birds from Medellin, State of Antioquia, U.S.C., which appeared to be new to science, and were named *Catharus phaopleurus* and *Automolus holostictus*.—Mr. A. H. Garrod read a report on the causes of death of the Indian elephant which died in the Gardens on July 7, 1875.—A communication was read from the Rev. S. J. Whitmee, of Samoa, on the habits of the fishes of the genus *Antennarius*.—A communication was read from Mr. G. E. Dobson, containing a monograph of the bats of the genus *Taphozous*, Geoffr.—A commuuication was read from Dr. Otto Finsch, containing notes on the pigeons of the genus *Chrysœna*.—A communication was read from Dr. J. S. Bowerbank, F.R.S., being the fifth part of his monograph of the siliceo-fibrous sponges.

Royal Microscopical Society, Nov. 3.—Mr. H. C. Sorby, F.R.S., president, in the chair.—A very interesting paper was read by the President, On a new method of measuring bands in spectra. It was first explained that by means of the ordinary quartz absorption band plate, the exact position of a spectrum line not coinciding with either of the absorption bands, could not be accurately determined; and the necessity for so doing having been shown, the author described and figured his new contrivance designed for the purpose. It consisted of a piece of quartz about $1\frac{1}{2}$ inches thick, and cut with parallel surfaces exactly at right-angles to the principal axis of the crystal, along the line of which there was no polarisation. This gave a series of seven dark bands when placed between two Nicol prisms and viewed through the spectroscope. By rotating the upper prism the position of the first band could readily be made to coincide with any given fixed line as D, and by the rotation of the lower prism the series of bands could be caused to traverse the entire spectrum, each half rotation moving them forward the precise amount of the distance existing between them. A graduated scale marked upon a circle attached to the lower prism enabled the position of the bands to be compared with great accuracy with that which they originally occupied, and of course also with that of any fixed lines shown in the comparison spectrum. A paper by Dr. J. J. Woodward (U.S.A.), on *Frustulia Saxonica*, was read by the Secretary.

CAMBRIDGE

Philosophical Society, Oct. 25.—Mr. J. W. L. Glaisher read a paper on Herwart ab Hohenburg's Tabulæ arithmeticæ προσθαφαιρεσεως universales, Munich, 1610. The book is a very large and thick folio, and contains a multiplication table up to 1000 × 1000, the thousand multiples of any one number being given on the same page. There is an introduction of seven pages, in which the use of the tables in multiplying numbers containing more than three figures, and in the solution of spherical triangles, is explained. Very little information with regard to the work is to be obtained from the mathematical bibliographers and historians, Heilbronner, Kästner, Scheibel, Marhard, Rogg, Montucla, Lalande, &c. De Morgan writes: "Herwart passes for the author, but nothing indicates more than that the manuscript was found in his collection. The book is excessively rare; a copy sold by auction a few years ago was the only one we ever saw." While preparing the report of the British Association Committee on Mathematical Tables, Mr. Glaisher had endeavoured without success to obtain some further information about this great multiplication table, which has never been exceeded, and which is only equalled by Crelle's Rechentafeln, which first appeared in 1820, and is now in general use. But recently he had found a correspondence of six letters between Herwart and Kepler, which are printed in vol. iv. (1863) of Frisch's complete edition of Kepler's works, and which throw light upon the table in question. In the first, dated September 13, 1608, Herwart mentions that he has been in the habit of using a special praxis for avoiding the labour of multiplication, and which his friends have recommended him to print. He adds that without it he should long ago have had to give up all mathematics which involved calculation, on account of his many occupations and because he was not a good computer. He encloses a page as a specimen. Kepler replies that he thinks the table will be useful, and he urges that its uses in the solution of spherical triangles should be noticed, pointing out its superiority in point of clearness to the "προσθαφαιρεσις Vitichiana," which is too complicated to be retained in the memory. Herwart replies that he had already thought of its application in prosthaphæresis; he suggests a title for the book, and asks for Kepler's opinion; and in the last letter of the correspondence Kepler proposes the title "Σεισαχθεια sive Novæ Tabulæ, quibus Arithmetici debitis inextricabilibus multiplicandi et dividendi liberantur, ingenio, tempori, viribusque ratiocinantis consulitur." It is thus proved that the table was printed from a manuscript which Herwart used himself, and which very likely he had made. As for the word prosthaphæresis, it is well known that the prosthaphæresis of the orbit is the angle subtended at the planet by the eccentricity, and De Morgan explained the use of the word on the title-page thus: "Prosthaphæresis is a word compounded of prosthesis and aphæresis, and means addition and subtraction. Astronomical corrections sometimes additive and sometimes subtractive were called prosthaphæreses. The constant necessity for multiplication in forming proportional parts for the corrections gave rise to this table, which had the name of its application on its title-page." But the prosthaphæresis referred to seems most likely a method of solving spherical triangles in which the product of two sines or of a sine and cosine is avoided by the use of formulæ such as $\sin a \sin b = \frac{1}{2}\left\{\cos(a-b) - \cos(a+b)\right\}$, and such a method is associated with the name of Wittich. This explains all Kepler's allusions, and why Herwart employed the word on his title-page, as he proposed to avoid the necessity of the transformation by rendering easy the operation of the simple multiplication. A copy of Herwart's work borrowed, through the kindness of Prof. Henrici, from the Graves Library at University College, London, was exhibited to the meeting.

MANCHESTER

Scientific Students' Association, Oct. 20.—Mr. Mark Stirrup gave a short account of a visit to the celebrated Chesil Bank, on the coast of Dorset, and exhibited some specimens of the pebbles therefrom. The source whence these pebbles were derived and their mode of accumulation, as explained by many writers on the subject, were referred to. All these explanations have failed to account satisfactorily for a deposit of such vast magnitude, and there is no doubt that the views recently enunciated by Prof. Prestwich, F.R.S. (see NATURE, vol. xi., p. 299), go far to clear up the difficulty.

PARIS

Academy of Sciences, Nov. 2.—M. Frémy in the chair. The following papers were read:—Determination of the class of envelope-curves which present themselves in questions of equality of size of two segments made on tangents of geometric curves, by M. Chasles.—On the steam carriage of M. Bollée, of Mans, by M. Tresca.—Fourteenth note on the electric conductivity of mediocre conductors, by M. Du Moncel. These experiments were with various metallic filings and the powder of metallic minerals, graphite, and retort charcoal, which were compressed into prisms between mica-plates. When heated, their conductivity at first diminishes somewhat, but it then increases very rapidly. When the heating ceases, it diminishes again, and after some time the intensity of the current becomes much less than it was at first. Thermo-electrical and chemical effects are also described.—On the useful effect of steam injectors (concluded), by M. Ledieu.—On the laws which govern reactions with direct addition (continued), by M. Markovnikoff.—On the unipolar electric excitation of nerves: comparison of the activity of the two poles during the passage of battery currents, by M. Chauveau. The subject was placed half in salt water, and a fine electrode applied to a point selected on the skin of the emergent portion; the other electrode was held in the liquid. Or the two electrodes were placed on two nerves sufficiently apart. M. Chauveau finds that for every healthy subject there is a certain moderate intensity of current, with which the contractions produced by the positive and negative excitation are equal in extent and duration; *below* this intensity the negative pole has the greater action; *above* it, the positive.—On the general arrangement of the nervous system in stylommatophorous pulmonate gasteropod molluscs, by M. Fischer.—Results obtained by means of sulphocarbonate of potassium on vines attacked by Phylloxera at Mezel. M. Dumas, summing up the testimony on this point, said the sulphocarbonates had everywhere proved effective (where used) in destroying the insect, and they rather improved than injured the quality of the vines.—On the method of Cauchy for the integration of an equation with partial derivatives of the first order, by M. Mansion.—M. Sainte-Claire Deville gave an extract from a letter by M. Fouqué, describing observations of volcanic phenomena in the island of Santorin.—The Perpetual Secretary called attention to a work of "Researches on the Combustion of Coal," by MM. Scheurer, Kestner, and Mennier-Dollfus; also to a memoir by MM. Marion and Borretzky, on the Annelids of the Bay of Marseilles. He further announced the publication, by M. Dummler, of a *résumé* of works of the Berlin Academy of Sciences from 1822 to 1872.

BOOKS AND PAMPHLETS RECEIVED

BRITISH.—Air and its Relations to Life: W. Noel Hartley, F.C.S. (Longmans).—The Princes of India: Sir E. Sullivan, Bart. (Stanford).—Inaugural Address of the West London Scientific Association and Field Club. Session 1875-6: Rev. G. Henslow, M.A., F.L.S.—Notes of Travel in South Africa: Chas. J. Anderson. Edited by J. Lloyd (Hurst and Blackett).—The Revised Theory of Light: W. Cave Thomas (Smith, Elder, and Co.)

CONTENTS

THURSDAY, NOVEMBER 18, 1875

MR. GLADSTONE AT GREENWICH

WE may surely regard it as a hopeful sign of progress that a whole page of the *Times*, as well as of other daily papers, of last Friday was practically devoted to the discussion of matters connected with Science and Art. When we find the daily papers giving so great prominence to these subjects, and when men of such position and mark as Prince Leopold, Mr. Gladstone, and the Lord Chief Justice, take what is evidently a genuine interest in the progress of science and art education among the lower classes, it seems quite safe to infer that this movement has at last taken a prominent and important place in the everyday life of the country.

Prince Leopold, in his address at Oxford, showed that he had taken some pains to become acquainted with the latest statistics of the Science and Art classes. The discrepancy between Prince Leopold's statistics and those of Mr. Gladstone has been commented upon in the *Times*. It would appear from an examination of the last Report of the Science and Art Department, however, that the figures which Prince Leopold gives for the number of students under instruction in science are probably the *number of papers worked* at the last May examinations. This, possibly, is an error in reporting. Mr. Gladstone, on the other hand, gives the right number—"about 48,000"—of the students under instruction *last January*; a different number, of course, to that in May 1874, when it was 53 050, or in May 1875, which has not yet been published, as far as we are aware. But in some way he has arrived at, or been furnished with, a wrong total for the number of Art students. This should be 54,800 odd, irrespective of the scholars in Elementary Day Schools. At the same time it is gratifying that a man like Mr. Gladstone should think it worth his while to take an interest in the matter at all, but when he does determine to think about it, the least he can do is to inform himself correctly as to statistics.

Mr. Gladstone set himself almost entirely to impress upon his audience the value of an education in the principles and practice of art; he attempted to show that really artistic handiwork had not only a refining, elevating influence even on the workman himself, but that it answered the requirement of utility in the best sense of the term. To his advocacy of the introduction of artistic taste into the commonest manufactures we can have no possible objection, but we distinctly demur to the ground on which he seems to have based the prominence that he gave it in his address. He found—wrongly, it appears—from the statistics that the proportion of students attending the Science classes was considerably larger than that of those who are attending the Art classes. According to the latest statistics this excess of Science over Art students is shown not to exist, and the inference that Science is getting more than its due share of attention, and that the claims of Art require special advocacy as being neglected, seems to us unwarranted on several grounds. The truth is the Art classes were established for many years before the Science classes, and the fact that there has been such a rush upon the latter simply proves that they meet a wider and deeper want than do the former; that, in short, the nation feels that it stands more urgently in need of science at present than of art.

We infer, moreover, from what Mr. Gladstone said, that he thinks the practical application of science ought to be endowed in preference to abstract scientific investigation and education in scientific principles. But is it not much more rational and really practical that the men who are getting their education at these Science and Art classes should be educated in the main principles and leading facts of science before they are taught how to apply them? How is the best work likely to be got out of a man? Is it by teaching him the practice of a few traditional rules, incapable of expansion, and which have no meaning for him; or by educating him thoroughly in the scientific principles and data on which his handicraft is founded, and then leaving him to learn in the workshop how these are applied in practice? One might as well expect a carpenter to make a workman-like chair or table before he has learned to use the plane or saw, as expect the best work to be produced by the former course. The principles or laws of science are comparatively few; their applications are endless.

The student who has an accurate knowledge of principles will readily understand the applications. One school will, as it were, fit him out with all that is necessary for all industrial progress. To teach the applied sciences on the other hand requires a special school for all the various possible permutations and combinations that may be rung on the general principles.

By looking to general science, again, the Government avoids the difficulties which must necessarily accompany, with all the fluctuations of trade, any attempt to teach applied science except in some very general forms. The fact is that the practical applications of science bring their own reward, and need no extraneous encouragement; instruction and invention in them may very well and without the least hardship be left to those whose pockets they fill. Art receives ample encouragement, and is well rewarded by the nation; let but an artist in any department show himself capable of producing good work, and he will soon find that both the Government and private individuals have plenty of rewards to bestow upon him. Science, on the other hand, receives not a penny in the way of assistance or reward, and yet the scientific investigator is the nation's servant and greatest benefactor. Pure scientific research is at present, like virtue, its own reward; the man who devotes himself to such research, unless he has some other means of gaining a livelihood, is likely enough to starve for all the help he will get from his country; and yet, as it has been shown over and over again, our country's prosperity, the progress of nearly all our industries, and even the very existence of many of them, are dependent on the discoveries of the scientific investigator who pursues his research on purely scientific principles, and with no practical end whatever in view. Our country has got at least as much glory, and we venture to think more practical benefit, from achievements in the region of pure science, as from all that has been accomplished in the domain of art, and yet no helping hand is held out to those who are able and willing to do their country the highest service, but cannot, because they must drudge for a living. The domain of science is every day becoming

more and more extended, her methods are becoming more and more complicated, and her instruments more and more expensive; in almost every department paths are being opened up which, if pursued to their end, would certainly lead to discoveries of vital importance to the best welfare and prosperity of the nation. Our public men are continually telling us that we are being outstripped by continental nations in fields which used to be peculiarly our own, and that simply because abroad every encouragement is given to scientific research, while here its existence is either ignored or it is regarded as a mere pastime. We can only think that Mr. Gladstone must have been imperfectly informed, or that he felt himself bound for the occasion to assume the position of special pleader on behalf of Art, which really can take very good care of herself.

We are grateful, however, for the unmistakable manner in which he referred to the City Companies. He put the case exactly as it ought to be put, and did not in the least exaggerate the crying scandal. Their pharisaical trumpeting of the pittances they dole out in the way of charity blinds very few, we should think, to the disgraceful way in which they discharge the stewardship of the enormous funds committed to their trust. What are these eleemosynary pittances compared to the sums they lavish yearly on their ponderous entertainments, relics of long past generations, when men were some stages nearer the lower animals than they are now, but which are now meaningless and out of date? These Corporations, though there are some wide-awake, practical, and, we must believe, advanced and cultivated men among them, seem to be quite unconscious of their lethargic, antiquated, and even dangerous position. We say "dangerous," for it is high time they should know that if they do not wake up out of their lethargy, and set their own house in order, they must very soon be wakened by a shock from without. The country cannot much longer forbear calling them to give an account of their valuable stewardship, and a sorry account, we fear they must render. It cannot be tolerated that while the advancement of the highest interests of the country is most seriously crippled for want of necessary means, those funds which were left by our benevolent predecessors in trust for the country's good, should rust in a useless napkin or be drawn upon only for the sensual gratification of those who foolishly fancy themselves their irresponsible trustees.

CHAMBERS'S ENCYCLOPÆDIA

Chambers's Encyclopædia, a Dictionary of Useful Knowledge for the People. Illustrated with Maps and numerous Wood Engravings. Revised Edition. Ten vols. (Edinburgh and London: W. and R. Chambers, 1874.)

WHEN the history of the English people during the present century comes to be written by some future Green—or it may be by the present one—the name of the publishing firm of W. and R. Chambers must be referred to with honour as having had a considerable share in fostering the great intellectual awakening among the people which was initiated in the earlier part of the century. By means of their *Journal*, which still maintains an honourable place among popular serials, their *Information*, their *Miscellany*, and other similar publications, they supplied the growing appetite of the people for useful knowledge with healthy and invigorating food, which at the same time stimulated a craving for more. We believe that in this way the Messrs. Chambers have done much to create the general want among the middle and lower classes which is now being gradually supplied by more organised and systematic means of instruction and culture. They were also among the first, if not the first, to publish for the use of schools a carefully compiled and almost complete series of text-books of science, a series which held its place for a long time, though no doubt now somewhat out of date, if not largely out of print. The crowning effort of this firm to provide "the people" with the means of obtaining useful and accurate information is no doubt to be seen in the "Encyclopædia" which they have brought out under the editorial care of Dr. Andrew Findlater.

Previous to the publication of this "Encyclopædia," which began to be issued in 1860, and to go no farther back than the present century, a large number of books of reference of this class had been published both in England and Scotland, but they were all works of a ponderous size and constructed pretty much after the plan of the "Britannica," consisting mainly of long treatises on the various departments of knowledge. The Messrs. Chambers, however, took as their model Brockhaus's well-known "Conversations-Lexicon," and have broken down, as they express it, the various masses of systematic knowledge, to as great a degree as is consistent with the separate explanation of the several fragments. No doubt this is the only satisfactory plan for a dictionary of universal information, which, first of all, ought to be a handy reference book. It is for this very reason that the alphabetical arrangement is used, and we do not see that much is gained by such an arrangement, if an encyclopædia is to consist of a collection of exhaustive treatises, requiring an enormous index to make them consultable. As a handy book of reference, then, the plan of "Chambers's Encyclopædia" is all that could be desired. Of course there is a limit to the cutting down of subjects for purposes of reference, and Dr. Findlater has shown great shrewdness and common sense in fixing this limit. Perhaps some might desire an encyclopædia with a more copious vocabulary, with a fuller list of subjects, more condensed information, and in every case where practicable a copious bibliography; but for the great bulk of the people, the encyclopædia before us will be found to answer with singular completeness all the purposes of a book of reference. Between the body of the work and the copious index there is little that any ordinary man will want to inquire about which he will not find information upon here, and that speedily. In many cases references to special authorities furnish the means of pursuing a subject further.

As to the quality of the work we can speak with almost unqualified approval. We have said that the "Encyclopædia" is modelled after the German "Conversations-Lexicon." Indeed, the Preface states that it was at first intended to translate almost literally the German work, but that after the work of translating had been gone on with for some time, it was seen that an encyclopædia adapted to the English public would have to be constructed on an independent basis. This has

evidently been done. We have examined carefully a large number of the articles, and of course the scientific ones especially, and considering the purpose and plan of the work, there is really very little room for criticism. All the scientific articles have evidently been written by men who have special knowledge of their subjects, and as a rule are masterly specimens of condensation, clear statement, and wonderful fulness of information. Such names of contributors as Tait, Deutsch, Alex. Bain, Alex. Buchan, Goldstücker, Dr. G. E. Day, Keith Johnston, Dr. Birch, Pengelly, Francis Francis, and many others, are guarantees that in all the principal departments thoroughly competent men have been secured to write. But while with such contributors the quality of the information was bound to be up to the mark, the Encyclopædia would have suffered much in other respects without a thoroughly competent organising head. It is, no doubt, mainly due to Dr. Findlater that uniformity and due proportion have been secured, and that throughout perfect clearness has been maintained. His singular adaptation to fill the post of editor of such a work has largely contributed to its success.

But it is not only in the larger and more important articles that accuracy and care are apparent; even in the case of unimportant towns which may occupy only three or four lines, the information may be depended on, and in the case of British towns at least, was obtained, we believe, in almost every instance at first hand from some one on the spot. But down to the minutest details throughout the work constant and thoroughly intelligent and competent editorial care is evident, and if the Messrs. Chambers are careful to keep their work up to date, and bring out new editions at the proper times, they need hardly fear a rival.

The edition which lies before us is not strictly a new, but a revised edition; the work has not been reset, and but little increase has been made in the number of articles. We have, however, taken pains to compare some of the principal scientific articles in the new edition with the corresponding ones in the old, and in every case, where it has been really necessary for such a work, a competent revising hand is evident. "Chemistry," for example, which was first written twelve years ago, has been brought fairly up to date, and, as chemists know, this implies a great deal. By a few additional sentences in "Astronomy," the direction of the most striking recent researches is indicated; so in "Meteorology" and other articles. Indeed, it is quite evident that the work has been subjected to a thorough revision, and that considerable alterations have been effected, quite sufficient to keep the work fresh until a completely new edition is called for: not a few of the articles have been entirely re-written. The illustrations are copious and, in the main, accurate and well-drawn, and there is an excellent selection of maps.

Of course there are points in the work that are open to criticism; some subjects may seem inadequately treated, and others at too great length, and evidences of local bias are occasionally apparent, while there is a tendency in many of the biographical articles, to ambitious writing and the "higher criticism," which are a little out of place in a staid book of reference. But these are matters of comparatively small importance, in which Dr. Findlater is probably a much better judge than we. Of the sterling merits of the work throughout there can be no mistake, and it will long remain a monument of Messrs. Chambers's enterprise and public spirit, and of Dr. Findlater's practical skill, judiciousnes,s and power of organisation., not to say wide and accurate knowledge. Not its least merit is that, like all Messrs. Chambers's serial works, it was issued in weekly numbers at three-halfpence, and we would advise all who can spare the pittance to become possessed of this "golden treasury" of knowledge.

EGYPT AND THE NILE

Four Thousand Miles of African Travel: a Personal Record of a Journey up the Nile and through the Soudan to the Confines of Central Africa. By Alvan S. Southworth, Secretary of the American Geographical Society. (New York: Baker, Pratt, and Co. London: Sampson Low and Co., 1875.)

MR. SOUTHWORTH, we may at once state, has broken no new ground; he has simply followed what are now considered beaten paths, although fifteen years ago there would have been few European footprints on the route; nevertheless, Mr. Southworth has gathered much useful information. This is given to the public in an agreeable form, with a tinge of American humour in some descriptions that breaks the usual monotony of a book of travels.

It appears that the author's love of adventure prompted him to visit the Soudan in the hope of following and eventually joining the expedition under the command of Sir Samuel Baker, in Central Africa. In Chapter III., "The Start for the Soudan," he writes:—"Alarming rumours of the death of Sir Samuel Baker and his whole party had been freely circulated in Cairo." . . . "Such a great undertaking as the Baker expedition was regarded by many of the finest minds in Egypt as too gigantic to move successfully among the unknown wastes of Ethiopia. In the first place, it is taking an army into a country foul with the unhealthiest malarias, and charred to desert sands by the fiercest of African suns." . . . "Therefore, when news came from Khartoum that Sir Samuel Baker was in distress at some point of the Nile Basin, I prepared to go to the Soudan in order to investigate his position and condition." With this object Mr. Southworth started from Cairo in company with two American officers, Generals Starring and Butler, and after a winter journey through the Korosko Desert, the party arrived in Khartoum on the 6th of February.

Chapter XI. will well repay perusal by those who take a desponding view of Egypt's future. The description given of the extreme fertility and boundless resources of the Soudan may be to a certain extent overdrawn; but even with the deduction of fifty per cent., the value of the country remains enormous. At the period of Mr. Southworth's visit to Khartoum, Moomtaz Pacha was the new Governor-General of the Soudan, a Circassian of great energy, who was determined to develop the cotton-producing powers of his almost boundless territory. Unfortunately he had forgotten that a necessary step preliminary to cultivation was a railway from Cairo, as no means of transport existed beyond the limited conveyance by camels. "Tell the American people," said the Governor-General of the Soudan to Mr. Southworth, "that I have found a new America in the heart of Africa."

"Moomtaz Pacha, who had been there but four months and a half, had done more work than all his predecessors combined. He was the first man who appreciated the resources of this country; who formulated plans to utilise them; and who with a resolute hand began what I am firmly convinced will eventually come to be a prosperous empire, reaching from the equator to the tropic of Capricorn, and from the Indian Ocean to the Desert of Sahara."

Mr. Southworth's evidence is extremely valuable at this moment of general depression, when doubts have been expressed concerning the future prosperity of Egypt. There is the unanimous testimony from numerous travellers that a mine of agricultural wealth lies upon the southern limit of the great Nubian deserts, simply requiring a line of railway for its immediate development. There are lands in many portions of the globe that are adapted by soil and climate for the cultivation of cotton, but in most cases where such facilities exist there is a scarcity of labour. In the Soudan we find not only an apparently boundless extent of fertile soil where the cotton shrub is indigenous, but a large population is at hand who are only too ready to work for a fair remuneration. It may perhaps be forgotten by many that the ancient historian Pliny calls attention to the "wool-bearing trees of Ethiopia." In the days of Herodotus, whose descriptions of Egypt are so graphic, cotton was unknown, and the Egyptians were renowned for the manufacture of the finest linen from the native flax; it was only in the reign of Mehemet Ali Pacha, the grandfather of the present Khedive, that cotton was introduced into Egypt. Curiously enough, this was seed from the "wool-bearing trees of Ethiopia," which was brought into Egypt by an enterprising French traveller upon his return from the Soudan. When we consider the important assistance that was rendered to England by Egypt during the American civil war by an extraordinary effort in the production of cotton, we must feel a more than usual interest in the development of the vast cotton-producing resources of the Soudan. It is the natural hot-bed of the cotton plant, where it has existed from time immemorial; we have only to construct a railway either to the Port of Souakim on the Red Sea, or direct to Cairo according to the plan of Mr. Fowler, and the Soudan will at once deliver its vast burden of riches.

Mr. Southworth upon his arrival at Khartoum discovered that owing to the impediments to navigation caused by the vegetable obstructions on the White Nile, it was quite impossible to carry out his original idea of joining the expedition of Sir Samuel Baker. The enterprising Governor of the Soudan, Moomtaz Pacha, showed him every attention, and invited him to an excursion by steamer up the White Nile. During this voyage Mr. Southworth was struck by the extraordinary fertility of the soil in the vicinity of the river, together with the great advantages of water communication as a means of transport from the interior.

In spite of the vast natural resources of the country, Mr. Southworth, who was now fairly behind the scenes, quickly perceived the moral cancer that preyed upon the Soudan and completely paralysed all progress; this was the slave trade, which engrossed the attention and energies of the population. He writes (page 355): "A slave expedition starting under the title of an ivory enterprise means war. As high as 5,000 soldiers are employed by a single trader. Agāte had over this number on the White Nile; Cushick Ali, 4,000; Gatāse, 4,000; Bizelli, 800. Thus the slave trade in the valley of the Upper Nile is sustained by an active force quite as large as the standing army of the United States." . . . "By examining the most exhaustive consular statistics on the ivory trade, I find that no expedition could pay the first cost. The traders do not expect it; so that when you read of a great ivory trader you may substitute, with little fear of doing an injustice, 'an infamous slave-trader.'" At the time that Mr. Southworth's sympathies were enlisted against this abominable traffic, he thus speaks (page 216) of the Khedive's expedition under Sir Samuel Baker to suppress the slave-hunters: "As long as Baker remained a Pacha at Gondokoro (now Ismailïa) there was no danger of a direct White Nile slave trade. Indeed, the traffic may be said to have been closed." . . . "When I say 'direct slave trade,' I mean no slaves could be made to descend within the reach or knowledge of Baker Pacha. But unhappily he could not cover a whole continent." In page 213 he writes: "Sir Samuel Baker has been in that region its only vigorous European combatant, and more to him than any other man will be due the praise of its utter eradication, if the day ever arrives."

Mr. Southworth, as Secretary of the American Geographical Society, has a perfect right to express his opinions upon the "sources of the Nile," although he did not personally travel far upon the White River. He is somewhat perplexed by the pretensions of Col. Long, who, as a member of Col. Gordon's staff, travelled up to the capital of the King M'Tésé, with whom Sir Samuel Baker had established a permanent alliance. Col. Long, on his return from the Victoria N'yanza Bay, which forms the embouchure of the Victoria Nile exit (discovered by the late Capt. Speke), continued his course down stream by canoe to Foweera, the headquarters of Rionga. He reported that the mighty Victoria N'yanza was only fifteen miles broad, and that Speke had greatly exaggerated the size. He further reported that he had himself discovered an immense lake a few miles south of M'rooli (N. lat. 1° 36′), which he suggested was the "source of the Nile." These pretensions were never accepted by geographers, it being well known that at certain seasons the Victoria Nile floods many leagues of country above M'rooli; this would give a stranger an erroneous impression of a permanent lake. The recent explorations of Mr. Stanley, who claims to have coasted in his boat 1,000 miles of the Victoria N'yanza along the southern, eastern, and northern shores, is a sufficient refutation of Colonel Long's disparaging assertion that Capt. Speke's Victoria N'yanza was only fifteen miles across. Mr. Southworth with true discrimination suggests on page 302: "It is possible that Col. Long's lake was only the Nile in a very swollen condition; for I have seen the Nile at latitude 13° N. at very high water resemble a vast lake." On page 316 Mr. Southworth writes: "Dr. Livingstone's claims may be considered as out of the question. Lieut. Cameron has almost completely proven that Livingstone never saw the Nile, but that his operations were confined to the Congo Basin." On p. 317 the author thus summarises: "It practically reduces the Nile problem to this. The

sources must be in the Albert and Victoria N'yanzas or their extensions; in the new lake of Col. Long; at the head waters of the Bahr-el-Ghazal, and in the sources of the feeders of the Blue Nile and the Atbara." We will dismiss the "new lake of Col. Long," but remind Mr. Southworth that he has omitted the most powerful of the White Nile affluents—the Sobat—N. lat. 9° 21'!

There can be no doubt the Victoria N'yanza is a mighty reservoir or principal source of the Nile, and the friends of the lamented Capt. Speke will rejoice in the triumph of his discovery now rendered certain by the survey of Mr. Stanley. The Albert N'yanza has never been visited by any Europeans except Sir Samuel and Lady Baker in February 1864; thus nearly twelve years have elapsed since its discovery, and yet no European has been able to reach its shores, although its waters were again sighted by Sir S. Baker during the expedition of the Khedive of Egypt.

There can be little doubt that Col. Gordon will succeed in exploring the Great Basin of the Nile, which will prove to be not only a source, but the general reservoir or basin that receives all equatorial affluents.

Although Mr. Southworth's travels do not include any new ground, his book affords much useful information, which will be received with more than ordinary interest at the present moment, when Egyptian affairs are prominently before the public.

OUR BOOK SHELF

Discoveries and Inventions of the Nineteenth Century. By Robert Routledge, B.Sc., F.C.S. With numerous Illustrations; pp. 594. (London: George Routledge and Sons, 1876.)

In this book "an attempt has been made to present a popular account of remarkable discoveries and inventions which characterise the present century." "The instances selected have been those which appeared to some extent typical, or those which seemed to have the most direct bearing upon the general progress of the age." "The author has endeavoured to indicate, if not to explain, the principles involved in each discovery and invention."

These extracts from the preface sufficiently explain the object of the work before us. Anyone who attentively reads this book must admit that the author has succeeded in fulfilling the promise of his preface. He has produced a work teeming with useful and exact information presented in a singularly lucid and taking style. Of course this book cannot in any way take the place of the acknowledged manuals on the several subjects of which it treats, but it is admirably adapted to awaken an interest, especially among the young, in those wonderful advances which natural science has made in the present century; and to supply such a general knowledge as shall convey a correct idea of the principles on which the application of science to arts and manufactures are based, along with a sufficiently detailed account of these manufactures themselves.

Books, the general plan of which resembles that of this work, have been too often produced by men who had no scientific knowledge of the processes they attempted to describe, and have therefore shown a lamentable deficiency in exactness of detail and accuracy of theory. That the book before us should have escaped these faults, faults for which no brilliancy of diction or popularity of style can atone, is to be traced to the fact that its author has evidently determined, and has been able to carry out his determination, to make the book a scientific one; to show, as far as could be consistently with the general tone of the work, that theory is necessary for correct practice, and that correct practice reacts upon theory. The contents of the book include an account of steam engines, iron, tools, railways, steam navigation, fire-arms, printing machines, light, the spectroscope, electricity, photography, aquaria, india-rubber, explosives, mineral combustibles, coal gas, &c. A very interesting chapter is devoted to New Metals, in which a clear and succinct account of the discovery and present method of producing sodium, potassium, aluminium, and magnesium is given. The gradual diminution in the cost of these metals, and therefore their increasing application in manufactures as chemical science has discovered easier methods for their preparation, is an argument in favour of the study of pure science which must appeal, one would think, even to the Philistines.

The title which the author has chosen for the closing chapter of his book, viz. "The greatest discovery of the age," might lead one to look for a glowing account of some new invention to economise labour or to annihilate pain, but when we find that the chapter is devoted to a sober account of Dr. Joule's experimental determination of the mechanical equivalent of heat, and to some of the consequences deduced therefrom, we are but the more convinced that this book must rank among the few popular works which are sure to be of service in spreading a knowledge of the incalculable benefits which science has bestowed upon the human race.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Scientific Research for the Promotion of Science

In Nature, vol. xii. p. 470, there are some valuable summaries of evidence taken before the Government Science Commission; but among them I was surprised to meet with the statement (by Captain Galton, R.E.) that, as one of the varieties of administration of several existing scientific institutions, "you have the Observatory at Edinburgh as part of the University of Edinburgh."

Now, inasmuch as I have for the last thirty years held the Directorship of the Edinburgh Observatory, by virtue of my appointment thereto signed by her Majesty, I should know something of the real facts of the case; and they oblige me to state that the Royal Observatory (the only Observatory) in Edinburgh is supported, in so far as it exists at all, by Government. It is responsible, moreover, solely to Government, in the person of the Principal Secretary of State for Home Affairs; it has never at any time received a farthing from the University of Edinburgh, whether for instruments, salaries, general maintenance, or particular services; and does not form any part of, nor belong to, nor did ever belong to, the said University in any manner whatever.

But the efficiency of the Observatory has been crippled from the beginning by the connection of its Director with the University; and as that offers a practical answer to the question much discussed in your pp. 429 and 470, touching whether there is, or is not, any difference in kind, nature, interests and feelings between institutions for the promotion of science by original observation on one side, and on the other the usually much larger and more numerous institutions for education,—I trust you will allow me a little space wherein to describe our actual and long-continued experiences here.

Built by the members of the late Astronomical Institution of Edinburgh between 1811 and 1830, this Observatory was, after many public petitions to that end, graciously taken up by Government in 1834, and its future utilisation secured by arrangements for the appointment thereto of a Royal Astronomer with an assistant, and a small allowance for ordinary working expenses. The first Astronomer so appointed was the late Thomas Henderson, the best man by far for such a post whom Scotland has ever possessed; and as he had at that time just returned from being Astronomer Royal at the Cape of Good

Hope, and had there secured and brought home the most astounding amount of both useful and even super-excellent astronomical observations that ever one man made in twelve months,—there was no apparent reason why he should not at once have been allowed to step straight into this new Observatory appointment, and commence its laborious duties forthwith.

But that was not to be; for he was privately informed that he must first and preliminarily be appointed a Professor in the University of Edinburgh. He started at and resisted the idea; he said he did not want to be a Professor, and would not be one; it was an occupation wholly foreign to his tastes, and entirely incompatible with the full and conscientious devotion of himself to being a working astronomer within the Observatory. Pressure, however, of powerful friends was brought to bear upon him; and he was made to understand that Government could not, or would not, whatever the secret reason, create and set agoing the new appointment for the Observatory on the Calton Hill, of "Astronomer Royal for Scotland," without first connecting it with a certain old and shameful sinecure in the University of Edinburgh, called the Professorship of Practical Astronomy.

He was indeed assured that he would, and should, never be called on to lecture in the Professorship; that it was a mere name and nothing more; and his form of appointment to the strangely and unnaturally duplex post of the old Professorship and the new Astronomer Royalship, was made out in words assigning clearly enough the work in the Observatory, of "with zeal and diligence making observations for the extension and improvement of astronomy, geography, and navigation, and other branches of science connected therewith," to be his only circle of duties and his only claim to salary, viz. 300*l.* per annum. But then how were those promises fulfilled; or rather, how were they neglected and overborne when the multitudinous heads of the great educational University of Edinburgh had once got poor Thomas Henderson, the first Astronomer Royal for Scotland, safe within their thrall as being also a Professor before them?

Why thus: they immediately began treading on his toes from every side; and with the most magnificent disregard that he had anything worthy of notice to do in the Observatory, they forced on his attention, both in season and out of it, "that while they were working so hard in the great educational hive, he was a mere drone, and yet was in receipt of a salary of 300*l.* per annum, an absolutely larger salary than any of themselves who bore the brunt and burden of the tuition of all the students." For the complainers, be it remarked, left out of view, that if their incomes did not mount up to 300*l.* in the shape of *salaries*, it was because they came to them chiefly in the form of students' fees; and in that phase sometimes reached 1,000*l.*, 1,300*l.*, and even 1,600*l.* per annum.

But this difference the teaching Professors could not see; and so, if, as they knew perfectly well, there were no students applying for Practical Astronomy Lectures, they determined that the Practical Astronomy Professor should still be educationally utilised, and as an assistant to other Professors, if not as a Professor on his own account. Wherefore Thomas Henderson was talked at, and talked at, until for one winter he was prevailed on to give lectures in the University to the Mathematical Class during the illness of its Professor. Then he was induced to take up the onerous position of Secretary to certain University trusts. And then, while that was still going on, he was over-persuaded into giving lectures for the then Professor of Natural Philosophy during one of his retirements; and then,—why, then, Thomas Henderson, who was all this time struggling almost superhumanly by night and by day to keep up his observations as Astronomer Royal for Scotland in the Royal Observatory, Edinburgh,—why, then—he died! Died too at the early age of forty-six years, and Scotland has not seen his like either before or since; for he was in fact the one and only high-class and complete practical astronomer whom his country and his nation have ever produced; and yet he was hurried to a premature grave, trampled on by an unsympathising *educational* University.

Of my own troubles in trying to fill this truly great man's place, I could tell a vast deal, but would rather merely refer to my last official Report to the Government-appointed Board of Visitors of the Royal Observatory, Edinburgh; wherein, after showing forth the recent attempts of the University authorities actually to "transfer" from the Astronomer Royalship of Scotland the *whole* of the salary originally appointed to that office by the Crown, and take it over to their own studentless Professorship, I have finally besought the Board to apply to Government to separate the two offices absolutely and for ever.

Most heartily convinced therefore must I be of the positive wisdom of those weighty words of Colonel Strange, alluded to in your p. 429; wherein, after stating his belief that there should be a Minister of Science, to look after the interests of institutions for *the promotion of science*, as entirely apart from any or all the institutions for *education*, whether in science or anything else, that most sage and experienced officer goes on to say:—

"That he considers education to be quite a different thing from national research, and that they should be kept as distinct as possible; and that one great evil now existing is the mixing up of those two things."

PIAZZI SMYTH,
Professor, and Astronomer Royal for Scotland
Royal Observatory, Edinburgh

Ericsson's Researches on the Sun

IN your interesting journal (vol. xii. p. 519) I see a description of an experiment by Capt. Ericsson, intended to measure the difference of temperature between the centre and the edge of the sun. I do not intend to make here any criticism on this experiment, but only to make some remarks on the final conclusions.

We must first distinguish two kinds of results—one directly given by the observation, the other by calculation.

In the first, we agree as far as is possible in considering the different methods of solving this question. He finds, indeed, that the intensity near the edge is 0·638 of that of the centre, the outer zone being in the mean line 49″ distant from the edge, and consequently large, 98″ = 1′ 38″. On my experimenting on a small area not exceeding one minute square, and distant from the centre 14′·920 = 14′ 55″·2 (and consequently distant in September from the edge 62″), I found 0·5586. The difference is indeed not very considerable, being 0·0794. Now Plana has shown, in the *Astron. Nachrichten*, No. 813, that such a small difference may lead to a very considerable difference in the value of the absorption.

The value of the solar atmospherical absorption, according to Mr. Ericsson, cannot be greater than 0·144 of the radiant heat emanating from the photosphere (page 520), and he then quotes my results, in which it is stated that 0·88 is absorbed by the whole atmosphere. He proceeds to remark: "It is unnecessary to criticise these figures presented by the Roman astronomer, as a cursory inspection of our table and diagrams is sufficient to show the fallacy of his computations."

I beg leave to observe that the fallacies are not only my own, but those of Laplace and Plana as well, who from the numbers of Bouguer's have arrived at a conclusion very similar to my own. The fallacy, I think, is rather in Mr. Ericsson's method of calculating. In a problem of so great difficulty, and where the great analysts have established very complicated formulæ, he makes use only of some very simple proportions, which are by no means justified, and with these he thinks his conclusion is very plain! I regret to say that such a method of computing in this case cannot be admitted, and consequently we are justified in attributing the difference of the results, not to the fallacy of our computation, but to the fallacy of those proportions assumed by Mr. Ericsson, unless he, or any competent mathematician, be able to show some great error in the formulæ of Laplace and of Plana.

Several objections besides may be made to his manner of experimenting, but of that on another occasion. In applying the numbers of Mr. Ericsson to the formulæ of Laplace and Plana, the result will be found to be not very different from mine. But at present I have no time to discuss these and other calculations, and also I wait for the new experiments which he has promised. I will only add that I do not share his opinion that the lenses and telescopes introduced in these researches by me do not give reliable results.

P. A. SECCHI,
Rome, Oct. 28 Director of the Roman Observatory

Sir G. B. Airy and the National Standards

IN NATURE vol. xiii. p. 35, the following statement occurs:—

"In the civic speeches which accompanied the ceremony [of conferring the Freedom of the City of London], great stress was laid on Sir G. B. Airy's services in connection with the Metric Standards."

This statement is not perfectly correct.

The expression of the Chamberlain of the Corporation, as recorded in the official register, and as correctly reported in the principal newspapers, was:—

"When the national standards of measure and ponderosity were by accident lost to the nation, you were applied to for the accomplishment of their restoration with that mathematical exactitude which was indispensable."

The statement in NATURE will be made correct by erasing the word "Metric" and substituting "National."

The Origin of our Numerals

MR. DONISTHORPE'S ingenious construction of our numerals by corresponding numbers of lines (NATURE, vol. xii. p. 476) induces me to offer a few remarks on this subject, which has a literature of its own. There can be no doubt, I believe, that our forms were derived directly from the Arab series called Gobar; that the Arabs had them from the Indians, and the Indians from the Chinese. My esteemed friend Dr. Wilson, of Bombay, published a "Note on the Origin of the Units of the Indian and European numerals," in 1858,* in which he showed the derivation of some of our numerals from ancient Indian forms found on cave inscriptions of Western India, on the Bhilsa Topes, and on coins. My remarks are founded wholly on the forms given in this note, which is little known, I believe, in England.

Dr. Wilson obtains our first four numeral forms from the Chinese, traced through different Indian script characters nearly as supposed by Mr. Donisthorpe. One, two, three horizontal bars and a square for 4. He also finds the eight in the forms , , and on the cave inscriptions.

Before proceeding to the other numerals I wish to notice a rule which may be deduced from the consideration of the changes in the forms of numerals in passing from one people to another, that the same form may be turned through angles of 90° or 180°, and may be inverted or reversed without altering its value. Even the same people have used a form turned in different ways for the same numeral. The Arabs used their 2, 3, and 4 in two ways, making angles of 90° with each other; the 2, 4, and 5 of Sacro Bosco and Roger Bacon were the Indian script Modi (and ours) turned through 180°, or upside down; other examples will be noticed.

The most important derivation by Dr. Wilson is that from the Chinese ten; this is found on the Bhilsa Topes with a circle round it (Dr. Wilson thinks to distinguish it from the oldest form of K found on the cave inscriptions). The nine is found on the Bhilsa Topes as , or one under ten, and on old coins thus: . The Indian caves give half of ten , , for five (as V is the half of the Roman ten, X). It is from this form that Dr. Wilson derives the Indian Modi and Nagari fives , , . It is here that I venture to differ slightly from Dr. Wilson. One of the cave forms of four is , which Dr. Wilson interprets (as in the case of nine) one under five, or five less one; now this form without the under bar, as well as the other forms of five, are, it seems to me, the halves not of the cross ( ) merely, but of the cross and circle thus: , , , which are as nearly as possible two half diameters and half circumference. The form is, I believe, the origin of our four, and not the Chinese or Indian square, as supposed. This I think will be evident when we compare the Arab four ( ) with the Indian four above. The Arab four s also employed thus: , which inverted gives , a sufficiently near approximation to our four.

Dr. Wilson has not been able to find the origin of our seven, but this is obtained from his Arab seven , by turning it round ( ) and making one leg shorter than the other, nearly resembling the Gobar seven . We may also find an earlier source in the Chinese seven turned round 180°, , which is almost exactly the German written seven. Neither six nor seven is to be found on the cave inscriptions. In Dr. Wilson's Arab series the Indian five is used for six, and the Gobar six, as well as ours, may be taken from the Nagari seven . We may also find an origin in the Chinese six , by omitting the horizontal bar, as in the case of the seven. That such liberties were taken is evident on a consideration of the five of Sacro Bosco and Roger Bacon ( ), the Indian five *without the bar*, and turned round 180°. If there is any merit in these suggestions it belongs to Dr. Wilson.

On the Cup-shaped Joints in Prismatic Basalt

THE difference between Mr. Mallet (NATURE, vol. xiii. p. 7) and myself is simply this. He asserts, as necessary to his theory, that the "convexities" should always project in the direction in which the cooling and consequent "splitting is proceeding" ("Proceedings of the Royal Society," No. 158, p. 182). I referred him to the beautiful specimen, in the hall of the Geological Society's Museum, of three columns, one of which exhibits an articulation in the shape of a double-concave lens; the adjacent convexities consequently pointing, in this case, in *opposite directions*.

Mr. Mallet's reply to this is, that the cooling must have proceeded, in this instance, in different directions, and met in the biconcave-lens-shaped articulation. Now, inasmuch as this articulation is only a few inches (three or four) thick, and shows no sign of seam or separation across it, and Mr. Mallet himself declares (in the article mentioned above) that the plane which separates the part cooled from above, from that which cooled from below, "consists of irregular fragments," I maintain that his explanation is inadmissible and self-contradictory. Any geologist who takes sufficient interest in the question to examine the columns for himself will be easily satisfied on this point.

A New Palmistry

THE proportions of the fingers in the two hands are not, I think, always the same. With me the index finger of the left hand is considerably longer than the ring; in the right they are very nearly equal. R. A. PRYOR

Hatfield, Nov. 12

OUR ASTRONOMICAL COLUMN

THE MINOR PLANETS.—The discovery of No. 154 by M. Prosper Henry at the Observatory of Paris, on November 6th, is announced in M. Leverrier's Bulletin and by circular with the "Astronomische Nachrichten;" and that of No. 155 by Herr Palisa at Pola on the 8th inst., in the Paris Bulletin of the 13th. They are of the same magnitude (twelfth) as the three previously detected during the present month.

The rapid increase in the number of small planets must soon occasion serious difficulty, not only in predicting their positions with sufficient approximation to allow of their being recognised without considerable expenditure of time and trouble, but likewise in securing observations, especially on the meridian, according to the system pursued for some years past at Greenwich and Paris, by agreement between the Astronomer Royal and M. Leverrier.

As regards the preparation of ephemerides, it is well known that the conductor of the "Berliner Astronomisches Jahrbuch," Prof. Tietjen, makes it a speciality of his work, with the aid of a numerous body of astronomers in various parts of Europe and in the United States, and hitherto he has succeeded in providing observers with an ephemeris of nearly every small planet detected to within a short time of publication. Thus, in the Jahrbuch for

1877, we find approximate places for 1875, of 134 out of 138 planets—materials for calculation not being available in four cases—and accurate opposition-ephemerides are given where the elements have been perturbed to the year, and for those planets for which Tables have been prepared. The initiated in these matters will be aware that a work of this extent involves a vast amount of labour, which will be greatly increased with the present rate of discoveries of new members of the group of small planets.

In some few instances the perturbations have been determined with every possible precision, with a particular object in view, as in the case of Themis, the motion of which was rigorously investigated by Dr. Krüger, for a determination of the mass of Jupiter; and for those planets whose perturbations have been thrown into the form of Tables, it was also necessary to settle the elements with great accuracy, though the results have not been in every case so satisfactory as might have been expected. We have now Tables of Amphitrite, by Becker; of Iris, Flora, and Victoria, by Brünnow; Egeria, by Hansen; Metis, Lutetia, and Pomona, by Lesser; and of Parthenope, Eunomia, Melpomene, and Harmonia, by Schubert.

Even with approximate places of these bodies, so long as they are situated within about 3° from the ecliptic, the charts of small stars now in the hands of astronomers allow of their being identified without much difficulty with the equatorial, and the errors of the predicted places being determined by this instrument, their meridional observation is greatly facilitated. Still, rough ephemerides must be prepared, and a considerable amount of time will be involved in ascertaining their errors, and as observations made with this purpose in view may be so conducted as to give positions pretty nearly as reliable as those generally resulting from meridional observations, we shall not be surprised to learn that the latter are soon relinquished, except perhaps for the older minor planets and for such as attain the brightness of stars of the eighth or ninth magnitude, and are accurately predicted. The subdivision of labour as regards observations does not appear to have so far worked very efficiently, though proposed many years since—another effort, however, may be necessary in this direction, and it may at least be expected that those who by their discoveries are so rapidly increasing the list of planets, will keep them in view for a sufficient length of time to allow of their elements being well determined.

Egeria, which has now about the brightness of an average star of the ninth magnitude, is favourably situated for observation; it has lately passed amongst the outliers of the Pleiades. The following places are for Berlin midnight:—

	R.A. h. m. s.	N.P.D. ° ′	Distance from earth.
Nov. 18	3 18 59	65 53·3	1·478
,, 20	3 16 32	65 47·8	1·479
,, 22	3 14 6	65 42·6	1·481

SCIENCE TEACHING TO YOUNG CHILDREN

THE leading article in NATURE of Oct. 28, on the Sixth Report of the Science Commission has made me think that possibly a short account of an attempt to teach science to boys younger than those to whom that report refers, may be not without interest for some of your readers.

There are at present about fifty boys in this school, varying in age from seven to fourteen, the majority of whom are going to one or other of the great public schools. In order to attain the high standard of classical work necessary, half the school-hours have to be given up to Latin and Greek. Enough time still remains, however, even after providing for the requirements of mathematics, French, and the usual English subjects, to enable every boy to learn either botany or chemistry. For this purpose the school is divided into three classes, the lowest of which contains about twenty boys, whose average age is nine. Class II. is composed of ten boys of an average age of twelve, while the first class contains twelve boys of an average age of twelve and a half. Class III. has two lessons in botany of three-quarters of an hour each, and one hour's lesson on physical geography in the course of the week. The boys in it are taught to distinguish the parts of a flower, and by the help of a chart similar to that given by Mrs. Kitchener in her "Year's Botany" to discover the order to which any plant belongs. The winter is employed in learning the chart, and in studying the characters of the different orders as shown on Henslow's Botanical Diagrams. Illustrations taken from Sir John Lubbock's and Mr. Darwin's books, of the relations between plants and insects, and facts bearing on the geographical distribution and economical uses of plants, add interest to these lessons. The second class also does botany, but is able to give two-and-a-half hours per week to it. The standard of knowledge aimed at is such as is contained in Prof. Oliver's or Mrs. Kitchener's books and the boys are expected to be able to find out any given plant in Bentham's British Flora. The boys in Class I. learn chemistry, and spend one afternoon of one-and-a-half hours at practical work in a small laboratory. Another afternoon is employed in listening to a lecture founded upon Miller's Chemistry (Text-books of Science series). Two additional half-hours are given to getting up the portion of Miller lectured on, so as to be able to answer questions on it at the beginning of the next lesson. The boys have also to keep notes of the lectures and of the laboratory work. The standard aimed at is the power to discover a simple acid and base, and an acquaintance with the text-book. During the summer the chemistry boys have a botany lesson once a fortnight, in order that they may keep up what they had previously learned. In addition to this regular work, Classes I. and II. have occasional lectures either on chemical physics, "Erdkunde," or some such subject. As regards marks, all the various school subjects stand on an equal footing.

The science lessons are very popular with the boys, as is shown by their frequently referring to them out of school, and by their occasionally bringing home plants in order to make them out. But we hope that the boys will retain some considerable amount of knowledge beyond the mere power of making out the flowers given to them, or that of doing simple analysis, and though perhaps few of the younger boys would be able to pass a thoroughly satisfactory *written* examination, in either chemistry or botany, yet a good deal more knowledge might be questioned out of even them by an experienced examiner than they would be able to put upon paper. Mere knowledge of the facts of either science is not the object at which we have been chiefly aiming. These sciences were chosen less as subjects of study than as instruments of training in order to cultivate the powers of observation, and to encourage a habit of inductive reasoning. If the teaching of science in its early stages is thus regarded more as a means than as an end, there is no child, who has begun to learn anything at all, who may not be taught some branch of it with advantage.

At the same time there is a danger to be avoided.

When we first began teaching botany and chemistry here, I was so strongly impressed by the truth of this view of the proper place of science in education, that I started by making the boys examine flowers and do simple reactions without making them learn anything by heart, hoping to induce them to collect their facts and build up their science for themselves. The result was that they did not know what to do with the facts which they collected, and kept losing them as fast as they picked them up. But since the botany boys have been set to learn the chart by heart, and since the chemistry boys have been using a text-book, the progress made has been far more satisfactory. A young child's reasoning powers are so feeble that he needs to be constantly guided in the use of them, and before being set to observe he requires to be furnished with a "cadre" in which to arrange his battalions of facts.

It may be asked why botany and chemistry should be chosen in preference to other sciences, such as geology or physics, which might seem likely to prove more attractive to boys. Botany was chosen because it is purely a science of perception, of observation and co-ordination of existing facts, and because it calls into play and directs into a useful channel that natural propensity of boys to collect and classify which is seen in butterfly catching and stamp albums. A good deal more might be made of entomology than has hitherto been attempted, but it is rather a holiday than a school subject, the bases of its classification are too minute and even arbitrary, and it has the disadvantage of leading almost of necessity up to subjects too wide for boys to grasp. Chemistry was chosen because it is a science of reflection, and forms the best introduction to the experimental method. In chemical analysis a boy has first to produce the results on which he must afterwards exercise his reason; he has to reflect on and draw his conclusions from not only what he sees, but what he does. He thus learns never to do anything without knowing why he does it and what result he expects to obtain. Chemistry also has the advantage of giving a first insight into the practical applications of mathematics. That indeed is the part of the subject which the majority of boys find most difficult. It is rare to find a boy who will readily work out arithmetically even a simple reaction. In the only possible rival to chemistry—physics—the simpler phenomena are much less varied and interesting, the bond of union between them is less apparent, the reasoning from effect to cause less patent, and there are comparatively few experiments which a child could perform for itself. Physics form an admirable lecture subject, but even then the necessary mathematical reasoning is far beyond the capacity of an average boy of twelve. Such subjects as geology and astronomy may be made most interesting, and a great deal may be done by directing children's attention to the physical actions going on in the world around them, but they are what, from a schoolmaster's point of view, I should call informational rather than educational sciences, their phenomena are generally too vast for a child's mind really to exercise itself upon them.

It will have been noticed that in no case are we able to give to science the full six hours per week recommended by the Commissioners. I would gladly do so, but do not think that it would be possible unless the standard for the classical entrance scholarships at the public schools, which of necessity fixes that of the first class at private schools, were lower than it is now, and although the entrance scholarships have raised this standard considerably above what it was only a few years ago, yet I do not think that it would be desirable to lower it, at least in translation and grammar. In composition, and especially in verse composition, I think it is a matter for consideration whether classical scholarship really benefits by expecting so much from very young boys; whether they would not learn to appreciate the delicacies of style more quickly and thoroughly if they did not spend so much time over artificial composition before they have gained that natural facility of expressing their thoughts in their own tongue which only practice and varied reading can give; and whether therefore some part of the time now given to that subject might not, in many cases at least, be more usefully employed on other subjects, such as science and English composition, or perhaps drawing, in which boys naturally take a keen interest, and which certainly tend to give breadth of view and largeness of mind, and what is equally important, "a ready wit." Even in translation boys fail much oftener from want of knowledge of English than from want of power to construe. At present the number of entrance scholarships in which science counts for anything is so small that they may be disregarded, and certainly nothing could be less desirable for the interests of science itself, or more productive of "cram," than for scholarships to be given to boys in science alone. Would it not, however, be possible for the classical composition standard to be lowered in a considerable number of scholarships, and for one-third or one-half of the marks in them to be given to science, including practical work? The remaining scholarships might keep to their present standard in every respect, a standard which is certainly not at all too high for boys who possess real literary power, and possibly not for average boys who do not seem to possess any special bias either towards the literary or the scientific side. A plan of this sort would avoid giving that encouragement to "modern sides" which would be given by special science scholarships, and that would be an advantage, for any bifurcating arrangement is always practically very difficult to work, and has never yet produced a satisfactory result either in science or in classics.

The Commissioners are, I believe, in the right in thinking that education should be brought under the great law of progress from the more general to the special, and that it will be quite soon enough for any ordinary student to begin to concentrate all his energies on that particular line of study which is likely to prove the most valuable to him in his future career, when he has entered the university, and ought therefore to be of such an age and discretion as to be able to decide for himself what will be the probable course of his future life. From this opinion it is true that Prof. Stokes dissents, on the ground that "a wider discretion should be left to the governing bodies or head masters as to the degree to which what has been called 'stratification' of studies should be carried out." Now I am convinced, not only from theory, but from practical experience, that though stratification is undoubtedly the right course for an adult to pursue, yet that the advocates of that system do not make sufficient allowance for the intense love of novelty innate in a child, nor for the incapacity of a brain not fully developed of sustained application to any one subject. We have been led here, little by little, to diminish the length of the lessons in every subject until now scarcely any lesson exceeds half, or at the most three-quarters, of an hour in length; and the masters all agree in saying that with fairly intelligent boys they can get quite as much work done in the shorter time as in the longer. No boy can fix his attention on one subject for long together, and the moment it flags he might just as well be out in the playground as in the school-room. But if, before he has got weary of one subject, another which interests him is brought before him, he will turn to it with as much zest as if he were just beginning work. It has more than once happened that a boy in this school has needed to give special attention to certain subjects. Formerly I used to take such a boy out of his less important classes, in order that he might give extra time to his special subject. But in no case have we found that such a boy at the end of the term has made any

sensible progress beyond his fellows who had continued doing their ordinary more varied work. Though some part of this might be owing to his being outside the regular classes, yet by far the greater part was due to the monotonous work palling upon him and dulling his brain.

The education of young children should be made like their picture-books. The pictures should be such as will induce the little learner to read and study the letterpress in order to find out more about them, and for that purpose they can scarcely be too numerous. A boy when his mind first opens to the world around him is like a man in a large strange house. He must needs go about and learn the arrangement of the building, peer into every room, examine the varied prospect from every window, before he can decide which rooms he will make his own; but when once he has made his choice, he will probably keep to one or two rooms and seldom enter the others.*

G. HERBERT WEST

Ascham House School, Bournemouth

THE THEORY OF "STREAM LINES" IN RELATION TO THE RESISTANCE OF SHIPS†

THE address of the President of a Section would year by year possess an appropriate interest, if it could always consist of an exposition of the progress made during the past year in the department of science which the Section embraces. And many of the addresses to this and other sections have conformed to this pattern with marked success.

But the adequate preparation of an address shaped in this approved mould would require a range of experience and a grasp of thought such as few possess; and custom has wisely sanctioned a type of address which, though less appropriate to the occasion, need not be either uninteresting or inapposite. And we, in this Section, have not to search far for instances in which its President has charmed and instructed us by a masterful exposition of some single subject in practical science, or by a timely reminder of the improvident manner in which we deal with some precious store of natural wealth.

I must express a hope that it will not be regarded as a conversion of liberty into license, if the subject I have chosen obliges me to introduce a further innovation, and to use diagrams and experiments in order to make my meaning clear.

I propose to treat of certain of the fundamental principles which govern the behaviour of fluid, and this with special reference to the resistance of ships. By the term "resistance" I mean the opposing force which a ship experiences in its progress through the water.

Considering the immense aggregate amount of power expended in the propulsion of ships, or, in other words, in overcoming the resistance of ships, I trust you will look favourably on an attempt to elucidate the causes of this resistance. It is true that improved results in ship-building have been obtained through accumulated experience; but it unfortunately happens that many of the theories by which this experience is commonly interpreted, are interwoven with fundamental fallacies, which, passing for principles, lead to mischievous results when again applied beyond the limits of actual experience.

The resistance experienced by ships is but a branch of the general question of the forces which act on a body moving through a fluid, and has within a comparatively recent period been placed in an entirely new light by what is commonly called the theory of stream-lines.

The theory as a whole involves mathematics of the highest order, reaching alike beyond my ken and my purpose; but I believe that, so far as it concerns the resistance of ships, it can be sufficiently understood without the help of technical mathematics; and I will endeavour to explain the course which I have myself found most conducive to its easy apprehension.

It is convenient to consider first the case of a completely submerged body moving in a straight line with uniform speed through an unlimited ocean of fluid. A fish in deep water, a submarine motive torpedo, a sounding lead while descending through the water, if moving at uniform speed, are all examples of the case I am dealing with.

It is a common but erroneous belief that a body thus moving experiences resistance to its onward motion by an increase of pressure on its head end, and a diminution of pressure on its tail end. It is thus supposed that the entire head end of the body has to keep on exerting pressure to drive the fluid out of the way, to force a passage for the body, and that the entire tail end has to keep on exerting a kind of suction on the fluid to induce it to close in again—that there is, in fact, what is termed *plus* pressure throughout the head end of the body, and *minus* pressure or partial vacuum throughout the tail end.

This is not so; the resistance to the progress of the body is not due to these causes. The theory of stream-lines discloses to us the startling but true proposition, that a submerged body, if moving at a uniform speed through a perfect fluid, would encounter no resistance whatever. By a perfect fluid, I mean a fluid which is free from viscosity, or quasi-solidity, and in which no friction is caused by the sliding of the particles of the fluid past one another, or past the surface of the body.

The property which I describe as "quasi-solidity" must not be confused with that which persons have in their minds when they use the term "solid water." When people in this sense speak of water as being "solid," they refer to the *sensation* of solidity experienced on striking the water-surface with the hand, or to the reaction encountered by an oar-blade or propeller. What I mean by "quasi-solidity" is the sort of stiffness which is conspicuous in tar or liquid mud; and this property undoubtedly exists in water, though in a very small degree. But the sensation of solid reaction which is encountered by the hand or the oar-blade, is not in any way due to this property, but to the *inertia* of the water: it is in effect this inertia which is erroneously termed solidity; and this inertia is possessed by the perfect fluid, with which we are going to deal, as fully as by water. Nevertheless it is true, as I am presently going to show you, that the perfect fluid would offer no resistance to a submerged body moving through it at a steady speed. It will be seen that the apparent contradiction in terms which I have just advanced is cleared up by the circumstance, that in the one case we are dealing with steady motion, and in the other case with the initiation or growth of motion.

In the case of a completely submerged body in the midst of an ocean of perfect fluid, unlimited in every direction, I need hardly argue that it is immaterial whether we consider the body as moving uniformly through the ocean of fluid, or the ocean of fluid as moving uniformly past the body.

The proposition that the motion of a body through a perfect fluid is unresisted, or, what is the same thing, that the motion of a perfect fluid past a body has no tendency to push it in the direction in which the fluid is flowing, is a novel one to many persons: and to such it must seem extremely startling. It arises from a general principle of fluid motion, which I shall presently put before you in detail—namely, that to cause a perfect fluid to change its condition of flow in any manner whatever, and ultimately to return to its original condition of flow, does not require, nay, does not admit of, the expenditure of any power, whether the fluid be caused to flow in a curved path, as it must do in order to get round a stationary body which stands in its way, or to flow with altered speed, as it must do in order to get through the local contraction of channel which the presence of the stationary body practically creates. Power, it may indeed be said, is first expended, and force exerted to communicate certain motions to the fluid; but that same power will ultimately be given back, and the force counterbalanced, when the fluid yields up the motion which has been communicated to it, and returns to its original condition.

I shall commence by illustrating the action on a small scale by fluid flowing through variously shaped pipes; and I must premise that in the greater part of what I shall have to say, I shall not require to take account of absolute hydrostatic pressures. The flow of water through pipes is uninfluenced by the absolute pressure of the water.

I will begin with a very simple case, which I will treat in some detail, and which will serve to show the nature of the argument I am about to submit to you.

Suppose a rigid pipe of uniform sectional area, of the form shown in Fig. 1, something like the form of the water-line of a vessel.

The portions AB, BC, CD, DE are supposed to be equal in length, and of the same curvature, the pipe terminating at E in exactly the same straight line in which it commenced at A, so

* My experience has been entirely with boys, but I feel sure that elementary science might be taught with at least equal advantage to little girls.

† Address to the Mechanical Section of the British Association, Bristol, August 25, 1875; by William Froude, C.E., M.A., F.R.S. President of the Section. Revised and extended by the author.

that its figure is perfectly symmetric on either side of C, the middle point of its length.

Let us now assume that the pipe has a stream of perfect fluid

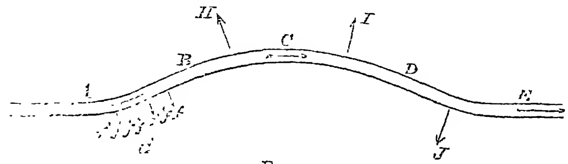

Fig. 1.

running through it from A towards E, and that the pipe is free to move bodily endways.

It is not unnatural to assume at first sight that the tendency of the fluid would be to push the pipe forward, in virtue of the opposing surfaces offered by the bends in it—that both the divergence between A and C from the original line at A, and the return between C and E to that line at E, would place parts of the interior surface of the pipe in some manner in opposition to the stream or flow, and that the flow thus obstructed would drive the pipe forward; but if we endeavour to build up these supposed causes in detail, we find the reasoning to be illusory.

I will now trace the results which can be established by correct reasoning.

The surface being assumed to be smooth, the fluid, being a perfect fluid, can exercise no drag by friction or otherwise on the side of the pipe in the direction of its length, and in fact can exercise no force on the side of the pipe, except at right angles to it. Now the fluid flowing round the curve from A to B will, no doubt, have to be deflected from its course, and, by what is commonly known as centrifugal action, will press against the outer side of the curve, and this with a determinable force. The magnitude and direction of this force at each portion of the curve of the pipe between A and B are represented by the small arrows marked *f*; and the aggregate of these forces between A and B is represented by the larger arrow marked G. In the same way the forces acting on the parts B C, C D, and D E are indicated by the arrows H, I, and J; and as the conditions under which the fluid passes along each of the successive parts of the pipe are precisely alike, it follows that the four forces are exactly equal, and, as shown by the arrows in the diagram, they exactly neutralise one another in virtue of their respective directions; and therefore the whole pipe from A to E, considered as a rigid single structure, is subject to no disturbing force by reason of the fluid running through it.

Though this conclusion that the pipe is not pushed endways may appear on reflection so obvious as to have scarcely needed elaborate proof, I hope that it has not seemed needless, even though tedious, to follow somewhat in detail the forces that act, and which are, under the assumed conditions, the *only* forces that act, on a symmetrical pipe such as I have supposed.

Having shown that in the case of this special symmetrically curved pipe the flow of a perfect fluid through it does not tend to push it endways, I will now proceed to show that this is also the case whatever may be the outline of the pipe, provided that its beginning and end are in the same straight line.

Assume a pipe bent, and its ends joined so as to form a complete circular ring, and the fluid within it running with velocity round the circle. This fluid, by centrifugal force, exercises a uniform outward pressure on every part of the uniform curve; and this is the only force the fluid can exert. This pressure tends to tear the ring asunder, and causes a uniform longitudinal tension on each part of the ring, in the same manner as the pressure within a cylindrical boiler makes a uniform tension on the shell of the boiler.

Now, in the case of fluid running round within rings of various diameter, just as in the case of railway trains running round curves of various diameter, if the velocity along the curve remain the same, the outward pressure on each part of the circumference is less, in proportion as the diameter becomes greater; but the circumferential tension of the pipe is in direct proportion to the pressure and to the diameter; and since the pressure has been shown to be inversely as the diameter, the tension for a given velocity will be the same, whatever be the diameter.

Thus, if we take a ring of doubled diameter, if the velocity is unchanged, the outward pressure per lineal inch will be halved; but this halved pressure, acting with the doubled diameter, will give the same circumferential tension.

Now this longitudinal tension is the same at every part of the ring; and if we cut out a piece of the ring, and supply the longitudinal tension at the ends of the piece, by attaching two straight pipes to it tangentially (see Fig. 2), and if we maintain the flow of the fluid through it, the curved portion of the pipe will be under just the same strains as when it formed part of the com-

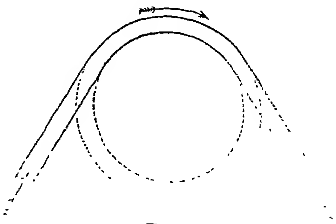

Fig. 2.

plete ring. It will be subject merely to a longitudinal tension; and if the pipe thus formed be flexible, and fastened at the ends, the flow of fluid through it will not tend to disturb it in any way. Whatever be the diameter of the ring out of which the piece is assumed to be cut, and whatever be the length of the segment cut out of it, we have seen that the longitudinal tension will be the same if the fluid be moving at the same velocity; so that, if we piece together any number of such bends of any lengths and any curvatures to form a pipe of any shape, such pipe, if flexible and fastened at the ends (see Fig. 3), will not be disturbed by the

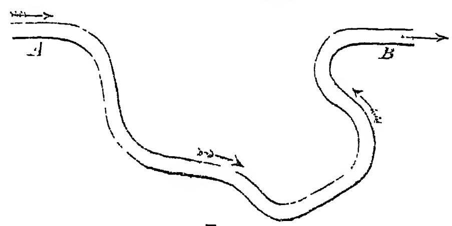

Fig. 3.

flow of fluid through it; and the equilibrium of each portion and of the whole of the combined pipe will be satisfied by a uniform tension along it.

Further, if the two ends of the pipe are in the same straight line, pointing away from one another (see Fig. 4), since the

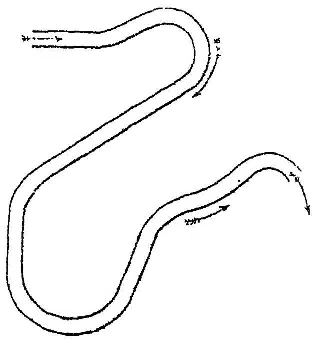

Fig. 4.

tensions on the ends of the pipe are equal and opposite, the flow of the fluid through it does not tend to push it bodily endways.*

This is the point which it was my object to prove; but in the course of this proof there has incidentally appeared the further proposition, that a flexible tortuous pipe, if fastened at the ends, will not tend to be disturbed in any way by the flow of fluid through it. This proposition may to some persons seem at first sight to be so paradoxical as to cast some doubt on the validity of the reasoning which has been used; but the proposition is nevertheless true, as can be proved by a closely analogous experiment, as follows:—

Imagine the ends of the flexible tortuous pipe to be joined so as to form a closed figure (see Fig. 5), there will then be no need for the imaginary fastenings at the ends, since each end will

* See Supplementary Note A.

supply the fastening to the other. Then substitute for the fluid flowing round the circuit of the pipe, a flexible chain, running in the same path. In this case the centrifugal forces of the chain running in its curved path are similar to those of the fluid flow-

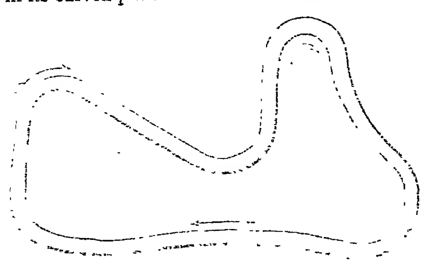

FIG. 5.

ing in the pipe; and the longitudinal tension of the chain represents in every particular the longitudinal tension on the pipe.

As a simple form of this experiment, if a chain be set rotating at a very high velocity over a pulley in the manner shown in Fig 6, it will be seen that the centrifugal forces do not tend to disturb the path of the running chain; and, indeed, the velocity being extremely great, the forces, in fact, tend to preserve the path of the chain in opposition to any disturbing cause. On the

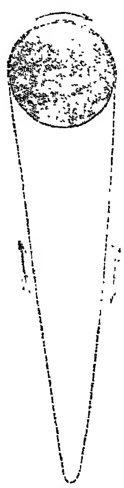

FIG. 6.

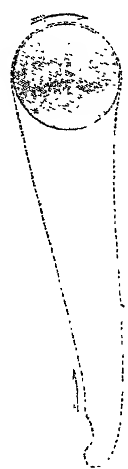

FIG. 7.

other hand, if by sufficient force we disturb it from its path, it tends to retain the new figure which has been thus imposed upon it (see Fig. 7).

The apparatus with which I am about to verify this proposition has been lent to me by Sir W. Thomson. It is one which he has used on many occasions for the same purpose; and I must add that the proposition in his hands has formed the basis of conclusions incomparably deeper and more important than those to which I am now directing your attention.

You observe the chain when at rest hangs in the ordinary catenary form, from a large pulley with a very wide-mouthed groove and mounted in a frame which is secured to the ceiling. By a simple arrangement of multiplying bands the pulley is driven at a high speed, carrying the chain round by the frictional adhesion of its upper semi-circumference. When at its highest speed the chain travels about 40 per second.

The idea that the chain when thus put in motion will be disturbed by its centrifugal force from the shape it holds while at rest must point to one of two conclusions; either (1) the chain will tend to open out into a complete circle, or (2) it will on the contrary tend to stretch itself at its lower bend to a curvature of infinite sharpness.

But you observe that no tendency to either change of form appears. On the contrary, the chain, instead of taking spontaneously any new form in virtue of its centrifugal force, has plainly assumed a condition under which it is with difficulty disturbed, alike from its existing form, or from any other which I communicate to it by violently striking it. Such blows locally indent it almost as they would bend a bar of lead.

In spite, however, of this quasi-rigidity which its velocity has imparted to it, it does, if left to itself, slowly assume, as you perceive, a curious little contortion, both as it approaches and as it recedes from the lower bend of the catenary; and it is both interesting and instructive to trace the cause of the deformation.

I have already explained that the speed of the chain subjects it throughout to longitudinal tension. Speaking quantitatively, the tension is equal to the weight of a length of the chain twice the height due to the velocity. This is $\frac{v^2}{g}$, and thus, as the speed is 40 feet per second, $\frac{1600}{32} = 50$ feet, or with this chain about 14 lbs.

Now in travelling through the lower bend of the catenary, the chain passes from being nearly straight, to being sharply curved and immediately straightened again, and this change of form involves a continued pivoting of link within link, the friction being called into action by the tension which presses the surfaces together. Each link thus in succession resists this pivoting with a definite force, and the resistance, in effect, converts what appears to be a perfectly flexible combination into one possessing a tangible degree of stiffness, and the oblique attitude assumed by the chain as it approaches the bend, and the slight back turn which it assumes as it emerges from the bend, are alike consequences of this factitious stiffness.

For in virtue of gravity, the running chain, like the chain at rest, tends always to maintain the original catenary; and in virtue of its speed of rotation, it seeks to maintain (not preferentially the catenary, but) whatever form it for the moment possesses. Hence its departure from the true catenary was, as you saw, gradual. But when the figure of equilibrium is once attained, the persistency of form imparted by velocity serves to maintain this figure as indifferently as any other. Hence the figure is that in which equilibrium subsists between the force of gravity seeking to restore the catenary, and the factitious stiffness resisting the necessity of bending and unbending.

The slowness with which the form is assumed, and its steady persistency when once assumed, alike bear witness to the truth of the proposition which it is the object of the experiment to verify.

The stream of fluid in the tortuous flexible pipe would behave in a strictly analogous manner.

(To be continued.)

NOTES

It is with great regret that we hear of the death of Dr. von Willemoes-Suhm, the distinguished naturalist assisting Prof. Wyville Thomson in the *Challenger*. Information of the sad occurrence has just been received at the Admiralty.

At the opening meeting of the Royal Geographical Society on Monday, the president, Sir H. Rawlinson, reviewed the progress of the Society and of geographical discovery during the past year. He announced that the Prince of Wales, the Vice-patron of the Society, had just sent the Society, as the first geographical result of his tour in the East, a very interesting collection of route-maps of Upper Egypt and its recently acquired dependencies, which had been executed in the Topographical Department of the Egyptian War Office by General Stone, Chief of the Etat Major, from materials furnished in one direction by Col. Gordon and the officers serving under his orders, and in another by Col. Purdy and the officers of the Darfur Expedition. These maps contain much new geographical matter. The President referred with great satisfaction to Stanley's exploration of the Nyanza, and exhibited a complete chart of the lake drawn by Stanley. As to Col. Gordon, who by last accounts had reached Appudo, 140 miles from the Albert Nyanza, if he could overcome the eight miles of rapids which lay before him, he would probably reach the Albert Nyanza with his steamer the *Khedive*, before Stanley. Both Gordon and his assistant Chipendall report, from native information, that the Nile leaves the Albert Nyanza by two channels. Dr. Pogge and Dr. Lasaulx, the only remaining members of the German African

expedition, have shifted their ground to the south, with the intention of starting from the Loanda base, and making their way *viâ* Cassange to the mysterious capital of Matiamno. The President then referred to Capt. Trotter's work on the Panjah River, and to the Russian scientific expedition to Hissar, by which we are now able to construct a reliable map of the country between the Upper Oxus and Jaxartes. Sir Henry then spoke of New Guinea, and of the failure of Macleay's expedition. D'Albertis has during the late spring and summer been occupied in natural history researches on Yule Island, while the Rev. S. Macfarlane and Mr. Stone have discovered and ascended for a distance of sixty miles a large river on the south coast of New Guinea. The river is from one to a quarter mile broad, and from three to twelve fathoms deep, and might easily be made navigable for more than 100 miles. It is proposed to call it the Baxter River. At the close of his address, the President observed that at the next meeting the subject of the Victoria Nyanza will be fully gone into, and that the discussion on that subject had better therefore be reserved until that occasion. Mr. W. L. Watts afterwards read a paper on his journey last summer across the Vatna Jökull, Iceland.

THE *Daily Telegraph* of Monday contains Mr. Stanley's letter which was sent home by the unfortunate Col. Linant de Bellefonds. It is dated "Mtesa's Capital, Uganda, April 12," and is principally occupied with an account of Mr. Stanley's voyage round the southern, eastern, and north-eastern shores of the Victoria Nyanza. His exploration has evidently been made with great care, and he has ascertained with considerable certainty that Speke was right in regarding the Nyanza as only one lake. It is, however, evidently thickly studded with islands, and its coast much broken up into bays and creeks by long promontories from the land. Stanley was most hospitably received and magnificently entertained by Mtesa, who, since Speke saw him, has, with his people, turned Mahommedan. Stanley speaks of him with the greatest respect, and believes that he might be made a most effective instrument for the civilisation of the region surrounding his capital. The *Telegraph* of Tuesday contains Mr. Stanley's map of the Nyanza, neatly reproduced.

MR. JAMES STUART, Fellow of Trinity College, has been elected Professor of Mechanism and Applied Mechanics at Cambridge University.

WE understand that the Council of the Scottish Meteorological Society have resolved to commence an investigation into the habits of the salmon. The point which is first to be investigated is the question of the earliness or lateness of the different rivers, and for this purpose they have entered into communication with Mr. Archibald Young, Fishery Commissioner, at whose suggestion various early and late rivers have been selected, and arrangements have already now been made for carrying on the necessary observations on the river Ugie, Aberdeenshire.

WE have received six large temperature and rain charts of the United States, constructed by Mr. Charles A. Schott from observations collected by the Smithsonian Institution, which show by lines the distribution of temperature for every 4° from 36° to 76°, and of rainfall for every two or four inches during summer, winter, and the year. The principle on which the temperature charts have been constructed, and which was fully described in NATURE in reviewing the annual chart in the small form in which it was first published, consists in representing actual mean temperatures, uncorrected for elevation. The whole form a set of six charts illustrative of the most prominent features of the climatology of the United States, and are calculated to prove of great utility in many practical matters.

THE Report of the Commission appointed by the Prussian Government for the scientific investigation of the Baltic and North Sea, for 1872 and 1873, has just been published. The Report (pp. 380), which is a very valuable one and well illustrated, contains discussions on the fisheries of the German coasts, by Dr. V. Hensen; and on the physical observations made at the various stations of the Commission, by Dr. G. Karsten; together with interesting papers by Dr. H. A. Meyer, Dr. P. Magnus, Dr. K. Möbius, and others, on the currents, temperature, and specific gravity of the sea, and on the botanical and geological results of the expedition which was undertaken during the summer of 1872 with the view of collecting data bearing on the physics, chemistry, and biology of the North Sea. We hope to examine this at length in an early number.

DR. BURMEISTER, Director of the National Museum of Buenos Ayres, has in course of preparation a complete scientific description of the Argentine Republic. The first volume, containing the history and geography, is already in the press. The second, containing the meteorology, physical geography, and biology, is in preparation. The work is in German, but the Argentine Government has undertaken a French translation of it.

DR. BURMEISTER has also nearly ready a description of a complete skeleton of the Fossil Horse of Buenos Ayres (*Hippidium neogaeum*, Owen), of which but fragmentary portions have been previously known.

AN important work on the Zoology of Eastern Asia will appear in Russia before the close of the current year. It will comprise the results of the journey undertaken by Colonel Przevalski in Western China, and it will include descriptions of many new and interesting species. It is not improbable that a translation will be published in English.

WE would draw the attention of our biological readers to Mr. G. E. Dobson's valuable Conspectus of the sub-order, families, and genera of Cheiroptera, arranged according to their natural affinities, in the "Annals and Magazine of Natural History" for this month.

WE have received Prof. Cope's systematic catalogue of Vertebrata of the Eocene of New Mexico collected in 1874, containing the account of forty-seven species, of which twenty-four are described for the first time. The genera *Bathmodon* and *Uintatherium* are placed in a new order—Amblipoda—by themselves, and the foot of the former is figured, with three phalanges to the hallux, which is evidently inaccurate.

WE have also received a paper by Prof. O. C. Marsh, on the *Odontornithes*, or birds with teeth, containing illustrations of parts of *Ichthyornis dispar* and *Hesperornis regalis*.

MR. W. H. DALL, of the U. S. Coast Survey, has published the results of his examination of Mount Saint Elias, Mount Fairweather, and other peaks of the range which skirts the coast of the narrow strip in the south of Alaska; Mount St. Elias, however, really seems to be in British territory. Very various heights have been given to the latter from La Pérouse downwards, varying from 12,600 to 17,800 feet, the British Admiralty Chart making it 14,970 feet. Mr. Dall, from many careful observations, gives the height as 19,500 feet, with a possible error either way of 400 feet. Mount Fairweather he gives as 15,500 feet; Mount Crillon, 15,900 feet, with possible error of 500 feet; Mount Cook, 16,000 feet; Mount Vancouver, 13,100 feet; and Mount La Pérouse, 11,300 feet, the last three being approximate. The names of Cook and Vancouver have been given by Mr. Dall to two high peaks of the St. Elias range to the southward and eastward of St. Elias; to a high peak near the sea, at Icy Cape, he has given the name of La Pérouse; Mount Crillon is to the south of Mount Fairweather. The following are the geological conclusions at which Mr. Dall arrives with regard to this range:—That these Alps are, like the high Sierra of California, mainly composed of crystalline rocks, and in their

topography, their small, pustular, basaltic vents, their associated marbles, quartzites, and later conglomerates, exhibit a close parallel to the Sierras; that parallelism in structure and composition implies parallelism in age and method of formation; and, finally, that the volcanic origin of the high peaks is opposed not only by analogy, but by the known facts." An examination of the clear sketches certainly seems to bear out Mr. Dall's conclusion that these peaks are not of the volcanic type.

LONDON has at last come in for her share of the disasters by flooding which have devastated so many river valleys in England and on the Continent. An unprecedentedly high tide caused the Thames to overflow its banks on the south side very early on Monday morning, flooding the streets and houses of Lambeth and other low-lying districts all along that side of the river, from Woolwich even to Kingston, we believe. The damage caused has been very serious and extensive, several feet of water rushing at one time through many streets on the south side, even at a considerable distance from the river. No one seems to have expected an unusual tide, though in March last year a similar phenomenon was looked for; the tide then, however, was seven inches lower than that of Monday. It is supposed that a very high spring tide with a strong gale blowing is the cause of the disaster.

THE force of the last hurricane in Paris was so great that its maximum could not be measured at the Montsouris Observatory, the magnetic anemometer having been broken by the rush of wind. The rate measured by Robinson's cups exceeded 70 kilometres per hour, when the apparatus was put out of order by the excess of central force.

MR. WILLIAM SANDERS, a well-known geologist in the West of England, died on Friday at his residence at Clifton, aged 76.

A COURSE of twelve lectures, by Mr. E. Bellamy, on the Anatomy of the Human Form, commenced last Monday, in connection with the National Art Training School, South Kensington. There are to be twelve lectures in all, to be delivered on Monday evenings.

WITH reference to the subject of the use of the movements of the sea as motive powers, referred to in NATURE, vol. xii. p. 212, Señor Don Eduardo Benot writes that the subject has been a study with him for many years, and he will be pleased to correspond with anyone who may wish to obtain information on the subject. Señor Benot's address is Barquillo 5, Madrid, Spain.

ACCORDING to a report presented by Count Hallez d'Arros to the Managing Committee, the Exhibition of Electrical Appliances, to be held at Paris in 1877, will be divided into the following groups:—1. History of Electricity; 2. Apparatus for Demonstration; 3. Piles and Batteries; 4. Electro-magnetism; 5. The Electric Telegraph; 6. The Electric Light; 7. Electric Motors; 8. Electrotyping; 9. Therapeutic Electricity.

A CORRESPONDENT at Belfast has sent us specimens of the caterpillar of *Arctia caja*, telling us at the same time that during this season, in which they have been particularly numerous, he has noticed that they have done much injury to textile fabrics laid on grass to bleach, by perforating them in circular holes, specially during sunshine after rain. The holes they make vary in size, some being very small, others large enough to admit the body of the animal. They are usually in clusters, and each is generally surrounded by a greenish coloured matter, apparently ejected by the caterpillar. This habit of *Arctia caja* is quite new to entomologists.

WE have received in a separate form, reprinted from the report of Major J. W. Powell's Explorations of the Colorado River of the West and its tributaries, a lengthy paper by Dr. Elliott Coues on the North American cheek-pouched rodent genera *Geomys* and *Thomomys*. The number of species of the former is given as five; of the latter two, of which one, *T. clausius*, is new, and is figured life size.

THE French Minister of Marine is establishing at the Depot of Maps, a new office for meteorology, which will be in some respects in connection with the Meteorological Office of the National Observatory. It will be placed under the control of Capt. Mouchez.

THE numerous reports as to the occurrence of a remarkable marine animal on the coast of New England during the past summer have induced the Boston Society of Natural History to prepare and distribute a circular calling for information on the subject.

IN a Congregation held at Oxford on Nov. 10, Prof. Bartholomew Price, Warren De la Rue, D.C.L., John Dale, M.A., and William Esson, M.A., were duly appointed visitors of the University Observatory. This is the first appointment of such visitors. The Observatory, which has been lately completed, took its rise, as our readers know, in the munificence of Dr. De la Rue.

MR. GEORGE SMITH, of the British Museum, left London last week for the East, to resume his researches in Assyria. He will be absent six months.

MESSRS. W. and A. K. Johnston have published a very clear map of India, to illustrate the travels of the Prince of Wales. It is on the satisfactory scale of seventeen miles to an inch, is fairly full but not too crowded with names, and has the proposed route of his Royal Highness clearly shown. Of course the route is liable to be altered, but anyone will be able to follow the Prince in the map without effort. Side by side with the principal map is a neat map of England on the same scale, showing at once the comparative sizes, and the fact that our country is only about twice the size of Ceylon. There is also a map of part of Europe, Asia, and Africa, showing the route from England to India. The blue surface of the wide Bay of Bengal has been utilised for a number of useful statistics concerning India. Anyone interested in following the Prince's route will find this map of great service.

THE success of the geographical play "Round the World in Eighty Days" has encouraged another Paris theatre to try an astronomical drama under the title of "Travels in the Moon." But the only astronomical part of the performance is a large moon which is exhibited in front of the theatre, showing to an admiring crowd the principal features of Beer and Madler's well-known lunar map.

CAPTAIN SOUTER, of the *Intrepid*, from the Davis Straits whale fishing, reports that while anchored in Isabella Bay on the 13th August he found it necessary, in consequence of the great body of ice coming down, to proceed on shore. After sailing some distance he came into a fine commodious natural harbour, not marked in the charts. There was nothing to show that it had ever been entered before. Captain Souter and other officers left in a cairn a writing indicating the discovery. Splendid water was found.

THE additions to the Zoological Society's Gardens during the past week include a Beisa Antelope (*Oryx beisa*) from Central Africa, presented by the Seyyid Burgash of Zanzibar; two Central American Agoutis (*Dasyprocta punctata*) from Central America, presented by Capt. E. Hairby and Mr. W. J. Henderson respectively; a Grey Ichneumon (*Herpestes griseus*), from India, presented by Mr. John Jennings; a Spotted Ichneumon (*Herpestes auropunctatus*) from Nepal, presented by Mr. L. B. Lewis; a Plantain Squirrel (*Sciurus plantani*) from Java, presented by Master E. H. Cole; a Malbrouck Monkey (*Cercopithecus cynosurus*) from E. Africa, presented by Mr. C. L. Norris Newman; a Dufresne's Amazon (*Chrysotis dufresniana*) from S. E. Brazil, presented by the Rev. A. Hibbet; a Mona Monkey (*Cercopithecus mona*), a Campbell's Monkey (*Cercopithecus campbelli*) from W. Africa, deposited.

THIRD REPORT OF THE SETTLE CAVE COMMITTEE (VICTORIA CAVE)*

WORK has been carried on almost uninterruptedly throughout the year (except from March 20th to May 20th, when it was stopped for want of funds), at a cost of 175*l.* 12*s.* 7*d.* Of this, 80*l.* 11*s.* 9*d.* was a balance in hand, 50*l.* the British Association grant, and 45*l.* 0*s.* 10*d.* raised by private subscription.

Great progress has been made in the past year in uncovering the glacial deposits at the entrance of the cave, and showing their relation to the older bone-beds containing the remains of man with the extinct animals. The boulders are seen to cover an area of at least 1,200 square feet.† They are of all sizes, and consist of dark and white Carboniferous Limestone, and the basement bed of that formation, Carboniferous Gritstone, and Silurian Grit. Some have travelled at least two miles, and others greater distances. They are various in size, from mere sand-grains to blocks several tons in weight. An interesting section was displayed, showing the passage of the boulder-beds in one part from a regular till with large scratched stones, through scratched gravel, sand, to laminated clay, and these were so interbedded as to demonstrate that some at least of the laminated clay is of glacial age and origin.

At length, after six years' work, we are able to say that we have reached the floor of the cave at the entrance. Several pinnacles of rock have been found by the removal of the boulders; they run in lines parallel with the joints of the rock above, and give testimony to the cave having been at some time occupied by a stream, similar rock-weathering occurring in other water-caves in Craven. The arched niches on the right of the cave at the entrance lead to the same conclusion.

And now, with the additional evidence of another year's diggings, we may again consider the question, the most interesting perhaps of all the problems before us: Are the glacial deposits which rest upon the older bone-beds, containing the extinct mammals and man, in the position which they occupied at the close of the glacial conditions, or have they subsequently fallen into their present site? We may again urge the reasons given last year (see Second Report), strengthened by enlarged sections and a wider experience, which go to prove the first alternative. To these arguments we may now add the following:—That the extent of the glacial deposits now exposed is so great that it is impossible that they can be a mere chance accumulation of boulders which have been re-deposited in their present position since glacial times. This being the case, it is clear from the position of the boulders beneath all the screes, that they are a portion of the general glacial covering of the valleys and hill-sides which was left by the ice-sheet at the time of its disappearance.

These are the main arguments to be derived from the cave itself, but further strong presumptive evidence, that the Pleistocene fauna lived in the North of England before the ice-sheet, exists as follows:—The older fauna once lived in this district, a point which admits of no dispute from its existence in the Victoria Cave, in Kirkdale Cave, Raygill Cave in Lothersdale, and perhaps in other caves. But their bones are now found nowhere in the open country. None of the river-gravels contain them; and just that district which is conspicuous by their absence, is also remarkable for the strongest evidences of great glaciation. Putting these facts together, the probability is very strong that it was glaciation that destroyed their remains in the open country. To suppose that these have been destroyed by other sub-aërial agencies, would be to ignore the fact that in the South of England and other non-glaciated areas, such remains exist both in the caves and river-gravels.

A few bones were found lying upon the boulders beneath the talus. They have been determined where possible by Prof. Busk, but they are only fragmentary and not of much interest; they were probably washed out of the Lower Cave-earth when it was exposed above the edge of the boulders. No fragments of bone were found throughout the 19 feet of talus which lies between the base of the Neolithic layer and the top of the boulders.

Work in Chamber D.—A considerable amount of work has been done in excavating this chamber which leads off from the principal entrance towards the right. It was choked to the roof over the greater part of its extent, with clay and limestone blocks. It is now 110 feet long, 20 feet wide, and 20 feet high at the entrance. Two galleries lead off from it on the right. One, the Birkbeck Gallery, is made easily accessible for a distance of 44 feet, in a N E. direction. Here it becomes very narrow and leads to a narrow chasm 20 feet deep. The other gallery is blocked at the entrance with stalagmite.

A magnificent series of bones was found in Chamber D. They were all carefully registered as to their position by Mr. Jackson. The Committee are much indebted to Prof. Busk for his kindness in determining them. He says: "They are a remarkably interesting collection, especially in the Bears, and I think the larger of the two skulls is by far the finest specimen of the kind yet found in this country."

"Out of about 269 specimens including detached teeth,

127 belonged to	Bear	
37 ,, ,,	Hyæna	
36 ,, ,,	Bos	
24 ,, ,,	Fox	
22 ,, ,,	Deer	15 Red Deer, 7 Reindeer
10 ,, ,,	Rhinoceros	
2 ,, ,,	Horse	
1 ,, ,,	Badger."	

To these we may add 1 of Pig, 2 of Elephant, and 1 of Hippopotamus. The Rhinoceros is *hemitœchus*, the Elephant *antiquus*, and the Hippopotamus, a portion of a tusk, is the only specimen of that animal found in the course of six years' digging. The careful registration of the remains has enabled your reporter to construct a section showing the distribution of the different animals throughout the different portions of the deposit. It is too bulky for publication, but the result may be given in words. The bones group themselves along two horizons separated by a greater or less thickness of laminated clay, cave-earth, and stalagmite. The lower extends from the back of the boulder-beds at the cave mouth, is continuous with that which contained the human fibula, and runs continuously as far as Parallel 42. The upper bed commences only at Parallel 15, close against the roof, and continues to Parallel 43. Where the upper bed commences, the two horizons are about twelve feet apart, but they gradually approach other, and at Parallel 35 not only touch, but seem to be somewhat commingled.

From this section we find that the following species are—

Peculiar to the Upper Bed.	Peculiar to the Lower Bed.	Common to both.
Badger.	Hyæna.	Man.
Horse.	Brown Bear?	Fox.
Pig.	*Elephas antiquus*	Grisly Bear.
Reindeer.	*Rhinoceros hemitœchus.*	Red Deer.
Goat or Sheep.	Hippopotamus.	
	Bos primigenius.	

Brown Bear has previously been found in the upper beds in other parts of the cave. The upper bed probably contains remains from the Reindeer period to the present, those of later date being mixed up with older in the mud at the surface. But as distinguished from the lower bed, the chief characteristics of the upper appear to be the presence of the Reindeer, and the absence of Elephant, Rhinoceros, Hippopotamus, and Hyæna.

In the upper bed the only sign of man's presence consists of the spinous process of a vertebra of a bear which has been hacked apparently by some cutting instrument with a tolerably regular edge. It might have been done with a bronze celt or polished flint axe. It is probable that Chamber D was never the resort of man within the historic period. The soft wet mud of the floor, and the lowness of the roof, render it most unlikely that anyone would take to it, except under the direst necessity, or in the pursuit of science.

In the lower bed again evidence of man's presence is but scanty. At the mouth, and close to where the human fibula was found, we have this year met with a piece of rib apparently nicked by human agency. The nicks appear to have been made by some clumsy instrument drawn backwards and forwards. They are in character totally unlike the square-troughed gnawings of rodents, and the furrows heavily ploughed by the teeth of carnivores.

And now, having restricted ourselves to the hard road of

* Abstract. Read at the Bristol meeting of the British Association, August 1875, by R. H. Tiddeman, M.A., F.G.S.

† The full report will contain two photographic plates giving a general view of the cave and a nearer view of the boulders.

fact, we may, perhaps, in conclusion, be permitted to indulge in a short flight of fancy. Let us endeavour to realise how great is the distance in time which separates the savage of Craven from our own day. We have the history of much of it in the Victoria Cave itself, and we may restore some of the missing pages from the surrounding district.

At the cave, Roman times are separated from our own by sometimes less than one, but not more than two, feet of talus, the chips which time detaches from the cliffs above. The Neolithic age, which antiquaries know was a considerable time before the Roman occupation, is represented by a layer in some places four or five feet beneath the Roman, in others even running into it. Then comes a thickness of 19 feet of talus without a record of any living thing. Judging by the shallowness of the Roman layer, this must represent an enormous interval of time. And this takes us down to the boulders, the inscribed records of the Glacial Period. They must represent a long series of climatal changes, during which the ice was waxing and waning, advancing and melting back over the mouth of the Victoria Cave. This period saw the Reindeer and the Grisly Bear occasionally in possession. Then we have an unconformity, a break in the continuity of the deposits, the boulders lying on the edges of the older beds. Time again! and that time long enough for changes to take place which allowed the district to cool down from a warmth suitable to the Hippopotamus, and become a fitting pasture-ground for the Reindeer. It was in that warm period that the early Craven savage lived and died.

But these are not all the changes which occurred in the North of England since that time. The age of the great submergence represented by the sea beaches of Moel Tryfaen and Macclesfield, and by the Middle-Sands-and-Gravels of Lancashire, has left no record up at the cave. Your reporter is of opinion that the submergence did not attain in that district a greater depth than six or seven hundred feet, and this would still leave the cave 750 feet above the sea, though it would cut up the land into a group of islands. The fact is sufficient for us, the depth is immaterial.

Upon no fact are geologists better agreed than upon the existence of a wide-spread submergence and emergence of land towards the close of the Glacial Period. No tradition is common to more races and religions than that of a great deluge. Where back in the past is the common point whence these two far-travelled, almost parallel rays of truth had their origin? In the opinion of your reporter the Craven savage who lived before the Great Ice-sheet, and *before the Great Submergence*, may form another of the many strong ties which bind together the sciences of Geology and Anthropology.

GERMAN SCIENTIFIC AND MEDICAL ASSOCIATION*

THE following communications were made to the various sections. Of many of these papers our space permits us to give little more than the titles and names of authors :—

Section 1. *Astronomy and Mathematics.*—The laws of comets, by M. von Hauenfels.—On the idea of space, by Prof. Hoppe.—On properties of tetragons between hyperbolas, by Prof. Reitlinger.—On the criteria of maxima and minima in definite integrals, by Prof. Zmurko.—On Voigtländer's newest telescopes, by A. Martin.—On the mathematical series called chains, by Dr. Günther.

Section 2. *Physics and Meteorology.*—The new polariscope of Mach, by Dr. Subic.—The glimmer combination of Reusch and their significance for theoretical optics, by Dr. Sohnke.—The relation between the temperature and the inner friction of gases, by Capt. Obermeyer.—Dr. Prestel showed his climatographical atlas of Germany.—On changes of induction-currents through iron nuclei, by A. Ettingshausen.—On the isogonic lines in Transylvania, by G. Schenzl.—On microscopical photography, by A. Martin.—On the increase of the velocity of evaporation through electricity, by Dr. Reitlinger.—On the temperature of steam given off by solutions of salts, by L. Pfaundler.—Method of representing the various constituents of weather in a short and exact manner, by Dr. Prestel.—The conducting powers of several acids for electricity, by Prof. Kohlrausch.—On mirror observations with minute mirrors, by Prof. Boltzmann.

Section 3. *Chemistry.*—On a new colouring matter, phlorein, by R. Benedict (already pubished in the *Annalen der Chemie*).—R. Böttger proved that Gore's inflammable antimony contains not only chloride of antimony, but also occluded hydrogen, transforming, as it does, ferr*i*cyanide into ferr*o*cyanide of potassium. The same chemist has found glycerine to preserve palladium-hydrogen for three months or longer. The same chemist also showed a new solvent for tri-nitro-cellulose, viz., sodic sulphydrate.—Dr. Schwartz showed the oxidation of ammonia to nitric acid by means of hypermanganate of potassium.—Dr. Meusel proved the transformation of ammonia in water into nitrites to be due to the presence of bacteria, and to be prevented by benzoic, carbolic, or salycilic acids, that kill the bacteria.—A. Mitscherlich showed a new air-thermometer.—A. Butlerow presented observations on the transformation of hydrocarbons CnH_2n into alcohols.—The same chemist has found a phenol $C_{15}H_{24}O$ in the juice of *Cynanchum acutum*.—L. v. Pebal showed new apparatus for disengaging gases, and new thermometers for lecture purposes.—A. Michaelis reported on the continuation of his experiments on aromatic compounds of phosphorus.—H. v. Richter on the action of cyanide of potassium on nitro-compounds, and on the transformation of aromatic amides into bromides.—M. Conrad on dichloro-aceto-acetic ether.—H. Schacherl demonstrated that hydrochloric acid and chlorate of potassium yield hypochlorous acid :—

$$2KClO_3 + 4HCl = 2ClO_2 + 2H_2O + Cl_2 + 2KCl.$$

—E. Urban communicated that phosphoric anhydride transforms allylic alcohol, not into allylene, but marsh-gas.—Prof. Butlerow insisted upon the necessity of introducing dynamical views into the constitution-theory of chemical molecules, and explained his intentions by drawing attention to the various decompositions which both cyanic and hydrocyanic acids offer under different circumstances.—I. Iobst sent a communication on a Bolivian bark *Quina cota*, which is free from quinine, but contains $1\frac{1}{2}$ per cent. of a new crystalline body not yet analysed.

Section 4. *Mineralogy and Geology.*—On a Labyrinthodont found near Brünn, by A. Markowsky.—Geology of the Vienna Waterworks, by F. Karrer.—On minerals enclosed in the volcanic conglomerates of the Swabian Alps, by Prof. Nies.—On the Brown-coal Flora of Styria, by C. von Ettingshausen.—On Baer's law respecting the flowing of rivers of a southern direction, by A. Dunker.—On the influence of plants for diminishing the surface of lakes, by Dr. Senft.—On a fossil resin, Hartit, by Dr. Hofman.—On the magnesites of Styria, by Prof. Rumpf.—On the results of deep borings in the North German Plain, by Dr. Huysser.—On the granites of the mountain-range, Böhmerwald, by Dr. Woldrich.—On earthquakes (trying to demonstrate the action of the moon on subterranean volcanic eruptions), by R. Falb.—On the falling in of abandoned coal-mines in Königshütte (Silesia), by Dr. Serlo.—On eruptive formations in the Fassa-valley and Fleimser-valley, by C. Dölter.—On a discovery lately made near Stuttgart, of eighteen Saurians, partly measuring as much as 0·9 metres in length, by Dr. Karpff.—On corals in Tertiary sediments of Krain, by W. Linhart.

Section 5. *Botany.*—C. von Ettingshausen communicated phyto-palæontological studies in their bearing on the transformation of species; also a paper on the transformation of *Castanea atavia* into *Castanea vesca*.—Dr. Eidam described the development of the sexual organs of Hymenomycetes.—On high pressure in the cells of plants, by Dr. Pfeffer.—On morphology of cryptogamea, by Dr. Prantl.—On the flora of Australia and of the Cape, by C. v. Ettinghausen.—On the sexual life of plants, by E. Strasburger.—On the vegetation of Mount Etna, by G. Strobl.—On Theophrastus as a botanist, by O. Kirchner.—On a monstrous organ in *Marchantia polymorpha*, by Prof. Leitgeb.—On acclimatising *Rheum Ribes* in Vienna, by Prof. Fenzl.—Morphology of mosses (Lebermoose) and application of phenol and essential oil of cloves for botanical preparations, by H. Leitgeb.

Section 6. *Zoology and Comparative Anatomy.*—On the zoological station at Trieste, and on a sponge, *Sycandra raphanus Haeckel*, by F. E. Schulze.—On the genus Myzostomum, by L. Graff.—On the penis of Scolytides and the chewing apparatus of the same genus, by Prof. Lindemann.—On *Ptychoptera contaminata*, by C. Grobben.—On the circulation of molluscs, by Prof. Kollmann.—On the curves described by the legs of insects, by V. Graber.—On noctilucous Dipteræ at the Aral lake-district, by W. Aleuitzin.—On the ear of Heteropodes, by Prof. Claus.—On *Podocoryne carnea*, by C. Grobben.—The typical forms of the skulls of cattle, by Dr. Wilckens.—On the differentiation in certain species of beetles (*Carabus monilis*, *arrogans*, and

* Continued from p. 34.

Ullrichii) produced by climate, by Dr. Kraatz.—On the anatomy of Turbellariæ, by L. Graff.

Section 7. *Anatomy and Physiology.*—On the texture of the cerebrellum of man, by B. Stilling.—On the time necessary for developing muscular currents, by H. Hermann.—On the nervus vagus, by Dr. Steiner.—Application of anilin-red for microscopical objects, by E. Hermann.—Contribution to the physiology of muscles, by Prof. Auerbach.—On Newton's law of temperatures with regard to animal heat, by A. Adamkiewicz.—Prof. Gscheidlen proved that the activity of nerves is connected with oxidising processes.—On the retina of snakes, by Dr. Flesch.

The Sections 8 (*Pathology*), 9 (*Medicine*), 10 (*Surgery*), 11 (*Ophthalmology and Otiatrics*), 12 (*Midwifery*), 13 (*Psychiatrics*), 14 (*Hygiene*), 15 (*Military Surgery*), and 20 (*Diseases of Children*), being devoted to medicine, must be omitted in this report; excepting, however, a paper read in Section 9, by Dr. Knapp, on the Styrian habit of arsenic-eating. The speaker introduced two men, fifty-five and twenty-five years old, who had been in the habit of eating arsenic for years, the former having contracted this habit in 1849, to save himself (in his opinion) from an epidemic of typhus then raging. The other, a farm-servant, applied arsenic to improve the health of cattle, and accustomed himself to its use. They have gradually increased the dose to about 0·5 gram. As_2O_3 or As_2S_3, taken once a week. They swallowed before the eyes of the Section 0·3 gr. of orpiment and 0·5 gr. of arsenious acid respectively. Only strong people seem to adopt this habit, and they do not appear to suffer in health through it. With women it has been known to produce abortus (see also Section 17).

Section 16 "Naturwissenschaftlische Paedagogic" (*on the Teaching of Science in Schools*) was composed of teachers, who discussed the means for teaching and the extent to which science should be taught in schools.

Section 17. *Agricultural Chemistry.*—On estimating atmospheric carbonic acid, by Dr. Fittbogen.—On experiments made in the agricultural station of Proskau on the influence of shearing in increasing the weight of sheep (it being found that shearing increases their appetite), and on the influence of arsenic in fattening animals, by O. Kellner. It appears that arsenic increases the power of digesting fat, and decreases the amount of nitrogen given off in urine, thus assisting materially in the formation of flesh.—On potato-feeding, by Dr. Wolf.—On the specific weight of seeds and on the bearing of analytical results on the physiological value of seeds, by G. Marck.—On fibrous plants and their cultivation in moors for the purpose of paper-making, by H. Stiemer.—On the value of animal protein, by Dr. Wild.—On the proportion of solid and liquid matter in plants in different periods of their vegetation, and on the decrease of salts in water used for watering fields in Westphalia, by Dr. König.—On the solubility of phosphates of lime, and on the treatment of bones with superheated steam, by Dr. Krocker.

Section 18. *Geography and Ethnology.*—Prof. Friesach explained a table destined for mariners to facilitate the finding of the shortest route between two points of the globe.—Dr. V. Zwiedinesk reported on a journey to the Wan Lake (Curdistan).—Von. Hochstaetter showed Mr. Mundy's photographs of New Zealand.—On the course of the Arctic vessel *Tegethof*, by Vice-Admiral Baron Wullerstorff.—On Arctic ice, by Lieut. Weyprecht.—On the project of connecting the Algerian-Tunisian plain (Chotto or Sebkhas) with the Mediterranean, by G. Stache. The author is of opinion that the advantages of this (Capt. Rondaire's) project are not in proportion to its difficulties and costs.—On Dante's views on the advancing and receding of the sea, by W. Schmidt.

Section 19. *Anthropology.*—On prehistorical remains (urns) at Maria-Rast, near Marburg (Styria), by Prof. Müllner. This burial-ground was visited by the Section, as also the field near Leibnitz, where various bronzes have been found, and the tumuli near Purgstall; Count Wurmbrand acting as guide.—The latter reported on burial-grounds in Upper Hungary.—On a burial-ground near Innsbruck, by Dr. Wieser.—On Slavian legends, by Prof. Müllner.—On Keltic remains in Styria, by F. Ferk.—On the cavern of Byci-Scala in Moravia, by H. Wankel.—On diluvial man, by Count Wurmbrand.—On lake-cities (Pfahlbauten) in the moors of Laibach, by Dr. Deschmann.—On prehistorical walls and ditches in Hungary, by Dr. Romer.—On the natural law of the formation of states, by L. Gumplowicz.—On prehistorical measures, by R. v. Luschin.—On Keltic warfare, by Dr. Weiss.

A. OPPENHEIM

SOCIETIES AND ACADEMIES

London

Mathematical Society, Nov. 11.—Prof. Cayley, F.R.S., in the chair.—Prof. Sylvester, F.R.S., gave an account of results arrived at in his communication "on the fifteen young ladies problem and a general mathematical theory of pure syntax." The problem, which was first considered by Mr. Sylvester more than twenty-five years ago, was not at that time published by him: it was then discussed by Prof. Cayley, next proposed by Rev. T. P. Kirkman in the "Lady's and Gentleman's Diary" for 1850: solutions were given in the "Diary" for 1851; but it was not until the year 1862 that an elaborate solution was given by Mr. W. S. B. Woolhouse in the volume for that year. The problem may be enunciated as follows:—"In a school of fifteen girls, a rule has been laid down that they shall walk out every day in rows of threes, but that the same two girls shall never come together twice in the same row. The rule is supposed to have been carried ont correctly during the six working days of the week, but when the time comes for their going to church together on Sunday it is found to be absolutely impossible to continue it any further. Can the rule have been carried out correctly during the six previous days?"—Other papers brought before the Society were: "On the relation between Bernoulli's numbers and the binomial coefficients," by Mr. J. Hammond. The paper, which was accompanied by a coloured diagram, showing how certain four determinants for the numbers are formed of selected coefficients, contained some interesting numerical results which follow directly from certain division formulæ given in a former paper by the same writer.—"On three-bar motion in plane space," by Mr. S. Roberts. In this communication the author determines three foci, any two of which may be taken as centres of the link movement and the nature of the linkwork in each case.—"Values of certain infinite products, with an application to the summation of the geometrical series of the *n*th order as a definite integral," by Mr. J. W. L. Glaisher, F.R.S.—"On the form of cam which, acting on a lever, shall communicate a motion such that the angular velocity ratio of the lever and cam is a given function of the angle described by the latter," by Major J. R. Campbell.

Geological Society, Nov. 3.—Mr. John Evans, V.P.R.S., president, in the chair.—Mr. Thomas Andrew, 18, Southernhay, Exeter; Mr. Harry M. Becher, White Lodge, Barnes, S.W.; Mr. Arthur Back Kitchener, F.C.S., 19, Buckingham Street, Strand, W.C.; Mr. Daniel Morris, Grammar School, Burnley; Mr. Christopher Thomas Richardson, M.D., 13, Nelson Crescent, Ramsgate; and Mr. Gustavus A. H. Thureau, Lecturer on Geology and Practical Mining, School of Mines, Sandhurst, Victoria, were elected Fellows of the Society.—On some new Macrurous Crustacea from the Kimmeridge Clay of the Sub-Wealden Boring, Sussex, and from Boulogne-sur-Mer, by Mr. Henry Woodward, F.R.S. The first species described by the author belonged to the fossorial family Thalassinidæ, six species of which belonging to four genera are now found on the British coasts. The known fossil species are from the Chalk of Maestrich, the Greensand of Bohemia and Silesia, the Chalk of Bohemia, the Greensand of Colin Glen, near Belfast, and the Upper Marine Series of Hempstead, Isle of Wight. All these are referred to the genus *Callianassa*, which also includes the species from the Kimmeridge Clay described in this paper. The fossil is seen in profile on several sections of the core, and has the enlarged hands of the fore limbs more nearly equal in size than in the living species of *Callianassa*; the carapace and segments of the abdomen are smooth, and the latter are somewhat quadrate in profile, contracted at each extremity, and not pointed, and the caudal plates are oval. For this Crustacean the author proposes the name of *Callianassa isochela*. The second species described belongs to the genus *Mecochirus*, distinguished by the great length of the fore-limbs, which is equal to that of the whole body, the oldest known species of which (*M. olifex*, Quenst.) is from the Lower Lias of Würtemberg. It was obtained, together with *Lingula ovalis*, from the Kimmeridge Clay of Boulogne, by Mr. J. E. H. Peyton, after whom the author proposes to name it *M. Peytoni*. In this species the fore-legs are very finely punctate, and measure seventy-five millims. in length. The rostrum is somewhat produced, and the carapace, which is finely granulated, measures thirty millims. in length. The antennæ are long and slender. The abdomen measures forty-five millims., and the epimeral borders of the segments are falcate. The species is intermediate in size between *M. socialis*,

Mey., and *M. Pearcei*, M'Coy, which the author regards as distinct. He also refers to *M. Peytoni* a pair of fore-limbs obtained from the Sub-Wealden boring.—On a new Fossil Crab from the Tertiary of New Zealand, by Henry Woodward, F.R.S. In this paper the author described a crab obtained by Dr. Hector, F.R.S., Director of the Geological Survey of New Zealand, from the "Passage-beds" of the Ototara series in Woodpecker Bay, Brighton, on the west coast of the south island of New Zealand. The new species belongs to the genus *Harpactocarrcinus*, A. Milne-Edw., which includes six species from the Eocene of southern Europe. Its nearest ally is *H. quadrilobatus*, Desmar., but its carapace is much more tumid, especially in the branchial and gastric regions; the surface of the anterior half of the carapace is nearly smooth, and that of the posterior half finely granulated. The rostrum is short and very obtusely tricuspidate, the orbits shallow and rounded, the hepatic margin bluntly toothed, with a stronger tooth at the epibranchial angles; the divisions of the regions of the carapace faintly indicated, and there is a slightly roughened line on the sides of the gastric intumescence. The characters of the jawfeet and of the chelæ are described by the author; of the latter the right is considerably larger than the left hand. The specimen was a female. For this species the author proposed the name of *Harpactocarrcinus tumidus*. Dr. Hector explained the sequence of formations in the locality from which the above crab was derived, and stated that the Ototara series is to be regarded as Cretaceo-Tertiary, containing some fossils of decidedly Cretaceous type, such as Saurian bones and fragmentary *Inocerami*, and other forms that are associated with decidedly Mesozoic fossils in the underlying strata. On the other hand, the occurrence of Tertiary forms such as *Nautilus ziczac* (or a nearly allied form), the gigantic Penguin (*Palæeudyptes antarcticus*, Huxl.), and a Turtle, indicate a fauna not unlike that at present existing in the vicinity.—On a remarkable fossil Orthopterous Insect from the Coal-measures of Britain, by Mr. Henry Woodward, F.R.S. The author commenced by indicating the importance of the examination of the Clay-ironstone nodules of the Coal-measures, in which so many valuable fossils have been discovered, including the remarkable insect described in the present paper. The specimen displays the characters of the four wings, only two of which, however, are nearly perfect, and these measure $2\frac{1}{4}$ inches in length and 1 inch and $1\frac{1}{4}$ inch in breadth, the hind wing being the broadest. The author described in detail the characters presented by the venation of the wings, which includes three straight veins running parallel to the fore margin, the third bifurcating near the apex, a fourth much curved vein giving origin to six branches, and having at its base a triangular space, from which arise the other veins of the wing. The body appears to have been about five lines broad between the bases of the wings. In front of the wings is the prothorax in the form of two large, rounded, dilated, and veined lobes; it measures fourteen lines across and six lines in length. In front of these lobes is the head, with its eyes produced in front into a slender process three lines long. This insect is considered by the author to be most nearly related to the Mantidæ, the characters of the head and thorax especially being to some extent paralleled in the existing genus *Blepharis*. The author proposed to name the species *Lithomantis carbonarius*, and suggested that *Gryllacris* (*Corydalis*) *brongniarti* probably belongs to the same genus.—On the discovery of a Fossil Scorpion in the English Coal-measures, by Mr. H. Woodward, F.R.S. The author commenced by noticing the various European and American localities in which fossil Arachnida have been found in the Coal-measures. Hitherto no true Scorpions have been recorded from the English Coal-measures; but in 1874 the author received from Dr. D. R. Rankin a specimen from the Coal-measures near Carluke, which he regarded as the fossil abdominal segment of a Scorpion; in April last he obtained a fossil Scorpion from the Sandwell Park Colliery, and in August Mr. E. Wilson forwarded to him several specimens of similar nature in Clay-ironstone nodules from Skegby New Colliery, near Mansfield. The specimens are all very imperfect, but the author states that they most closely resemble an Indian form, which is probably *Scorpio afer*. He refers the English species provisionally to the genus *Euscorpius*, Meek and Worthen, and proposes to name it *E. anglicus*.—The Drift of Devon and Cornwall, its origin, Correlation with that of the South-east of England, and place in the Glacial Series, by Mr. Thomas Belt, F.G.S. The author described the general characters of the drift in the district under consideration, and stated that on the uplands the drift consists of undisturbed gravels and travelled boulders, which occur only in isolated remnants on the lower ranges, and that in the lowlands and valleys within 100 feet of the present level of the sea the gravels are widely spread, and show signs of sudden and tumultuous action. Between the upland and lowland gravels he considered that great denudation had taken place. He maintained that the boulders and the materials of the gravels had been distributed by floating ice, and that their presence on the summit of Dartmoor indicated that the water on which the ice floated must have extended up to 1,200 feet above the present sea-level; but he argued that this water was not that of the sea, because no old sea-beaches or remains of marine organisms are to be found in the region, although freshwater shells are preserved. He described these phenomena to the presence of a great freshwater lake, produced by the drainage of Europe being dammed back by a great glacier flowing from the north-west (Greenland) down the present bed of the Atlantic, and over the northern parts of the continent. The author discussed the characters of the superficial deposits in the southern and south-eastern counties, and indicated the points in which these seemed to bear out his hypothesis. The sequence of phenomena assumed by the author is as follows:—Accepting Mr. Tylor's notion that the actual sea-level must have been lowered during the Glacial period in consequence of the great accumulation of water in the form of ice at the poles, he seeks a point of departure at the Glacial period in the first evidence of such a lowering of the sea-level. The Weybourne sands and the marine beds of Portland Bill were deposited when the sea was at about its present level, and the Bridlington Crag probably belongs to the same period. The fossils found in these deposits show that the waters were cold. The first stage of the Glacial period is that of the older Forest-beds, and the immigration of a number of great Mammalia and of Palæolithic man indicates that the sea had retired from the British Channel and the German Ocean, leaving these islands connected with the Continent. A great river probably ran southwards through the region now submerged. The second stage is marked by the continued advance of the ice from the north, the retreat of the southern fauna and Palæolithic man, and the arrival of Arctic Mammals. The third stage saw the culmination of the Glacial period and the greatest extent of the Atlantic glacier, which reached to the coast of Europe, blocked up the English Channel, and caused the formation of an immense lake of freshwater by damming back the drainage of the whole of north-western Europe, as already indicated. In the fourth stage the Atlantic glacier began to retreat, and the sudden breaking away of the barrier of ice that blocked up the mouth of the Channel caused the tumultuous discharge of the waters of the great lake, by which the spreading of the lowland gravels was effected. To this cause the author attributes the formation of the Middle Glacial sands and gravels of Norfolk and Suffolk. During the fifth stage the ice of the German Ocean continued to retreat; but there was a temporary advance of the Atlantic glacier, which again blocked up the Channel, and produced a second great lake, which, however, did not attain so great a height as the first, and its waters were not discharged in the same tumultuous fashion. At this period the Upper Boulder-clay of Norfolk and Suffolk was formed; but the author is not convinced that this formation is represented south of the Thames except by the "Trail" of the Rev. O Fisher. In the sixth and last stage the Atlantic ice retreated as far as the north of Scotland, but the sea had not returned to its former level. The British Isles were connected with the Continent and with each other. To this the author assigns the last great Forest period, and the arrival of Neolithic man and the associated fauna from the Continent.

Astronomical Society, Nov. 12.—Prof. Adams, president, in the chair.—A valuable series of solar photographs were presented to the Society by the executors of the late Prof. Selwyn. They represent a period of rather more than eleven years, and so cover a complete cycle of sunspot frequency. The negatives are upon glass and have been taken upon a scale of four inches to the sun's diameter. The casket in which the Freedom of the City of London had been presented to the Astronomer Royal was shown to the meeting, and Sir G. B. Airy gave an account of the work that had been going on at the Observatory during the recess. Attention has been paid to the positions of the satellites of Saturn in connection with the ephemerides, which have been published by Mr. Marth in the *Monthly Notices* and *Astronomische Nachrichten*. A new eight-year Greenwich catalogue of stars is being published. Stella-spectroscopy has also been energetically followed up, and though the observations were at first somewhat discordant, latterly they have grown more consistent,

and the results which have been obtained in the main verify those of Mr. Huggins as to the approach and recession of stars from and towards us in the line of sight. The Astronomer Royal remarked that Mr. Huggins had in this direction had the privilege of starting a new science, and it would be their duty at the Observatory to revise it; they intended to follow up the matter still further, but there were great difficulties still to be overcome, difficulties which no one could appreciate who had not attempted delicate work of the kind. They had also at the Observatory been applying themselves to photography, and had taken negatives of the sun with considerable regularity, though there were fewer spots to be observed now than at any former period which he could remember. Sir G. B. Airy also laid before the Society a map of the stars in the neighbourhood of Mars during its next opposition in 1877, and drew attention to the great advantages which this opposition would offer for the determination of the solar parallax.—Mr. De la Rue gave an account of the preparations that are being made both in France and Austria for the cultivation of physical astronomy. At Vienna an observatory is in the course of erection outside the city, on an area of some fifteen or seventeen acres. A central dome is being erected of 42 feet in diameter, which is to hold a 27-inch refractor, by Grubb, of Dublin.—Prof. Pritchard gave an account of the new Physical Observatory at Oxford, and of the mounting of the 12¼ inch refractor by Grubb, which has recently been bought by the University.—Lord Lindsay read a note on the progress of the reduction of his observations of the transit of Venus; and Mr. Bidder exhibited at the meeting and described an observing chair of simple and inexpensive construction.

Physical Society, Nov. 13.—Prof. Gladstone, F.R.S., president, in the chair.—The President stated that since the last meeting of the Society, Prof. Everett's important work on the Centimetre-Gramme-Second System of Units had been published by the Society. The book is based on the recommendations of a committee of the British Association, and consists of a collection of physical data concisely presented on the above system, a complete account being added of the theory of units.—Dr. Stone then read a paper on Thermopiles. He has recently been engaged in some experiments with a view to ascertain the best alloy for use in thermopiles. The thermo-electric power of a metal or alloy appears to be quite unconnected with its power for conducting heat or electricity, or with its voltaic relation to other metals, neither does it appear to have any relation to specific gravities or atomic weights. The thermopiles employed were of a form slightly modified from that employed by Pouillet in his demonstration of Ohm's law. Alloys are frequently more powerful than elementary metals, thus: 2 parts antimony and 1 part zinc have a negative power represented by 22·70, while that of antimony is 6·96 or 9·43, and of zinc is 0·2. A strange exception, however, is that of bismuth and tin, for while the power of bismuth is + 35·8, when the two metals are alloyed in the proportion of 12 to 1, the power becomes − 13·67. Dr. Stone first used a couple consisting of iron and rich German silver (that is, rich in nickel). This was characterised by great steadiness, but the electromotive force produced by moderate differences of temperature was not great. He then used Marcus's negative alloy, consisting of 12 parts antimony, 5 of zinc, and 1 of bismuth, but the crystalline nature and consequent brittleness of this mixture were found to be great objections to its practical use. It occurred to Dr. Stone that the addition of arsenic might diminish the brittleness without injuring the thermo-electric power, and on trial it was found that an alloy of zinc, antimony, and arsenic, with a little tin, formed a much less brittle mass than Marcus metal, with quite as great or greater thermo-electric power. A set of twelve couples of this alloy and German silver was exhibited. The electromotive forces of this set and of a similar one of twelve iron and German silver couples were determined by Mr. W. J. Wilson, and found to be, for one alloy and German silver couple with difference of temperature of 80° C., $\frac{1}{108}$ of a Daniell's cell. The electromotive force of one couple of the iron and German silver set was $\frac{1}{548}$ of a Daniell's cell. The ordinary method of applying heat by a trough of hot water is objectionable, for the water short-circuits some of the current. This is evident from the fact that if oil heated to the same temperature be substituted, a considerably greater deflection is obtained. Another method suggested by the author, which would tend to economy, is to allow petroleum to volatilise in the neighbourhood of one face of the pile, thus chilling it, and to ignite the mixture of air and gas so produced at the other face. Clamond's pile, consisting of iron and an alloy of zinc and antimony, was employed for some time, but although good results were obtained, the iron is liable to rust at the connections.—Dr. Guthrie remarked that in researches of this nature the main object in view was to ascertain what relation, if any, existed between the direction of the current and the amount of heat-flow. He referred to the experiment with a tangle of fine platinum wire, by which it is found that if either end of the wire be heated, a current flows towards the tangle, and this takes place however well the tangle may be annealed. Dr. Guthrie suggested that the great effect which alloying one metal slightly with another has on its position in the thermo-electric series may perhaps be connected with its change in conducting power for heat.—Mr. Walenn referred to experiments which he made some years since on thermopiles when used at high temperatures. The most powerful currents were obtained with a couple in which amalgamated copper was employed, but the power was soon lost in consequence of the volatilisation of the mercury. Subsequently he employed wires of wrought iron and German silver, and although the results were not specially remarkable at moderately high temperatures, the power became great when the connections were raised to a red heat.—Prof. Foster called attention to Matthiessen's table of the electric conductivities of metals and alloys in relation to the use of the latter in thermopiles. The fact shown by Matthiessen that the conductivities of alloys are greatly influenced by changes of temperature, will probably, he considers, be found to have some connection with their thermoelectric action. He also mentioned, as a fact which should be remembered when considering the construction of thermopiles, that the presence of minute traces of impurity completely changes the electric conductivity of a metal.

Anthropological Institute, Nov. 9.—Col. A. Lane-Fox, president, in the chair.—Major T. F. Wisden was elected a member.—Mr. Francis Galton, F.R.S., read the following papers:—"Heredity in Twins." On comparing the number of twins found among the uncles and aunts of twins with those found in similar classes of society generally, it appears that twin-bearing is hereditary, in so far that there is an excess per cent. of three individuals of twin birth in the former group. It further appears that the male and female lines contribute the twin-bearing tendency in identical proportions. The families are very large in which twins are born; even those of their parents average nearly seven persons, but the twins themselves appear neither to many so frequently nor to be so prolific as other persons. However, the common belief that both twins are in no case fertile is quite untrue.—"A Theory of Heredity." Starting with the generally admitted view that the body consists of a multitude of organic units, each of which is to a certain degree independent of the rest, and with certain postulates which that view implicitly recognises, there exists a firm basis on which to establish a theory of heredity. By these and their necessary consequences, the object of double parentage, and therefore of sex, was first explained by the likeness and dissimilarities observed between brothers and sisters, and the still more remarkable similarities and contrasts between twins of the same sex, were then accounted for. It was argued that the germs which were selected for development into the bodily structure had very small influence in an hereditary point of view, but it was those germs that were never developed but remained latent, that were the real origin of the sexual element; by this hypothesis the almost complete non-transmission of acquired modification was explained; also the occasional fact that strongly marked characteristics in the parents were sometimes barely transmissible, and again that of certain diseases skipping alternate generations. It was further supposed, in the successive segregations and segmentations of the earliest germinal matter, that the divisions were never precise, and therefore that alien germs were ultimately included in each structure; thus latent germs of all kinds became distributed over all parts of the body. This accounted for much that Mr. Darwin's theory of Pangenesis over-accounted for, and was free from objections raised against the latter. The assumed evidence that structural changes under modified conditions of life reacted on the sexual elements was then discussed, and it was pointed out that much that had the appearance of heredity was not so in fact, but was due to changes of the sexual elements collaterally with the structural ones. A modification of Pangenesis was adopted, as a subsidiary part of the main theory, to account for the occasional and limited transmission of acquired modification. The precise character of the relationship that connects the offspring with the parents was then defined.—Mr. F. W. Rudler, F.G.S., read a report on the Department of Anthropology at the Bristol meeting of the British Association.

Institution of Civil Engineers, Nov. 9.—Mr. Thos. E. Harrison, president, in the chair.—The paper read was on the Manora Breakwater, Kurrachee, by Mr. William Henry Price.

CAMBRIDGE

Philosophical Society, Nov. 1.—Mr. Pearson read a paper on Aristotle's notion of "Right-Handedness;" and added some remarks on a theory of his own on the subject.

BOSTON

Natural History Society, May 5.—This was the Annual Meeting, when Prof. Hyatt, the Custodian, presented his report, in which he described the condition of the numerous collections belonging to the Society. The following papers were read:—On some of the habits of the Blind Crawfish (*Cambarus pellucidus*), and the reproduction of lost parts, by F. W. Putnam.—Synopsis of the Odonata of America, by Dr. H. A. Hagen.

PARIS

Academy of Sciences, Nov. 8.—M. Frémy in the chair. The following papers were read:—Discovery of two small new planets, at the Observatory of Paris, by MM. Paul and Prosper Henry, by M. Leverrier.—Memoir on measurement of the affinities in the reaction of two solutions on one another, taking as bases the electromotive forces, by M. Becquerel.—On the alcohols which accompany vinic alcohol, by M. Is. Pierre.—On the exhaustion of the soil by apple-trees, by M. Is. Pierre. He estimates that an annual supply of about 80 kilogrammes of manure would be required for a single tree, to maintain the original fertility of the ground.—Observations by M. P. Thenard on M. Pierre's communication.—M. de Lesseps presented the second volume of his work on the History of the Suez Canal.—On the separation of mixed liquids and on new maximum and minimum thermometers, by M. Duclaux. It is always possible to begin with a mixture (at a given temperature) such that on lowering the temperature very little (much less than the tenth of a degree), it divides into two layers of equal volume; *e.g.* a mixture of 15 c.c. amylic alcohol, 20 c.c. ordinary alcohol, and 32.9 c.c. water, at 20°. The thermometers on this principle are easily made, cheap, solid, and resistant to shocks and pressure, though, of course, a special mixture is required for each.—Note on the determination of cafeine, and the solubility of this substance, by M. Commaille.—On a process for separating cholesterine from fatty matters, by M. Commaille.—On the various modes of structure of eruptive rocks, studied with the microscope, by M. Michel Levy.—Researches on the inversion of cane-sugar by acids and salts, by M. Henry.—Comparison of unipolar excitations of the same sign, positive or negative: influence of increase of the current on the value of these excitations, by M. Chauveau. In medical use of electricity, he finds that to manage the current with regularity, unipolar excitation should be used with the positive pole for motor, and with the negative for sensitive, nerves.—On the anatomy and histology of Lucernaria, by M. de Korstneff.—Treatment, with sulphocarbonates, of the spot which indicated the appearance of Phylloxera at Villié-Morgon, by M. Duclaux.—On electro-capillary currents produced by mineral caustics, by M. Onimus.—On the influence of acids on coagulation of blood, by M. Oré. Neither acids nor alcohol coagulate albumen when injected directly into the circulation; and most substances insoluble in water, but which cease to be so in presence of acids and of alcohol, may be injected without causing coagulation, after being submitted to the action of these.

GENEVA

Society of Physics and Natural History, Oct. 7.—Prof. Alfred Gautier gave an account of the meteorological observations made in Labrador by the Moravian missionaries at various stations in that northern region. The first notice, published by him in June 1870 (*Archives des Sciences*, tome xxxviii. p. 132), referred to the first documents of that kind sent by the missionaries from 1778 to 1780, and published in the Phil. Trans., vols. 69 and 71; then a second series, made from 1841 to 1843, contained in the *Annales* of M. Lamont, of Munich. A new series of observations has been undertaken since 1867, by means of thermometers sent from Geneva by M. Gautier, and it has been continued more or less regularly by the missionaries. Results have been received from four stations; that of Hopedale, from 1868 to 1874; Zoar, for one year, from Sept. 1870 to Sept. 1871; that of Hebron, from Sept. 1869 to August 1870; Rama, the most northerly, from July 1872 to June 1874. Hopedale is situated in 55° 39′ N. lat. The annual means of temperature in Centigrade degrees, drawn from three observations daily, made at 7 A.M., 12 noon, and 7 P.M., are as follows:—

December 1868	to	November 1869	–	3°·04
,, 1869 ,,		,, 1870	–	3°·42
,, 1870 ,,		,, 1871	–	2°·83
,, 1871 ,,		,, 1872	–	2°·32
,, 1872 ,,		,, 1873	–	3°·63

The mean of five years is thus – 3°·09. Compared with the mean of Edinburgh (in an even more northerly lat., 55° 57′), which is about 8°·4, it indicates the enormous difference existing between the temperatures of corresponding latitudes on the western coast and in the eastern regions of the North Atlantic. The mean of the seasons at Hopedale deduced from the collective observations is as follows: Winter, – 18°·0; spring, – 5°·5; summer, 9°·0; autumn, 1°·3. The minimum temperature in winter is from –26° to –36° below zero. The absolute minima observed have been – 38° on Feb. 3, 1870, and – 39° on Feb. 2, 1873; on March 1, 1874, – 35° was observed. In July and August there was not much frost, and vegetation prospered. The thermometer rose to 29° and even 30°, which it reached on July 26, 1871. The daily variations resulting from five years' observations rose in the mean to 4°·49. Its monthly maximum was 6°·6 in June 1873, and its minimum 1°·4 in November 1869. It is accidentally sometimes much more considerable. The most notable instance was on Oct. 11, 1871, when the thermometer, which indicated – 4°·2 at 7 A.M., sank at 7 P.M. to – 27°. The barometric observations made at Hopedale present inconsiderable variations. In the neighbouring districts these variations being often very sudden and very extended, it may be asked if the instruments used are in a satisfactory condition. Since the heights reached vary between 29 and 30½ English inches, it may be presumed that the tube is quite free from air? This is a point deserving a special inquiry. From the three daily observations made at the station of Zoar from September 1870 to August 1871, may be deduced a mean annual temperature of – 2°·26. Zoar is situated in about 56° of N. lat. At Hebron two daily observations at 7 A.M. and 2 P.M. during one year, from September 1869 to August 1870, give a mean of – 3°·6. The latitude is about 58° 20′. The two previous years gave an annual mean of – 4°·5, and besides former observations in 1841–2, a mean of – 5°·3. Finally, at Rama, situated in about 60° N. lat., the annual mean in 1872–3 was about – 5°·6.

THE OXFORD BOTANIC GARDEN

EVERYONE who knows Oxford remembers the quaint old Botanic Garden by Magdalen Bridge at the foot of the High Street. Nearly two centuries and a half have passed since St. James's Day, 1632, when the Vice-Chancellor and the authorities of the University walked in procession from St. Mary's Church to lay the foundation of the main gateway afterwards completed by Inigo Jones. The expense of this and of the high stone walls which surround the garden and protect it from the wind exceeded 5,000*l*., a large sum even in those days, but which was provided by the munificence of Lord Danby, who afterwards bequeathed some property as an endowment.

The Oxford Botanic Garden is the oldest in Britain, and there are but two or three of earlier date in other countries. The space of this article would be insufficient to do justice to the place which belongs to it and to its successive professors in English scientific history. A few only of its traditions will be enough to show that it has always been a place for study as well as for instruction. Evelyn visited it in 1654, when "the sensitive plant was shown as a great wonder." Twenty years after (1676) Sir Thomas Millington, the Savilian Professor, first divined the fundamental fact of sexual reproduction in flowering plants. Five years later (1681) Bobart, "over-seer of the physick gardens," experimentally demonstrated the function of pollen. At the beginning of the eighteenth century the Oxford Botanic Garden solved another great problem. Although Ferns bear no flowers, the world shared the opinion of Columna that they must have flower-produced seeds, because, amongst other reasons, "the book of Genesis said nothing about plants being destitute of them." Fern seed then came to be regarded as existent although invisible, and then by a not unusual transition as the cause of invisibility in its possessors. Morison (1715) disposed of these fancies by demonstrating that the asexual spores of Ferns were actually their means of reproduction. In 1736 the garden —then under the charge of Dillenius, the editor of the third edition of Ray's "Synopsis," and the author of the "Historia Muscorum"—was visited by Linnæus. Here he resided for some weeks, and many particulars have come down to us of discussions amongst the living plants, in which he endeavoured to convert Dillenius to his newly published Sexual System. Passing over Sibthorp and his splendid work on the Botany of Greece, it must not be forgotten that in the Oxford Botanic Garden Daubeny anticipated Draper in demonstrating (1836) that the light belonging to the red end of the spectrum is most effectual in promoting the evolution of oxygen by plants. There is something perhaps characteristic of the habits of forty years ago in his using port wine as one of his absorptive media.

It might be supposed that a place so venerable in its aspect, so interesting in its traditions, would be a source of some pride to the members of an ancient University, and that they would be anxious to give it the needful support to enable it to be as useful now as it has been in the past. Unhappily, the facts show the reverse of this. Notwithstanding the efforts of the present professor, the garden and its buildings have been for some time allowed by the University to sink into neglect, and it is now proposed—mainly at the instance of the Regius Professor of Medicine—to abandon the site altogether and create a new garden in the modern suburb of Oxford and in the vicinity of the New Museum.

It will, of course, be assumed by all who are unacquainted with the real state of the case that the present site is quite unfitted for its purpose; yet there is the very highest authority in such matters for saying that the facts are all the other way, and the Professor of Botany strongly opposes the removal. Soil and situation are all that can be desired, and far better than can be obtained in the "Parks," where the soil is poor and the ground is wind-swept. A moderate outlay compared with that which removal would entail would make the present garden an all but ideal establishment for the prosecution of every branch of modern botanical research, while, if half a mile distant from the professorial suburb, it is on the other hand ready of access to most of the colleges, where undergraduates reside.

The argument used in favour of the removal is the advisability of bringing together all the scientific institutions of the University. In pursuance of this policy an astronomical observatory has also been built in the Parks at considerable cost, although Oxford already possessed in the Radcliffe Observatory an institution of this kind. If it were profitable for students to rush in hot haste from astronomical instruction to the lectures of the Botany Professor, such a juxtaposition might be desirable. But this sort of omnivorous study is a thing to be discouraged. In the present state of science an hour now and again spent in a professor's lecture-room is of the slenderest value. Oral teaching must be supplemented by workroom study, and if Botany in its modern aspects is to be effectively studied in Oxford at all, students must be encouraged to give to it considerable portions of whole days rather than a mere sporadic attendance. This demand for centralisation does not make itself felt in the other studies of the University, and as regards proximity to the Radcliffe Library, the Botanic Garden already has a fair library of its own.

If the truth must be spoken, this unhappy scheme is one more phase of the feverish æsthetic activity which in modern Oxford seems to have taken the place of enthusiasm for learning. This is not the place to criticise the New Museum erected at vast cost for the scientific studies of the University, but we may challenge any impartial man of science to stand before that fanciful building, half municipal, half monastic in its aspect, and fail to see that it bears the impress of the fleeting artistic aspirations of a period rather than of the sober needs of scientific study. The same impulse which in building a laboratory must needs reproduce the abbot's kitchen at Glastonbury will now, if it have its swing, transform a botanic garden into a pleasure ground, in which the needs of study must once more be subordinated to artistic effect, and conservatories will be built not so much to grow plants as to show how such things can be constructed in the neo-Gothic manner. Forming part of the "Parks," and contiguous to a suburb of villa residences, it will immediately become a pleasant lounge, and the mem-

bers of the University will of course not be satisfied unless the time of the gardeners is pretty fully occupied with decorative floriculture. Comparing such a prospect with the old Garden, one turns to a place whose trim extent is ample for purposes of study, whose old-fashioned aspect is pleasing to the eye without much need of "bedding out," and which is supplied with substantial buildings well adapted for library, herbarium, laboratory, and museum, or which might be made so at comparatively little expense. It is true that the green-houses are dilapidated and antiquated, but they could be reconstructed against one of the old walls, and this at a much less cost than they could be erected in the "Parks."

The hammer and the chisel resound throughout Oxford. The great court of Christ Church is to be surrounded with useless cloisters. The University Church, having been restored thirty years ago, is to be re-restored in a more critical manner. The beautiful old library of the Bodleian is in no small peril. The secret of all this is easy to read. A new distribution of the funds of the University and colleges is believed to be imminent. From one point of view it is desirable that these should be husbanded to the last penny, in order that new endowments for study and research may be adequate and comprehensive. From the other point of view it is only desired at Oxford *stare supra antiquas vias*, and the money must be got rid of before the time of redistribution arrives. Oxford, alas!—and those who regard her most lament it most—has grown careless that her life should pulsate with the life outside her. What new word in science ever now resounds from Oxford laboratories? Her energies seem lulled in the lethargy of a fastidious, almost feminine, culture. Her professors cannot be denied the possession of capacity and laboriousness, yet if perchance any new teacher is summoned from without to join their number, his friends lament him as one who has fallen away into an intellectual Capua.

To examine is the crown as to be examined is the commencement of an Oxford career. And those who are content that this should be the University's "measure of sufficiency" are only careful that buildings and appliances ancillary to examinations and studies preparatory for them should be after the newest fashion in taste and fitted to excite the admiration of relatives who visit Oxford at Commemoration-time. No one doubts that examinations are useful, and in Oxford, at least, no one will deny that Mr. Ruskin has not written on architecture in vain. But Oxford will not satisfy the hopes of those who look to its treasuries for things new as well as things old, till she has learnt to look upon examinations as by no means a sufficient *raison d'être*, and the wisdom of spending as little as possible upon the decoration, and as much as possible upon the efficient equipment of her workrooms and laboratories.

LOMMEL ON LIGHT

The Nature of Light, with a General Account of Physical Optics. By Dr. Eugene Lommel, Professor of Physics in the University of Erlangen. (London: H. S. King and Co., 1875.)

THIS book forms the nineteenth volume of the International Scientific Series. Nearly all the volumes have passed through more than one edition, and with few exceptions the works are of singular merit. They are, moreover, issued at so low a price that they cannot fail to have largely extended an interest in science and given the public a sound acquaintance with the special subjects upon which they treat. In the long list of the forthcoming volumes of the series, we are glad to find that some of the most eminent English and European men of science have consented to take a part.

In the present treatise, Prof. Lommel has given an admirable outline of the nature of Light and the laws of Optics. Unlike most other writers on this subject, the author has, we think wisely, postponed all reference to theories of the nature of the light until the laws of reflection, refraction, and absorption have been clearly set before the reader. Then in the fifteenth chapter Prof. Lommel discusses Fresnel's famous interference experiment, and leads the reader to see that the undulatory theory is the only conclusion that can be satisfactorily arrived at. A clear exposition is now given of Huyghens' theory, after which follow several chapters on the diffraction and polarisation of light-bearing waves. The reader is thus led onwards much in the same way as the science itself has unfolded, and this we think is the surest and best way of teaching natural knowledge.

Let us now look a little more closely at the book before us. It is evidently a translation, and as such the author's meaning must to some extent suffer, but on the whole the translator has done his work fairly well. We regret, however, to meet with some inaccuracies in the use of terms that ought not to have escaped revision. For example, on p. 228 we read: "The intensity (or energy) of light depends on the *liveliness* of the vibrations." The word *liveliness*, though used less objectionably in other parts of the book to express brilliancy, is here most likely to mislead the reader. For liveliness one may take to mean either extent and vigour or quickness of vibration; if the reader has the former meaning uppermost, he has of course gained a right conception, but if the latter, an erroneous idea is conveyed. The ambiguity of the word is fatal to its use in the passage we have quoted. Again, on p. 250 the word *fluids* is used when *liquids* should have been employed; the passage as it stands runs: "Glowing *fluids*, between the molecules of which the force of cohesion still acts, exhibit a continuous spectrum." This, of course, is not true of elastic fluids, as gases and vapours. The same error we notice also elsewhere, *e.g.* on p. 242. Again, on p. 261, the translator makes Prof. Lommel say: "When a telescope is used for the purpose of observing a diffraction image, *it* is formed in the focal plane of the objective." What is formed? Surely not the telescope Throughout the chapters on diffraction the term "elementary rays and elementary waves" is incessantly used; the more familiar term, "secondary waves," is not employed; we think it would have been well to have helped the general reader by a reference to the latter expression in a footnote or otherwise.

So likewise we find the term "fasciculus of rays" everywhere employed, where it is common for us to use the term pencil or group; it would have been pleasanter to have varied the expression occasionally by the use of one or other of its synonyms. On p. 249, "consistence of the chord" hardly expresses with sufficient exactness the word "density" for which it is used. Freshness

of expression is welcome, but not at the expense of accuracy.

Then, again, we wonder what was the object of the translator in tacking on to many words their German equivalent; if the meaning were doubtful to him, or could not be rendered, that would be all very well; but when a plain man finds in the text the statement that

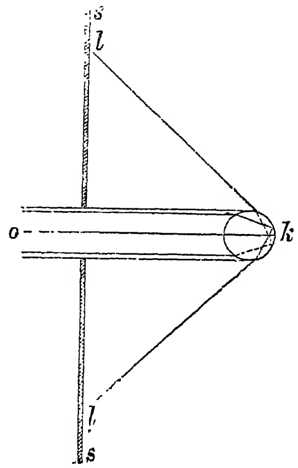

FIG. 1.—Refraction and internal reflection in a raindrop.

solid bodies are held together "by a powerful force which is termed the force of cohesion (Zusammenhangkraft)," he is apt to be a little frightened. The translator possibly felt that after the insignificance of our English term, it was necessary to give a powerful German word to express the powerful force. This, however, does not explain the occurrence of German expressions elsewhere in brackets.

These little defects are perhaps incidental to the first edition of a translation; of Prof. Lommel's work we have already expressed our high opinion. The explanations of phenomena are extremely clear and precise, and here and there appendices furnish elementary mathematical reasonings which, though wholly omitted from the text, are desirable in some places to give the reader a more complete knowledge. The chapters in which the undu-

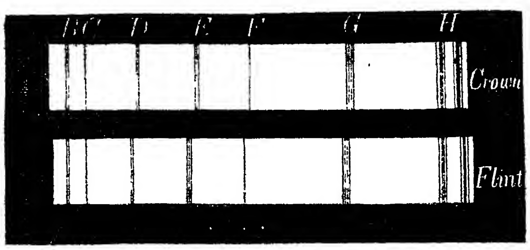

FIG. 2.—Spectra of crown and flint glass.

latory theory is employed to explain the phenomena of reflection, refraction, &c., seem to us extremely useful and clearly written. Nowhere, in an elementary book, have we met with so simple and elegant an explanation of the reason why the energy of a vibration is proportional to the square of its amplitude as that given by the author on pp. 227 and 228.

Here is a simple experiment to illustrate the formation of the rainbow, that we have not before seen in a text-book:—

"Upon a glass sphere *k*, filled with water and having a diameter of four centim. ($1\frac{1}{2}$ in.), a beam of solar light of equal or greater diameter than the sphere is allowed to strike horizontally, and there is then seen upon a large screen *ss*, placed in front of the sphere, and perforated in its centre to allow the passage of the incident rays, arranged concentrically to the aperture and at a distance from it which is nearly equal to that of the sphere from the screen, a beautifully coloured circle, in fact a circular spectrum, the colours of which are arranged concentrically, and in such a manner that the red is outside and the violet on the inside. At a still greater distance from the centre of the screen a second similar but much fainter circle is observed, the colours of which however succeeded one another in the inverse order, the red appearing on the inside, and the violet at the outer periphery." (p. 122.)

The different dispersive power of bodies is instructively shown by comparing the spectra given by crown and flint glass (Fig. 2), wherein it is seen that although the total dispersion, that is the length of the spectrum, is exactly the same, the mode of dispersion is different. By the position of the Fraunhofer lines in the two spectra, "it is rendered evident that the less refrangible rays are more closely approximated in passing through the flint glass, whilst the more refrangible are separated further from one another than by the crown glass." (p. 139.)

The difference in the nature of the dispersion is subsequently shown (chapter xviii.) to be caused by a difference in the rate of propagation of the various undulations when passing through many solids and liquids. Hence "the proposition that all kinds of

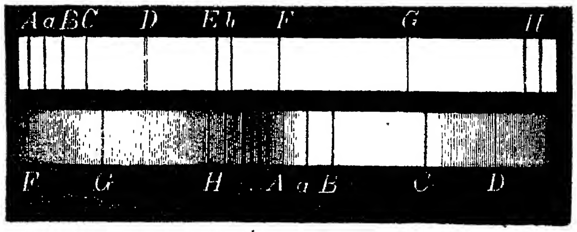

FIG. 3—Unusual dispersive power of Fuchsin.

light are propagated with equal rapidity, which was shown to be true of the free ether of the universe, is found to be no longer admissible for the ether contained in the interior and occupying the interstices of the particles of natural substances." Very strikingly is the influence of the nature of the material particles on the velocity of propagation exhibited in those substances in whose absorption spectra one or more very dark lines appear. "If we introduce, for example, an alcoholic solution of the aniline colour 'fuchsin,' into a hollow prism, and look through it at a brightly illuminated slit, we obtain a spectrum in which blue and violet are less deflected than yellow and red. What is elsewhere the end of the spectrum here appears at the commencement; towards the middle it fades, and in the centre the green, being absorbed, is absent (Fig. 3). From this behaviour the conclusion may be drawn that in 'fuchsin' the blue and violet rays are propagated with greater velocity than the red and yellow. This phenomenon, which was discovered by Christiansen, and was shown by Kundt to be presented by a great number of absorbing substances, has been called the *anomalous dispersion of light.*" (p. 244.)

The phenomena of absorption are treated very fully in this volume.

A pretty mode is given by the author on p. 177 of showing how the absorption bands yielded by a coloured body, gradually thicken, but are not displaced, when greater depths of colouring matter are used. "To demonstrate this a number of gelatine discs coloured with

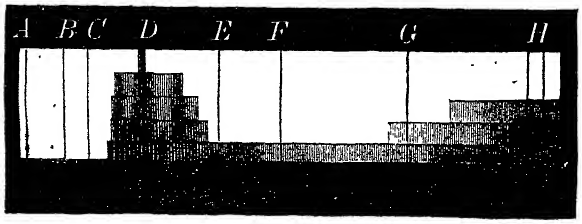

FIG. 4.—Absorption of colouring matter of litmus.

litmus may be used, which are placed between two colourless glass plates in a graduated manner. If these be placed before the slit, there will be seen in the aperture (Fig. 4) the graduated amount of absorption corresponding to the different thicknesses of the gelatine. In the case of the thinnest layer only a thick dark band is seen in front of D, whilst the thickest layer only permits the red end of the spectrum to be seen. The appearance of this spectrum explains why a layer of litmus gradually increasing in thickness first appears whitish, then blue, then violet, and finally purple red."

The next diagram (Fig. 5) represents the absorption

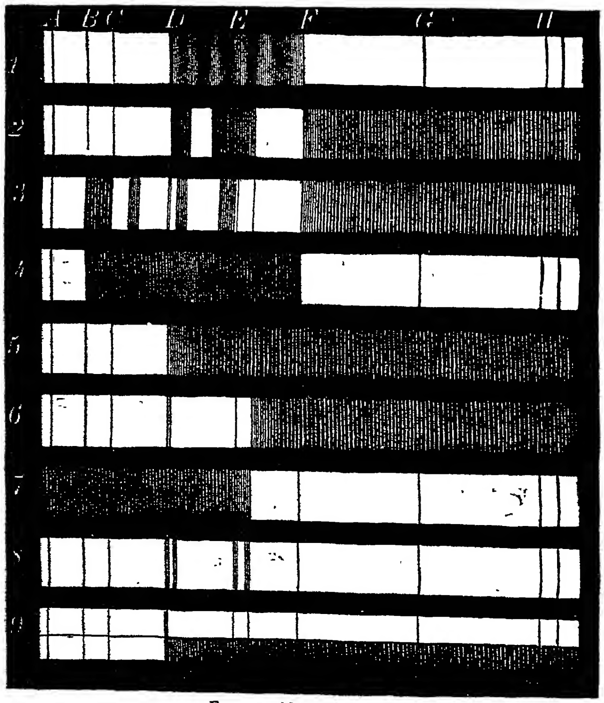

FIG. 5.—Absorption spectra.

spectra given by different bodies, the Fraunhofer lines being used as convenient standards of reference. The uppermost band, 1, is the spectrum as modified by transmission through a solution of permanganate of potash; the absorption by blood diluted with water is shown in 2, the violet end of the spectrum being cut out and two broad bands between D and E making their appearance; an alkaline solution of chlorophyll gives the absorption shown in 3; glass coloured blue by cobalt is shown in 4, and coloured red by oxide of copper in 5; solution of bichromate of potash is given in 6, and of ammoniacal oxide of copper in 7—these two are seen to transmit complementary colours, and hence their conjunction cuts off the entire spectrum. When the upper half of the screen is white and the lower half covered with red paper, the

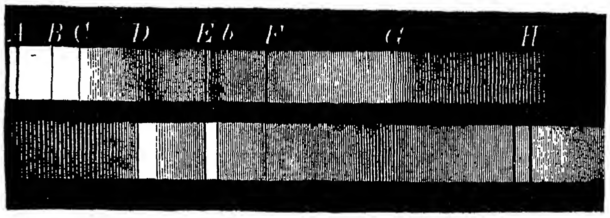

FIG. 6.—Absorption and fluorescing spectrum of napthalin red.

effect shown in 9 is obtained. No. 8 shows the absorption lines produced by glass containing didymium in combination; to the eye such glass appears colourless, but the characteristic bands in the spectrum enable the faintest trace of that metal to be detected. Conversely by heating the oxide of didymium to incandescence, bright lines appear in the spectrum of the emitted light in the place of the dark lines. As is well known, the oxides of didymium and erbium are rare examples of glowing solids giving a linear and not a continuous spectrum.

Concerning the production of these bright lines, Prof. Lommel remarks further on (p. 250): "The vibrations which the molecules of solid and fluid [liquid] bodies exhibit under the influence of the force of cohesion, do not prevent the simultaneous occurrence of those vibrations within each molecule to which the molecule is attuned owing to its chemical composition. As a general rule the latter are not visible, because the bright lines which correspond to them disappear upon the bright background of the continuous spectrum. The characteristic linear spectrum which discloses to us the chemical quality of a body is much better and more clearly

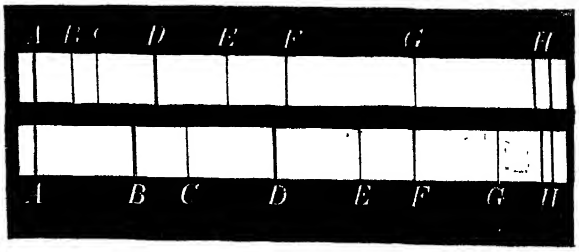

FIG. 7.—Comparison of prismatic with grating spectrum.

seen when its molecules, freed from the chains of cohesion, enter into the gaseous condition." We ought in fact to find the traces of its linear spectrum in a glowing liquid; if, for example, the metal sodium be heated to incandescence in nitrogen, the yellow portion of the spectrum should be more pronounced than the remaining regions; and if the glowing liquid metal could slowly pass into glowing gas, the extinction of the whole spectrum, except the characteristic D lines, should proceed imper-

ceptibly. From the law of continuity this must necessarily be the case in the transition of every solid into a gas, yet we are not aware of any definite experiments on this point.

The reciprocity of radiation and absorption is well illustrated by a comparison of the fluorescent and absorption spectrum of what the translator terms napthalin red; we presume rosaniline is meant. If the solar spectrum be projected upon a glass cell containing this liquid, the fluorescence exhibited in Fig. 6 (2) is seen. In the upper diagram is shown the absorption spectrum obtained by transmitting the solar spectrum through the same solution, and it will be clearer to the eye than it is in the diagram, that the three regions of strong fluorescence are in the same position as the three principal absorption bands. By employing a solution of proper strength, it will be found indeed that "every dark band in the absorption spectrum corresponds to a bright band in the fluorescing spectrum." (p. 190.)

The last diagram we give shows in an instructive manner the irrationality of the dispersion spectrum, by a comparison of the normal spectrum yielded by a diffraction grating with the ordinary prismatic spectrum (Fig. 7, 1). The last sentence in chap. 19, referring to this diagram, is badly translated, and certainly ought to be amended, for as it stands at present it is unintelligible.

We have said enough to show that Prof. Lommel's treatise is a useful contribution to the International Series, and is a book that can thoroughly be understood and enjoyed by any intelligent reader who may not have had any special scientific training. The familiar chromo-lithograph of different spectra which adorns the title-page of the volume has by this time lost its novelty and become wearisome. No book on chemistry, astronomy, or physics seems to be issued without it. Though the spectroscope is a wonderful and powerful instrument, yet the prominence of this subject is a little apt to throw equally valuable instruments into the background.

W. F. B.

DARWIN ON CLIMBING PLANTS

The Movements and Habits of Climbing Plants. By Chas. Darwin, M.A., F.R.S., &c. Second Edition, revised. With Illustrations. (London: J. Murray, 1875.)

THIS volume is a reprint of Mr. Darwin's well-known treatise on the habits of climbing plants, published in 1865 in the ninth volume of the "Journal of the Linnean Society," with such additions and corrections as the progress of knowledge since that time has rendered necessary. Although the subject had been investigated previously to that time by the German physiologists Palm and Von Mohl, it was Mr. Darwin's publication, describing many facts not previously recorded, that first introduced the remarkable phenomena connected with it to the notice of the general public. The phrase Climbing Plant is used by Mr. Darwin as a generic term for all those which, provided themselves with but weak stems that have no power of standing erect, avail themselves of the assistance of neighbouring plants for the purpose of raising their foliage and flowers to a considerable height from the ground. The plants included under this head are arranged in four divisions, according to the part that is modified in order to subserve this purpose: (1) Twining Plants (called in the first edition Spiral Twiners), in which the stem is the climbing organ; (2) Leaf-climbers, which climb by the aid of the petiole or some other portion of the leaf; (3) Tendril-bearers, by far the most numerous class, which are provided with tendrils specially contrived for this purpose; and (4) Hook and root-climbers, which climb by the aid of hooks on aërial roots, or merely scramble over other plants. In all these classes except the last, the mechanical means by which the climbing is effected is a sensitiveness and power of revolution possessed by the extremity of the stem or tendril, or by the petiole.

The origin of this peculiar power is one of the most interesting points of the inquiry. In some cases, as Passifloraceæ and Cucurbitaceæ, it is possessed by nearly or quite every species of the order; other orders, as Leguminosæ, include species belonging to two or three divisions of climbers, along with a large number which do not possess the power; while in others, as Compositæ, Rubiaceæ, Scrophulariaceæ, and Liliaceæ, it belongs to only a very few out of a large number of genera. From these facts, and the wide separation, on any system of natural classification, of the orders which contain climbing plants, Mr. Darwin draws the conclusion that "the capacity of revolving, on which most climbers depend, is inherent, though undeveloped, in almost every plant in the vegetable kingdom"—a conclusion which seems to us strongly confirmed by the fact that sensitiveness and a slight power of spontaneous motion are possessed by some parts of flowers where it is of no use for climbing purposes, as the flower-stalks of *Maurandia* and *Brassica Napus*; and by the remarkable observation of Fritz Müller—one of the most interesting additional notes in the present volume—that "the stems, whilst young, of an *Alisma* and of a *Linum*," which do not climb, "are continually performing slight movements to all points of the compass, like those of climbing plants."

These observations lead Mr. Darwin to a discussion of the nature of the difference between the so-called "spontaneous" power of motion of some plants and that possessed by animals, which he sums up as follows:—

"It has often been vaguely asserted that plants are distinguished from animals by not having the power of movement. It should rather be said that plants acquire and display this power only when it is of some advantage to them; this being of comparatively rare occurrence, as they are affixed to the ground, and food is brought to them by the air and rain."

In the present work Mr. Darwin makes ample reference to the light that has been thrown on the habits and movements of climbing plants by researches of a later date than the publication of the first edition, especially those carried out in the Würzburg Laboratory by De Vries and Sachs; and one of the most important of the additions is a paragraph wherein he expresses his partial dissent on one point from the conclusions of the last-named high authority. In his "Text-book of Botany," Sachs attributes all the movements of tendrils to rapid growth on the side opposite to that which becomes concave; these movements consisting of revolving nutation, the bending to and from the light and in opposition to gravity, those caused by touch, and spiral contraction. While

conceding this view with regard to all the other causes of movement, Mr. Darwin finds a difficulty in accepting it as regards movement caused by curvature from a touch, or what is ordinarily called sensitiveness. On this point he remarks that the movement of Revolving Nutation (Sachs's term for "the continuous self-bowing of a whole shoot successively to all points of the compass") differs from that due to touch, in so far that in some cases the two powers are acquired by the same tendril at different periods of growth; and the sensitive part of the tendril does not seem capable of nutation. A more important cause of hesitation is the extraordinary rapidity of the movement. Mr. Darwin has seen the extremity of a tendril of *Passiflora gracilis*, after being touched, distinctly bend in twenty-five seconds, and often in thirty seconds; and he doubts whether it is possible to believe in such rapidity of growth as would account for such movement. In reference to this we may simply remark that instances are on record of extraordinarily rapid growth—as in the case of the flower-stalk of *Vallisneria* to the extent of half an inch in an hour or more—even without any abnormal irritation.

The student will find in Mr. Darwin's work a *résumé* of everything known to the present date on this interesting and curious department of Vegetable Physiology.

OUR BOOK SHELF

Report of the Meteorological Reporter of the Government of Bengal for 1874; *and Administration Report of the Meteorological Reporter to the Government of Bengal for* 1874-75. By W. G. Willson, Officiating Meteorological Reporter. (Calcutta: Bengal Secretarial Press, 1875)

THIS Report, drawn up by Mr. W. G. Willson, who has acted as officiating reporter during the absence of Mr. Blanford, keeps up the high character of the previous reports of this Office It contains not merely the dry details which form an integrant part of such reports, but also an able discussion of them both in their practical and theoretical bearings. As regards new observations, the most important are those from Sibsagar, situated in the north-east of the Assam Valley. The large barometric oscillation from 10 A.M. to 4 P.M., which on the average of the twelve months of 1874 amounted to 0·133 inch, will indicate their high strictly meteorological value. The hourly observations of the different instruments made on four days of each month at a number of the stations are a valuable piece of work, and the discussion of the results three or four years hence will be looked forward to with much interest by meteorologists. An admirable feature of these reports are the averages, corrected up to date in all instances, which are given with the discussion of each meteorological element, thus affording the means of an immediate comparison of the monthly results with the best averages that can possibly be had. Of these averages and comparisons we would direct special attention to those of the rainfall, which is of so great importance in Indian meteorology. Rainfall averages for different periods were prepared during the past year for the information of the Government of India. These have since been further amplified and corrected, and the present report gives the average monthly and annual rainfall for 146 stations, and incomplete averages for some months for other twenty-three stations. An example of the practical application of the rainfall discussions of the Office is given in the report. A forecast of the rainfall was called for by the Government from the Office in the latter part of July 1874, when considerable apprehensions were entertained regarding the prospects of the principal rice-crop of the year. A comparison of the peculiarities of the rainfall up to the end of July with those of past years, and the general similarity of the meteorological circumstances with those of 1872, induced Mr. Willson to submit the opinion that the rainfall in the latter months of the monsoon would turn out as favourable as in 1872, a forecast which fortunately was fully realised.

The inter-relations of the pressure, temperature, winds, and rainfall are particularly inquired into, and some of the results are of very high importance, of which those referring to the weather of January, April, May, and June may be specially referred to. From a careful examination of the observations, Mr. Willson infers that during the hot weather months there is an upper westerly current from the heated plains of Northern India blowing towards the cooler regions of Assam above the southerly winds of the delta; and that, if this be so, the vapour carried from the Bay of Bengal by the southerly winds in the hot weather months is mostly diffused upwards and thence transferred by the upper westerly current to Assam, where it descends, and, meeting the cold north-easterly surface winds, its vapour is precipitated in the copious rains which fall in Assam in this season. According to this view, the excessive rainfall of Assam in May 1874 is completely accounted for by the very unusual strength of the southerly sea winds over the delta in that month; by the abnormally low surface-pressure and high temperature over the plains of Northern India, and by the relatively high surface-pressure and low temperature over Assam. It will be seen that there is here indicated a further development of the important practical question of the prediction of the character of the coming season. As regards these and many other questions of meteorology, still more important observations and discussions may be looked for from the reports of the new Meteorological Department now being organised by Mr. Blanford for the whole of India, including British Burmah and the islands of the Bay.

LETTERS TO THE EDITOR

Oceanic Circulation

I HAVE, at Prof. Thorpe's suggestion (vol. xii. p. 514), compared the results obtained by the use of Prof. Hubbard's Table of the expansion of sea-water with that obtained from Muncke's, and find them almost identical. Both give 2 feet 6 inches as the amount by which the expansion of Column B * (lat. 23° N.) exceeds that of the Equatorial Column. Muncke's Table gives 3 feet 6 inches as the amount by which Column A (lat. 38° N.) exceeds that of the equatorial, while, according to Prof. Hubbard's Table, it is 3 feet 4 inches, being a difference of only 2 inches.

Dr. Carpenter objects † to my result on the ground that I have omitted the consideration of the inferior salinity of the equatorial column. Had I taken this into account, he thinks I would have found that it makes a difference in the opposite direction of about 1 foot in 1,026, which would more than neutralise the whole $3\frac{1}{2}$ feet of slope derived from temperature. I do not know upon what grounds he believes that the difference in salinity is so great between the equatorial and Atlantic columns. Certainly the researches of the *Challenger* Expedition do not warrant any such conclusion. It is true that there is an excess of salinity in the surface-water of the North Atlantic, but it does not extend to any great depth. This superior salinity of the warm upper stratum of the North Atlantic, it may be observed, is an additional evidence that the water is of Gulf-stream origin.

* Columns A, B, and C refer to Dr. Carpenter's section as given in my paper on the "Crucial Test" argument, read before the British Association at Bristol, and published in full in the *Philosophical Magazine* for September. A refers to North Atlantic column in lat. 38°, B to column in lat. 23°, and C to equatorial column.

† See NATURE, vol xii. p. 533.

Through the kindness of the Hydrographer of the Admiralty, I have been favoured with all the observations made in the *Challenger* of the specific gravities of the Atlantic at intermediate depths between surface and bottom. From these observations it will be seen that there is scarcely any sensible difference between the mean specific gravity of the equatorial and the two Atlantic columns.

The following Table shows the mean specific gravities of the three columns :—

Atlantic.			Equatorial.		
	I.	II.		III.	IV.
Depth in Fathoms	Lat. 38° 3′ N. Long. 39° 19′ W. Specific gravity at 60°.	Lat. 20° 58′ N. Long. 22° 57′ W. Specific gravity at 60°.	Depth in Fathoms.	Lat. 1° 22′ N. Long. 26° 36′ W. Specific gravity at 60°.	Lat. 3° 8′ N. Long. 14° 49′ W. Specific gravity at 60°.
Surface	1·02684	1·02635	Surface	1·02616	1·02591
100	—	1·02732	50	1·02630	1·02658
150	1·02677	1·02658	90	1·02627	—
250	1·02641	1·02642	100	—	1·02543
400	—	1·02609	200	1·02607	1·02620
500	1·02608	1·02600	300	1·02618	1·02610
1500	1·02607	1·02620	400	—	1·02629
			1500	1·02618	1·02613
	1·026211 = mean of Column A.	1·02623 = mean of Column B	Mean specific gravity of columns.	1·026181	1·026223
			Mean of the two.	1·026202 = Mean of Equatorial Column C.	

The mean specific gravity of the equatorial column as proved by the two soundings III. and IV. in the Table is 1·026202; and 1·026211 of sounding I. of the Table may be regarded as the mean specific gravity of the North Atlantic Column A, for the observations were made at a place on the same latitude, and only about two degrees to the east of that column. Consequently the specific gravity of Column A exceeds that of the equatorial by only ·000009, a quantity which does not amount to one inch in 1,500 fathoms! Sounding No. II. of the Table, made at a place a few degrees to the east of Column B of the section, gives 1·02623, which may be regarded as the mean specific gravity of that column, and the more so as another sounding made in this region gives identically the same mean value. The difference between the Equatorial Column and Atlantic Column B in lat. 23° N. therefore amounts to only ·000028, or 3 inches in 1,500 fathoms. It must of course be observed that as the specific gravities in the table are not taken at equal intervals the mean of the figures does not represent the mean specific gravity of a column. The number of fathoms represented by each separate value must be taken into account in determining the mean value of a column.

My result is, therefore, not materially affected, even after I have thus taken into account difference of salinity, and computed the amount of expansion according to Prof. Hubbard's Table. The surface of the North Atlantic in lat. 38° to be in static equilibrium must be 3 feet 3 inches above that of the equator, and in lat 23°, 2 feet 3 inches above it.

It is perfectly true that according to the gravitation theory the ocean is never in a state of static equilibrium, but it must be observed that as the surface-flow according to this theory is from the equator polewards, it is the equatorial column that is kept constantly below the level necessary to static equilibrium; hence, were I to make allowance for want of static equilibrium, I should make the slope greater than 3 feet 6 inches. Dr. Carpenter's objection that the force of my argument rests on the assumption that the sea is in equilibrium is based on a misapprehension of the problem, for in reality, by not making allowance for want of equilibrium, I give his theory an advantage which it does not deserve. Were the surface-flow from the North Atlantic to the equator, there would then be some force in his objection, for by leaving out of account want of equilibrium I would be making the slope greater than it should be. Dr. Carpenter states that his objection met the approval of General Strachey and Sir William Thomson at the British Association meeting. If it did, it shows that they must either have misapprehended my argument or his objection to it.

I have again to remind Dr. Carpenter that "viscosity" can have nothing to do with the question at issue. The water has to flow up the "gradient," and that by means of gravity. This is mechanically impossible, whether water be viscous or not.

It is needless to quote the opinions of Lenz, Arago, and Pouillet. They were not in possession of sufficient data to enable them to determine the question with certainty. The question, be it observed, is not "Can difference of temperature produce circulation?" Everyone will admit that were there no other agencies at work but equatorial heat and polar cold, a difference of temperature would soon arise which would induce and sustain a system of circulation; but this condition of things is prevented by the equatorial waters being swept away by the winds as rapidly as they are heated. I submit that I have proved that this is the case in reference to the Atlantic. If I am wrong, let it be shown where my error lies. JAMES CROLL

Edinburgh, Nov. 10

Refraction of Light and Sound through the Atmosphere

THERE is in Upper Thibet a plateau called the "Kyan Chu Plain," on which phenomena of mirage are frequently seen. The plain is at a height varying from 15,000 to 16,000 feet. A cold wind comes down from the surrounding mountains, while an exceedingly hot sun heats the ground. While marching through this plain on Aug. 19 I saw the mirage in perfection. A mountain in front of us, at a distance of about five miles, appeared to be situated on the border of a lake of a deep and rich blue. A shepherd with a flock of sheep seemed to wade through the water, and the reflection of each sheep was most distinct and sharp. The effect was so complete that one of my companions proposed to leave the pool of water at the side of which we had encamped for breakfast, in order to go to the borders of the lake.

I measured the temperature of the air at various heights from the ground. The following readings were obtained :—

Height above ground.	Dry Bulb.	Wet Bulb.
5 feet	49°	32°
4 inches	55°	38°
1 inch	56°	39°

The ground at that place was stony, and no accurate measurement of its temperature could be taken. A few miles further on, however, a sandy ground was found to have a temperature of 90°.

The difference between the temperature of the ground and that of the air was painfully striking to me, as, owing to blisters, I had to walk with bare feet. My feet felt burning hot, while the remainder of the body was unpleasantly cold. The mirage was seen in its greatest perfection at about 9 o'clock A.M.

Such a condition of the atmosphere must, according to Prof. Reynolds, prevent any sound from being heard at a great distance, owing to its refraction upwards. Such was really the case. A rifle fired by the above-mentioned companion at a short distance remained almost unheard.

With regard to the question whether our better hearing at night is due to the absence of disturbing noises, or to the cause suggested by Prof. Reynolds, I wish to remark that the Upper Himalayas are particularly free from any disturbing noises, yet the increase in our power of hearing at night is most marked.

Road, N.W., Nov. 20

Evidences of Ancient Glacier Action in Central France

HAVING read with much interest Dr. Hooker's contribution to NATURE on "Evidences of Ancient Glaciers in Central France," I am tempted to send you a few remarks which may interest those who look out for glacial phenomena wherever they travel.

When travelling in Auvergne with Sir William Guise in 1866, we unfortunately missed the transported erratics in the Tranteine Valley, described by Dr. Hooker. We saw, however, examples of what we believed to be ice-borne erratics, on more than one occasion, and consulted M. Lecoq on the subject at his residence at Clermont Ferrand. He had observed travelled boulders in certain localities, but, as mentioned in the note-book of Sir William Guise, "attributed to transport by snow many of the effects generally assigned to glacial action."

I would also ask attention to a subject which appears to me of considerable interest with regard to the age of the most modern

of the lava currents of Auvergne. M. Lecoq had in his museum some fossil remains of the Marmot, the Mammoth, and the tichorhine Rhinoceros, and he distinctly told us that these relics of northern mammalia, which geologists are accustomed to associate with glacial times, were mostly found in cracks and fissures in the lava-streams near Clermont Ferrand. From this it would appear that the latest lava streams of Auvergne had become cold, consolidated, and fissured before the introduction of the bones and teeth of the northern quadrupeds into the fissures.

But if this prove to be true, on further investigation, I do not wish to imply that there have been no volcanic eruptions in Central France since the last outpour of lava currents, or the days of the Mammoth. On the contrary, I think the evidence is the other way. I have just returned from a visit to the extinct volcanos of the Haute Loire and the Ardêche, where I was accompanied by my friends Sir William Guise, Capt. Price, and Mr. Lucy; and I believe there is evidence of a certain amount of volcanic action in the Ardêche since the outpouring of the later lava-streams. There are outbursts of volcanic ash and scoriæ which form what are termed "chimneys," and which are blown right through the most recent lava-currents. Both near Montpezat, so admirably depicted by Mr. Scrope, and near the bridge at La Beaume, there are outbursts and eruptions through the basalts, which dislocate and throw off the basaltic columns. It is not improbable that some of these attempts at forming a volcano happened in the Ardêche during the fifth century, when the Archbishop of Vienne, Alcimus Avitus, in his homily on the "Rogation Days," speaks of "frequent shocks of earthquakes," and "fires often blazing," and "piled up mounds of ashes." Gregory of Tours also speaks of stags and wolves wandering about Vienne. These wild animals may have been driven from the forests of the Ardêche, by these last volcanic eruptions, as far as Vienne. W. S. SYMONDS

Communication of Information among Bees

SOME two or three years ago a swarm of bees entered a very small hole under the slates near the eaves of the roof of my house in the Highlands, and established themselves for the summer but died out in the subsequent winter. I infer that there were no survivors among the bees to remember the circumstance (see Appendix to Kirby and Spence's "Entomology") and to account in any degree for what occurred this summer.

The house is of four stories, and stands in the garden, in which, about fifty yards from the house, on the other side of a hedge, are my beehives. For a few days, during which there were the usual indications of swarming being imminent in one of the hives, a great many bees found their way into the lower rooms of the house; there was a constant hum of bees in one of the chimneys, at the top of which there was always a group flying about. The top of this chimney is about thirty feet horizontally from the settlement of the old swarm, and fifteen feet above it; there was also occasionally a cluster of bees on the roof of a "semi-detached" lower building (the kitchen) on the other side of the house from the old settlement, but *as far as we saw* no bees visited the old settlement, and nothing indicated any intention of the swarm to go there, though we expected it to make for the house and probably for the chimney I have mentioned. In due time the swarm came off and rose unusually high, and I immediately made some smoke in the chimney to prevent their entering it. Presently the swarm settled on a low apple-tree and was snugly hived in the usual way in a straw "skep" about noon. Next day, however, about 10 A.M., the swarm left its "skep" and made for the old settlement without any hesitation, and there they established themselves in spite of all we could do.

Of course the whole proceedings may have been disconnected, but the impression left on my mind was that the queen, or her counsellors, had previously "prospected," and resolved to go to the old settlement as an eligible "location," and that the common bees learned somehow that "the house" was to be their destination, but that some of them fancied the chimney, others the roof of the kitchen, and others wandered vaguely in at various open windows, while the queen knew exactly where she wanted to go, but got confused the first day.

The manner in which the bees learned that the house was to be their destination may have been that the queen in her investigations had left strong traces of herelf at the chimney and on the roof of the kitchen, which attracted the bees to these places, and a general odour of royalty about the house which induced the bees to come in at the windows; but it may have been that there was some "talk" in the hive about it. In connection with Sir John Lubbock's papers, the incidents may be worth your notice.

There has also been some question as to the distance bees go in search of "pasture." It may be worth noting that at Arisaig House, I am told, bees are to be found in the peach-house every spring at the time of the blossom, while, so far as I can learn, there are no hives within ten miles but my own, which are separated from it by an arm of the sea (Loch Ailort), a mile wide with islands, and a second arm of the sea (Loch-na-Nuadh), two miles wide without islands, the whole distance being about four miles from the hives to the peach-house.

A New Palmistry

I HAVE lately consulted two standard works upon the proportions of the human figure to which Prof. Ecker does not refer in the suggestive paper of which I gave an abstract in NATURE (vol. xiii. p. 8), in the hope of finding some definite information as to the relative lengths of the "index" and "ring" fingers. In the first of these two works, Quetelet's "Anthropométrie" (Bruxelles, 1870), no mention whatever is made of the proportions of the several digits, whether of hand or of foot; while from the second authority, the "Proportionslehre" of Carl Gustav Carus (Leipzig, 1854), all the information that can be derived, meagre as it is, is purely inferential. In the skeleton of a hand represented at Fig. 4, Taf. iii. of this fine folio work, the "index" is considerably longer than the "ring" finger; and in the letter-press explanatory of this plate, a table is given of the lengths of the various factors of the digits, *e.g.* the metacarpals and the three phalanges, in "modulminutes," constant lengths, each of which is equivalent to about seven millimetres. Now the length of the "index" is twenty-three, while that of the "ring" finger is only twenty "modulminutes," the former thus exceeding the latter digit by about twenty-one millimetres, a difference much greater than any which has been recorded by Prof. Ecker. In the extended left hand of an *ideal* (sexless) figure, at Taf. iv. (*ibid.*), the "ring" and "index" digits are of the same length, the former being perhaps a shade longer.

Regiments and large asylums would be a fertile field for the further investigation of this interesting and highly suggestive subject. J. C. GALTON

IN Mr. J. C. Galton's interesting article bearing the above title, in NATURE, vol. xiii. p. 8, no mention is made of the position of the hand at the time of making the observation as to the comparative length of the fingers. Perhaps Mr. Galton will kindly make it known whether Dr. Ecker has specified the position which he adopted. That the position makes some difference may be clearly seen in the following manner:—

Place the hand, back upwards, horizontally across the front of the chest, and observe the comparative length of the "index" and "ring" fingers. Then, by a motion of the wrist, moving the arm as little as possible, turn the hand outwards in the same plane, until the fingers stand at right angles to their first position, and again observe the two fingers. Naturally the "index" will appear to be longer in the first position than in the second, on account of the different condition of the muscles. Neither of these positions is likely to be adopted by anyone investigating the subject, but in any comparison of results *one and the same* position should be referred to as a standard, and this standard should specify whether the hand is held with the back or the face upwards. Dissimilarity between the two hands, as mentioned by Mr. Pryor, appears to be common. F. T. MOTT

Leicester, Nov. 19

I HAVE made a collection of over fifty outlines of the fingers of European hands (right and left). At present I find that the tendency in the female hand is to a proportionately longer third than index, in *both* hands, than in the male. In all the hands I have examined, the third finger of the left hand (when longer than the index) is also proportionately longer than the same finger of the right. In this series I have found only one case of an index longer than the third, and only one in which they were equal (both males). These are all carefully drawn into a pocket-book, care being taken that the hand is perfectly free from any muscular strain, which alters the result very appreciably; and the race, sex, and general physical characteristics are noted on the sheet. The list at present includes some eminent classical

scholars, a distinguished artist, and numbers of persons of more than average culture; yet there appears to be no correspondence between the mind and the length of the index finger.

R. A. N.

Extraordinary Tides

In last week's "Notes" you say, speaking of the unprecedentedly high tide of the 15th inst., that "no one seems to have expected an unusual tide." Allow me to state, sir, that in the *Spectator* of Nov. 7th, 1874, I predicted this extraordinary tide. As a matter of fact, the tide was higher than that of March 1874, through the unusually swollen state of the river by floods and the N.W. gale.

No extraordinary tide can occur this side of March 1878.

4, Buccleuch Place, Dulwich B. G. Jenkins

Further Linkage Work

In the interesting communication to Nature, vol. xii. pp. 214–216, Prof. Sylvester gives account of the Hart and the Sylvester-Kempe "linkages." Of four points, three have work assigned. Problem: To employ the nondescript point.

First.—The Hart linkage yields the *Cissoid*, exactly as that curve is defined. Thus, with p circling, q resting, and s tracing straight line; r traces cissoid. Second.—The Sylvester-Kempe linkage yields the *Hyperbola*, in that curve's simplest vector form. Thus, with r opposite, to p resting, and pq, ps in constant directions; r traces the hyperbola whose assymptotes are these directions. Geo. J. P. Grieve

Burntisland, N.B.

A Criminal Dog

I was so much pleased with the anecdote in Nature (vol. xiii. p. 36) of the criminal dog who buried the cat he had murdered, that I told my wife; but I did not mention the breed of the dog.

She said, "Was it not a retriever? because they always bury their food, so that it may become *high*." I could but answer that it was a retriever, and added that I was afraid she had hit upon the real reason for the act. R. S. Culley

General Post Office, Nov. 12

OUR ASTRONOMICAL COLUMN

The Binary Star 44 Bootis.—In No. 2,064 of the *Astronomische Nachrichten*, Dr. Doberck, of Markree Observatory, has given an orbit of this binary, and a comparison with measures to the present year. The elements are—

Peri-astron passage	1783·01
Node	65° 29′
Peri-astron from node on orbit	1° 18′
Inclination	70° 5′
Excentricity	0·71
Semi-axis major	3″·093
Period of revolution	261·12 years.

Dr. Doberck makes no reference to Sir W. Herschel's second measure in 1802, giving for the angle 62° 59′, or less than 3° in advance of his measure 1781, August 17, when the companion was first detected. The measure of 1802 was registered s.p. and "corrected by a subsequent observation to n.f.," as Sir John Herschel states in Memoirs R.A.S. vol. v. p. 46; but it is now pretty evident, from a projection of all the measures to 1875, that the quadrant was correctly registered s.p., and consequently the angle for 1802·246 should be 207° 1′ according to our present method of reckoning. The angle calculated for this time from the above orbit is 206° 55′, and this close agreement must be taken as very satisfactory evidence that Dr. Doberck has given us something like the true orbit, notwithstanding the difficulty of the case. It had been surmised that Sir W. Herschel's measures were to be increased 180°, Struve, in 1819, obtaining an angle of 228°, and Herschel and South, in 1821, 229°, but the position of the companion on the preceding side of the principal star, instead of the following side where it had been seen in 1781, was accounted for both by Sir John Herschel in his "Micrometrical Measures of 364 Double Stars," and by Struve in "Mensuræ Micrometricæ," by supposing motion in an orbit passing nearly through the eye of the observer, with the longer axis of the ellipse but slightly inclined to the meridian. Dr. Doberck finds an inclination to the tangent plane of the heavens, of 70°. Calculating from his elements, the following appear to have been the angles and distances from 1785 to 1800:—

1785·0 ...	Position	74°·0	...	Distance	0″·85
90·0 ...	,,	98·3	...	,,	0·55
92·5 ...	,,	132·0	...	,,	0·50
1795·0 ...	,,	162·7	...	,,	0·53
1800·0 ...	,,	199·0	...	,,	0·86

The calculated distance for epoch of Sir W. Herschel's measure in 1781 is 0″·89, and for that of 1802, 1″·05; the observed distances being only by estimation in diameters of the companion, giving "½ or ¾ diameter" of smaller star in 1781, and "barely ½ diameter" in 1802, with power 460 in both years, are perhaps sufficiently well represented, though very admissible correction to one or two of the elements may diminish the distance in 1802 or increase that in 1781.

For comparison with future measures we have from Dr. Doberck's orbit—

1876·0 ...	Position	241°·45	...	Distance	4″·887
78·0 ...	,,	241·71	...	,,	4·928
80·0 ...	,,	241·97	...	,,	4·971

The Minor Planets.—In No. 35 of the Circulars of the *Berliner Astronomisches Jahrbuch*, Prof. Tietjen notifies an arrangement which has been entered into by the Observatories of Leipsic, Leyden, Lund, Pola, and Vienna, for the more systematic and regular observation of the small planets. These Observatories have agreed to report to the editor of the *Jahrbuch*, every fortnight, the names or numbers of the planets which have been observed, with the dates of observation and the limits within which the planets whose positions are more uncertain have been sought. These communications will be so timed that they may arrive at Berlin on the 1st and 15th of the month, and will be there arranged, printed, and circulated. An invitation is extended to those Observatories where the small planets are occasionally, though not regularly, observed, to join in the proposed scheme. In the same manner the state of calculation as regards the various members of this group will be made known. The Milan Observatory has already engaged itself to calculation for No. 151.

Mr. Daniel Kirkwood, of Bloomington, Indiana, writes with reference to the resemblance which exists between the elements of certain minor planets, instancing as the most striking case that of No. 54, Alexandra, and No. 141, Lumen. An inadvertent application of the angle usually designated ω (or the distance of perihelion from node) in the wrong direction, renders the similarity between the orbits of these planets somewhat less striking than in Mr. Kirkwood's communication, but there is nevertheless considerable resemblance, as the following figures will indicate:—

	Alexandra.	Lumen.
Perihelion	294° 16′	341° 32′
Node	313° 49′	318° 59′
Inclination	11° 47′	11° 33′
Excentricity... ...	0·1987	0·2233
Mean distance ...	2·7093	2·7095
Period	1628·9 days. ...	1629·0 days.

The Zodiacal Light.—Those who are interested in the observation of this phenomenon will do well to be on the alert during dark evenings in the winter months. The most conspicuous exhibitions of the light in this country during the last few years have occurred in the month of January, the long standing recommendation to

expect the most notable displays in the evenings about the vernal equinox having thus been by no means justified in the result. The light was perceptible for a short time last Sunday evening, without any yellowish tinge, and the position of axis somewhat doubtful from the indifferent state of the sky. Prof. Heis's observations in December from 1851 to 1870, place the mean position of the apex on the equator in R.A. 349°, or with about 82° elongation from the sun: this refers to the eastern arm of the phenomenon.

THE RAINFALL

THE extraordinary rainfall of the past year will make 1875 memorable in the annals of meteorology. With scarcely an exception every part of Great Britain has suffered from a plague of rain; from the Continent and from North America there come the same tidings of incessant rain and vast inundations. Even in a country so far distant as China we hear of unprecedented rains. The following statistics concerning a rainfall that occurred in China between last August 31st and September 1st will be read with astonishment. Our information is derived from the bulletins of the Meteorological Observatory of the Fathers of the Society of Jesus at Sikawei, on whose accuracy of observation we may doubtless depend. The readings show that between four and seven o'clock in the morning of September 1st the mean rainfall per hour was 32·7 millimetres, which makes the astonishing rate of 1·287 inch for each of those three hours. Well may the compiler remark, "We think there are few examples of such a figure, except in the case of waterspouts."

The total quantity that fell in the garden of the Jesuit Observatory during the twenty-four hours that elapsed between four o'clock on Tuesday, 31st August, and the same hour in the afternoon of Wednesday, 1st September, was 218 millimetres, or no less than 8·59 inches for the rainfall of a single day! After this the records of rainfall in Great Britain look insignificant. Nevertheless the fall has far exceeded the ordinary statistics. At Balbriggan, a town a few miles north of Dublin, the rainfall from 9 A.M. on the 13th inst. to 9 A.M. on the 14th inst. was two inches. This is the greatest fall in twenty-four hours which occurred in that town for the last ten years.

It is important to obtain statistics from the southern hemisphere. It is probable a vast drought must somewhere compensate for the floods of water poured over a large part of the northern hemisphere.

THE WORK OF THE CHALLENGER*

THIS report is dated from Hilo Hawaii, August 18, and describes the cruise of the *Challenger* from Yokohama to the Sandwich Islands. The *Challenger* left Yokohama on the 16th of June, and ran an easterly course between the parallels of 35° and 40° north latitude, as far as the meridians of 155° east. She then turned nearly directly southwards and reached Honolulu on the 27th of July. Twenty-four observing stations were established, at each of which most of the desired observations were made.

On the 17th of June, Prof. Thomson's Report goes on, we sounded in 1,875 fathoms with a bottom of bluish-grey clay and a bottom-temperature of 1°·7 C., forty miles to the south-east of No Sima Lighthouse. The trawl was put over, and it brought up a large quantity of the bottom, which showed the clay was in a peculiar concretionary state, run together into coherent lumps, which were bored in all directions by an Annelid of the Aphroditacean group. In many cases the Annelids were still in the burrows. Among the clay there were large lumps of grey pumice. The hyoid zoophytes were represented by a very remarkable species, apparently referable to the genus *Monocaulon* of Sars, a Corymorpha-like solitary polyp with adelocodonic gonophores; but instead of being of the proportions usual in its group, the stem in one of our specimens measured upwards of seven feet in height, while the polyp-head was nine inches in diameter across the proximal row of tentacles. We afterwards got another fine example of the same species at a depth of 2,900 fathoms (Station 248). The temperature of the surface of the sea stood during the day at nearly 23° C., considerably above the temperature of the air; and a serial sounding gave the isotherm of 10° C. at a depth of little more than 200 fathoms. We were therefore evidently under the thermic influence of the Japan current, which was found by observation to be running in an easterly direction at a rate of $1\frac{1}{2}$ knots an hour. The thermometers registered a uniform temperature of 1°·7 C. from a depth of 1,000 fathoms to the bottom. About twenty Albatrosses of a nearly uniform brown plumage with whitish heads, probably the young of the common North-Pacific species in their second year's plumage, followed the ship.

On the following day there was a stiff breeze from the southward, and with a heavy sea. We sounded, however, successfully in 3,950 fathoms, our deepest sounding in the North Pacific position by dead reckoning lat. 34° 43′ N., long. 144° 2′ E., with a bottom of "red clay." The high surface-temperature continued to be maintained; and the position of the isotherm of 10° C., at station 239 at a depth of nearly 300 fathoms, indicates that up to this point, at all events, there was no diminution in the influence of the "Kuro-Siwa."

On the 21st the temperature-observations gave a singular result. The surface-temperature had fallen to 18°·2 C., and the belt of water above 10° C. was reduced in depth to considerably below 100 fathoms, while all the isotherms, at all events to a depth of 400 fathoms, rose in proportion. There seems to be little doubt, from a comparison of the American temperature-results with our own, that this sudden diminution of temperature is due to a cold surface-flow from the Sea of Okhotsk, probably through Pico Channel or Vries Strait. Very likely its effect may not be found to be constant; and at this season it possibly attains its maximum from the melting of the snow over the vast region drained by the Amoor and the Udi and Siberian rivers with a southern outflow.

On the 26th of June we sounded in 2,800 fathoms. Several forms were met with which apparently do not occur on the surface, particularly a number of species of a group which is so far as we know entirely undescribed. It seems to be intermediate between the Radiolarians and the Foraminiferas, resembling the former in the condition and appearance of the sarcode and in the siliceous composition of the test, and the latter in external form. The broken tests of these organisms are extremely abundant in the "red clay" soundings; a sufficient number of observations has not yet been made to enable us to say with certainty what is their bathymetrical distribution. From a zoological point of view the haul of the 28th was remarkably successful; there were one or two fishes, a *Scalpellum*, a number of annelids, particularly a prominent aphroditacean; Echinoderms of the genera *Pourtalesia*, *Archaster*, *Brisinga*, and *Antedon*; a fine species of *Cornularia*, several examples of *Fungia symmetrica*, and some *Actiniæ*. The general distribution of temperature remained much the same, the isotherm of 10° C. retaining its position near the 200-fathom line.

We trawled on the 2nd of July in 2,050 fathoms with a bottom of light brownish ooze with many *Globigerina*-shells. The bag brought up a number of lumps of pumice, and among them a very characteristic assemblage of deep-sea animals, the most interesting an undescribed

* Abstract of "Report to the Hydrographer of the Admiralty on the Cruise of H.M.S. *Challenger* from June to August 1875," by Prof. Wyville Thomson, F.R.S., Director of the Civilian Scientific Staff on Board. Read at the Royal Society Nov. 18.

species of *Hyalonema*, which occurred in considerable numbers and in an excellent state of preservation. The form of the sponge-body is almost spherical, with a comparatively small oscular opening, and the coil is much shorter than in *H. Sieboldi*, in the largest specimens not more than six inches in length. One remarkable point was, that in no case was there a commensal *Palythoa* connected with this sponge; the coil was always perfectly clean. The spicules of the network and of the sarcode closely resemble those of the Japanese species, but they all present marked specific differences in detail of form.

On the 12th of July the trawl was lowered at a depth of 2,740 fathoms. The net contained very few animals, and was greatly torn and frayed; but in a kind of packet formed by an accidental folding of the net, there were about a hundredweight of black mammillated concretions, which, when they were poured out on the deck, had very much the appearance of potatoes. The external surface of the concretion was slightly rough, and a number of small animal forms, particularly a minute rhizopod in a membranous tube, nestled in the crevices. The nature of these concretions will be discussed hereafter.

On the 14th of July we reached the point lat. 38° 9′ N., long. 156° 25′ W., whence we turned southwards towards the Sandwich Islands. For the last few stations the temperature of the water had been gradually sinking, and the influence of the Japan current dying out; the isotherm of 10° C. was now only 100 fathoms below the surface.

On the 17th of July we sounded in 3,025 fathoms, the bottom still "red clay;" and on the 19th in 2,850 fathoms. A serial sounding taken at the latter station to 1,500 fathoms showed a considerable rise in the temperatures near the surface, the isotherm of 10° C. having again sunk to a depth of 200 fathoms, and that of 15° C. corresponding with the 100-fathom line.

On the 24th, in 2,775 fathoms, the Albatrosses which had followed the ship, to the number of from fourteen to twenty daily since we left Japan, left us. In the evening of the 27th, the *Challenger* anchored in the harbour of Honolulu.

This cruise naturally divides itself into two parts: a section about 3,170 nautical miles in length, including the stations from No. 237 to No. 253, very slightly to the northward of east, between the parallels of 35° and 38° N. lat.; and a meridional section of 1,128 nautical miles, along the meridian of 155° W. long. The first of these sections corresponds very closely in relative position with the section in the Atlantic between Sandy Hook and the Açores, and the points of resemblance and difference between them, when fully worked out, must prove most instructive. The two sections cross the two great deflections to the northward of the equatorial current, in the Atlantic the Gulf-stream, and in the Pacific the "Kuro Siwa;" and the thermic influence of the two currents is fairly contrasted. The influence of the Gulf-stream, if not absolutely greater (and this is a point which it will be somewhat difficult to determine), is at all events much more concentrated and effective, owing to the continuity of the coast-line of the American continent, to the way in which the water of the equatorial current is driven into the Gulf of Mexico and superheated there, afterwards to be kept together and ejected in a defined stream through the Strait of Florida, and to the absence of periodical winds in the Atlantic. In the Pacific, on the other hand, the main flow of the equatorial current is weakened among the passages of the Malayan Archipelago; and although a large part of it is directed northwards by the broken barrier formed by the Fiji Islands, the New Hebrides, and Papua, it almost at once enters the region of the Monsoons, where it is thwarted for half the year; and it can only be regarded as comparable with that portion of the reflux of the Atlantic equatorial current which passes outside the West Indian Islands. It passes the south coast of Japan nevertheless as a very palpable and apparently a permanent current, exercising a very perceptible thermic influence to a depth of at least 300 fathoms.

In traversing the Pacific the influence of the Japan current appears to be gradually lost, while I am still inclined to believe that in the Atlantic the Gulf-stream is banked down against, and reflected from the western coast of Europe. It is a question of great complexity; but it seems to me that it is consistent with our experience that the temperature of the water of the ocean at any one place is due in a great measure to the temperature of the source of that water—not entirely due, for in passing through a long distance the temperature of even the greatest masses of water is certainly gradually altered by conduction and mixture.

The suggestions of Dr. Carpenter and Mr. Buchanan that the existence of a deep layer of warm water in the Atlantic might be connected in some way with the mean annual temperature of the area, and the absence of ocean-currents, are very suggestive; and I looked forward with great interest to an opportunity of testing them in the corresponding position in the Pacific. But there seems to be no trace of anything of the kind; as the influence of the equatorial reflux becomes weaker the temperatures fall uniformly.

To show that the conditions in the two oceans differ more in degree than in kind, I give in Plates I. and II. curves constructed from serial soundings along nearly corresponding lines in the Atlantic and Pacific. Curves A and B are added on Plate I. to show the position of the deeper belt of abnormally warm water, which makes its appearance near the coast of Europe.

There seems to be little doubt that the enormous mass of cold water which fills up the trough of the Pacific is like the cold bottom-water of the Atlantic, an indraught from the Southern Sea. The more the question is investigated the less evidence there seems to me to be of any general ocean circulation depending upon differences of specific gravity. It seems certain that both in the Atlantic and in the Pacific the bottom-water is constantly moving northwards; and I am now very much inclined to refer this movement to an excess of precipitation over the water-hemisphere, a portion of the vapour formed in the northern hemisphere being carried southwards and precipitated in the vast southern area of low barometric pressure. I hope to enter fully into the discussion of this matter on a future occasion. The temperature of the water is greatly lower in the Pacific for the first thousand fathoms than in the Atlantic in the corresponding latitude of 35° N. There is one very remarkable difference between

the two basins. While in the Atlantic it seems certain that the temperature sinks gradually, though very slightly, for the last thousand fathoms to the bottom, it appears that in the Pacific the minimum temperature of 1°·7 C. is reached at a depth not greater than 1,400 fathoms, and that from that depth to the bottom the temperature is the same.

The soundings from Yokohama to Honolulu are remarkably uniform in depth, the twenty-two soundings on one line which are unaffected by the neighbourhood of land giving an average of 2,858 fathoms. The nature of the bottom is also very uniform; and, according to the nomenclature which we have adopted, it is in each case noted on the chart as "red clay." It is usually, however, somewhat greyer in colour than the typical "red clay," and contains a large proportion of the tests of siliceous organisms, a proportion which increases with increasing depth, and a considerable proportion of pumice in different states of comminution and decomposition. The clay contains scarcely a trace of carbonate of lime, although the surface swarms with ooze-forming foraminifera. In some cases the trawl came up half full of large lumps of pumice, which seemed to have been drifted about till they were water-logged, and to be softening and becoming decomposed; these pieces of decomposing pumice were often coated and pervaded throughout with oxide of manganese. Over the shale area the red clay was full of concretions, consisting mainly of peroxide of manganese, round, oval, or mammillated and very irregular, varying in size from a grain of mustard-seed to a large potato. When these concretions are broken up, they are found to consist of concentric layers having a radiating fibrous arrangement, and usually starting from a nucleus consisting of some foreign body, such as a piece of pumice, a shark's tooth, or a fragment of any organism, as for instance in one case a piece of a Hexactinnelid sponge, of the genus *Aphrocallistes*, which was preserved as a very beautiful fossil in the centre. The concretions appear to form losse among the soft clay; the singular point is the amount of this manganese formation, and the vast area which it covers.

We were particularly successful during this cruise in getting good samples of the fauna from great depths; and we found that the fauna of the North Pacific at depths of from 2,000 to 3,000 fathoms, although not very abundant in species, is by no means meagre. For each of six dredgings and trawlings at depths greater than 2,000 fathoms, we found along with a few fishes a fair representation of all the larger invertebrate groups; and in one dredging, No. 253, at a depth of 3,125 fathoms, we took a small sponge, a species of *Cornularia*, an *Actinia*, an annelid in a tube, and a Bryozoon. We were again struck with the wonderful uniformity of the fauna at these depths; if not exactly the same species, very similar representatives of the same genera in all parts of the world. I am glad to be able to report that everything is going on in a satisfactory way in the departments under my charge.

ACOUSTIC CLOUDINESS

WHEN the weight and number of the guns in action are taken into account, the following extract from "My Experiences of the War between France and Germany," vol. ii. pp. 285-9, by Archibald Forbes, will probably be regarded as the most extraordinary instance of "acoustic cloudiness" hitherto recorded. The complete reversal of the optical and acoustical conditions on two succeeding days renders the case very perfect. I am indebted for the extract to the obliging kindness of Mr. James Kenward, of Birmingham.

"The morning of the 6th presented a remarkable contrast in every respect to that of the preceding day. The latter had been cold to the chilling of the marrow, and so thick that nothing was to be seen half a mile away. The former was clear, bright, and warm as a morning in the end of March. Yesterday the air was charged with sound; to-day there reigned the stillness of an Arcadia that knows not war. Men looked at each other in blank amazement. Had Paris, forts, big guns, bombardment, and the no-bombardment on the eastern side alike been spirited away? Had the French reply shut up our pretty Spandau toys in one day? Or, on the contrary, had those pieces of finished mechanism stove in the forts and batteries bodily? And if we were going up to Montmorency, should we see the white flag on the top of Montmartre in token that all was over? Men were reticent in expressing speculations, but at the corners of the straggling lanes of Margency I heard the words 'Capitulation,' 'Parlementaire,' muttered as the feldgensdarmes and the orderly-men gossiped in little groups. Making the best of my way to head-quarters, I found head-quarters in ignorance and suspense. Nobody could interpret this strange, ghostly silence. There had come from Versailles on the previous night a telegram stating that the King was well pleased with the results which the day's bombardment had achieved. So it was plain the silence was not on our part due to coercion. 'Negotiations, then?' I suggested to my friendly interlocutor. 'No, that cannot well be,' was the reply, 'since in that case we should have received instant instructions to silence our Maas Army batteries, and this has not been the case.' 'Are they firing, then?' I asked, for it might be that I had been struck with sudden deafness. 'No, it would seem not, I can hear nothing. The silence is a puzzler, but we are sure to hear all about it within a few hours.' Determining to anticipate by personal investigation the information which was kindly promised me, I rode off to the front of Montmorency, whence there lay spread before the eye the wide panorama of the north side of Paris. Still all was silent as the grave. There was the white foreground, the ice-bound river, and the St. Denis chimneys smoking lustily according to their wont. Neither from the east nor the west came there the slightest sound of firing. A slight haze-bank hung over Le Bourget, which might have been snow, fog, or the filmy smoke of a cannonade; but, if the latter, it must have surely been audible. There I found three mounted officers, and we had a little talk about the position. They inclined to the armistice-negotiations theory, more especially as they had not heard a single shot since morning. As we spoke, there came a white jet of smoke out of the grey side of La Briche. No sound; for all the noise it made it might have been an escape of steam. But in a second or two we did hear something—the close swish of the shell, and then the explosion about fifty yards to the right. La Briche could not resist the temptation of the group. 'No negotiations, then, that is certain,' was the remark as we broke up and went our several ways.

"This action of La Briche rather intensified the puzzle, because it seemed to knock away the only explanation. I could not go to the south, but I could visit the batteries about Pont Iblon, and get at the root of the matter.

. . . .

"I came on to Gonesse alone. What was my surprise to find all the German batteries from Gonesse to Sevran firing away vigorously! They had been at it since eight in the morning. In Gonesse I learned that the firing on the south side was believed to have recommenced at the same hour, and was certainly going on. Yet at Margency and Montmorency we could not hear a sound. It was all owing to the air; it was to-day as non-conducting of sound as it had been the reverse yesterday. Even in Gonesse we could not hear the guns that were thundering, so to speak, at our elbows."

The condition of things here so graphically described discloses a state of the atmosphere precisely similar to that existing at the South Foreland on the 3rd of July, 1873. There, as here, the belching of the smoke from

the 18-pounder, the howitzer, and the mortar, resembled noiseless jets of steam, projected, "so to speak, at our elbows." JOHN TYNDALL

Royal Institution, Nov. 17

CHARLES BLACKER VIGNOLES, F.R.S.

THIS celebrated engineer died on the 17th instant at Hythe, at the age of eighty-three years. Although he won his fame mainly as an engineer, yet his services to science were of considerable importance. Mr. Vignoles was descended from an ancient French family which had taken refuge in England after the repeal of the Edict of Nantes. His father, Capt. Vignoles, was an officer in the 43rd Regiment of the Line, and his mother was a daughter of Dr. Charles Hutton, the celebrated mathematician and professor at the Royal Military Academy, Woolwich. When young Vignoles was only twelve months old, his father lost his life at the storming of Pointe-à-Pierre, Guadaloupe, when Sir Charles Grey, the commander of the British forces, gave the former a commission in the army. Thus his career has been an unprecedentedly long one. His grandfather, Dr. Hutton, undertook his education, and the pupil certainly turned out a credit to his teacher. For a short time before the conclusion of the great war which ended in 1815, Vignoles served under the Duke of Wellington on the Continent, and after visiting America about 1822, he returned to England and threw himself enthusiastically into the engineering profession. The railway movement was just then gathering strength, and Vignoles was associated with some of the earliest efforts to establish lines in this country. After the Liverpool and Manchester Railway Bill was thrown out of Parliament in 1824, he was, in 1825, selected by Messrs. Rennie to take charge of the new surveys which the Liverpool Committee ordered. From this time forward Vignoles was ever in the van of the railway movement, and had the foresight to predict, amid some incredulity and ridicule, to what gigantic results it would lead. In 1826 he was employed by Messrs. Rennie to make surveys for a line from Nine Elms, Vauxhall, Dorking and Shoreham, to Brighton; and in 1834 he escorted M. Thiers over the railways which had been built under his superintendence. The great French Minister's dictum was, "I do not think railways are suited for France." In England, in Ireland, on the Continent, and in America, Mr. Vignoles took a prominent part in the carrying out of great railway and other engineering works. Probably one of his greatest works was the magnificent suspension bridge over the Dnieper at Kieff, commenced in 1848 and finished in 1853, at a cost of 432,000*l*. A fine model of this is now in the Crystal Palace.

Mr. Vignoles became a member of the Institution of Civil Engineers in 1827, and was elected President in 1870, when he gave a very able address on the progress of engineering. In 1842 he gave a series of remarkable lectures as Professor of Civil Engineering at London University College. In 1855 he was elected a Fellow of the Royal Society; he was also a Fellow of the Royal Astronomical Society, and was for long a regular attendant at its meetings. The Eclipse party of 1860 was to a great extent indebted to him for all the local arrangements, and its success was mainly due to his exertions. He was also Honorary Treasurer of the Expedition of 1870, was on board the *Psyche* when she struck, and was afterwards indefatigable in aiding the necessary arrangements. In the early part of its career he took an active part in the meetings of the British Association, contributing several papers to the Mechanical Section.

As might be expected, Mr. Vignoles was a man of great energy and strong physical constitution. On the Thursday before his death he attended the annual inspection, in his capacity of Lieutenant-Colonel, of the Engineers and Railway Volunteer Staff Corps. On the Saturday following he was struck with paralysis, and remained unconscious till his death on the following Wednesday. He was buried yesterday at the Brompton Cemetery.

THE GERMAN COMMISSION ON ARCTIC EXPLORATION

FURTHER details concerning the work of this Commission appear in a recent number of the *Karlsruher Zeitung*.

The Commission cannot recommend another Arctic expedition. The task of special geographical discovery, to whose solution previous expeditions have contributed, must, since the polar regions have been opened up at many points, give place to the task of exploring in detail the region of which we now have a general knowledge, and on the results thus attained to construct a sure basis for wider researches. "Without such an established basis, every new Arctic expedition might, according to the circumstances, accomplish more or less good results, but for this a considerable expenditure of public means would be the less advisable, that we may have a sure expectation, by following a different course from that hitherto pursued, of accomplishing, more slowly perhaps, but all the more surely, the exploration of the Arctic zone, and at the same time solve very important problems in science."

The Commission unanimously agree that the exploration of the Arctic region should be undertaken. The last part of the Report, without pretending to be complete, discusses very important questions in all departments of science, the solution of which is to be obtained by Arctic exploration. The majority of meteorological and hydrographic problems, many questions in the regions of terrestrial magnetism and physical astronomy, a number of questions in the department of natural science, in other words, the discovery of the laws of periodical phenomena and of the variations from these laws, cannot be accomplished by an Arctic expedition of the kind hitherto sent out. Such an expedition cannot remain for any length of time at a number of points, and can therefore furnish observations bearing only on time and place, which do not in the least enable us to conclude what would be the condition at another time.

It is otherwise with those scientific problems in which the establishment of facts is of importance, as in the majority of problems in natural history, and in many of the other regions of natural science and geography. For such problems an expedition of the usual kind would accomplish very valuable results. For the solution of other problems the establishment of observing stations is desirable, from which, through as long a period as possible, observations of periodical phenomena should be undertaken. But in order to be able to generalise the results, corresponding observations should be made from time to time at intermediate stations and in regions lying in the neighbourhood. A German expedition would thus erect observing stations on particular points, and then would make such arrangements that, according to the special circumstances of the stations, or to accomplish special scientific objects, exploring journeys could be made from the stations as a basis, by land and water, in sledges, ships, or boats. This combined system of fixed stations and exploring journeys would give us at least the prospect, by the minute exploration of any particular region in which it might be employed, of enriching our knowledge with a plentiful supply of facts.

The problems indicated by the Commission for Arctic exploration can only be fully solved by means of a connected system of stations and exploring journeys in the Arctic region, and thus the way be opened up to the hitherto entirely unexplored portion. Explorations must thus be carried on by the three great water approaches,

which lead to the polar sea—between Greenland and Spitzbergen, between Spitzbergen and Novaya Zemlya, and through Behring Strait—and which have a physical connection, which is shown very distinctly in the isothermal curves. In this undertaking the co-operation of all States having an interest in these researches should be sought. Through the simultaneous action of different States a circle of observing points would be formed, which would sub-divide a common work having the same end in view, so that the combined labour of several nations would entail less sacrifice to each than has hitherto been the case. The Commission also recommends the above principles for the guidance of other nations, and thus an international alliance might be formed through which the highest scientific results would be attained. The Commission points out that one immediate result of the Second German Expedition is that the region between the west coast of Greenland and the east coast of Spitzbergen would be a suitable field for German research. As we have already stated (NATURE, vol. xiii., p. 33), they recommend a principal station to be established on the east coast of Greenland, with secondary stations on Jan Mayen Island and the west coast of Spitzbergen.

In the region indicated for observation, which can easily be reached from Central Europe, and whose exploration has for European States the greatest scientific and practical interest, German explorers have made a happy commencement, and established a claim for Germany to continue the work thus begun. The Commission urge Germany to set about at once fitting out an expedition for the occupation of the above region. They believe that if diligent preparations were made, the expedition might be ready to start in 1877. Finally, they recommend the appointment of a Scientific Commission to draw up full instructions for the guidance of the expedition in all departments.

THE FAUNA OF THE CASPIAN SEA

OSCAR GRIMM has given in Von Siebold and Kölliker's *Zeitschrift* a brief account of his exploring expedition to the Caspian Sea last year, which will make naturalists look expectantly for the completion of his descriptions. The character of the fauna of the Caspian has interest for the evolutionist in natural history, as well as for the geologist. It will afford evidence not only of modification of animal life, but also of successions of change in physical geography. Two months were spent at Baku, and one month on board a steamboat in dredging from Baku to Krassnowadsk, thence to the Balchan Bay on the east coast, by the island of Tscheleki, southwards to Astrabad, and thence by Enzili and Lenkoran to Baku. Dredging was carried on up to a depth of 150 fathoms, and an enormous quantity of specimens was obtained, including six new fishes (Gobius and Benthophilus), twenty species of Mollusca, including four species of Cardium, four of Adacna, and three of Dreyssena; thirty-five species of Crustacea, principally colossal forms of Gammaridæ; and twenty species of Vermes. The eastern coast adjoining the sandy steppes was almost destitute of marine life, owing to the quantity of sand blown into the sea. The western part of the sea gives depths of 517 fathoms, and has a very abundant fauna. At one haul of the dredge in 108 fathoms, not far from Baku, there were taken 350 specimens of Gammaridæ, 150 *Idothea entomon*, fifty colossal Mysis, six species of fishes, and many large Mollusca.

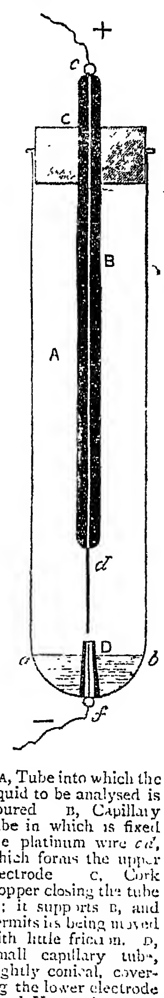
One hundred and twenty species in all were taken, of which eighty are new to science. Many more might be expected to reward dredgings in the deeper parts of the sea. Those already known fall into two classes: (1) those derived from still existing or already extinct species, or but slightly differing from species living in the nearest seas; and (2) those which are identical with those of other seas. The latter are species possessing special tenacity of life, such as *Sabellides octocirrata*, *Mysis relicta*, and *Idothea entomon*.

Relationship is shown between the Caspian fauna and the faunas of the Aral and Black Seas, and the Northern Ocean. But the connection with the latter is more recent than with the Black Sea, for *Phoca*, *Coregonus leucichthys*, and other forms, not existing in the Black Sea, are common to the Northern Ocean and the Caspian. The geographical changes which Dr. Grimm conceives to have brought about these results will be better understood, and their probability may be more easily criticised, when the complete account of the Caspian Fauna is published.

*NEW FORM OF TUBE FOR OBSERVING THE SPECTRA OF SOLUTIONS**

WE have the honour of presenting to the Academy an eminently useful spectro-electric tube; † it realises, in fact, a certain number of advantages, which are as follows:—

1. Constancy of spark permitting prolonged observation of spectra. 2. Suppression of the meniscus, and consequently of the absorption which it produces by partly concealing the spark. 3. Electrodes enclosed in a special tube, which preserves the solution from contact with impurities. 4. Possibility of collecting entirely the substance examined. 5. Possibility of arranging a series of spectroscopic tubes, enclosing solutions of the various bodies, thus permitting rapid demonstrations and comparisons.



A, Tube into which the liquid to be analysed is poured B, Capillary tube in which is fixed the platinum wire *c d*, which forms the upper electrode C, Cork stopper closing the tube A: it supports B, and permits its being moved with little friction. D, Small capillary tube, slightly conical, covering the lower electrode *f*. *d*, Upper electrode. *f*, Lower electrode. *a b*, Level of liquid.

The closed tube A of eleven centimetres in height, and $1\frac{1}{2}$ centimetres in diameter, is traversed by a lower platinum electrode *f*; in the mouth of A is fixed a cork stopper C, pierced by an orifice through which passes a capillary tube B. B is traversed by a platinum wire *c d*, terminated at the upper end by a ring, and at the lower end by a point *d*, opposite *f*. *d* and *f* are the electrodes. The important part of the apparatus is a small capillary tube, slightly conical, one centimetre in height, moveable, and which covers the lower electrode *f*, topping it by $\frac{1}{2}$ millimetre.

To work the apparatus, pour into the tube A the solution to be examined, taking care that the electrode *f* and the tube D are only immersed to half their height. Let *a b* be the level of the liquid; capillary force determines the ascent as far as the point D, on which is formed an immovable drop which is vaporised when an induction current is put on by *c* and *f*. The observations may then continue a very long time without intermission, allowing the spectra to be observed and drawn with the greatest ease.

This very simple apparatus has rendered us so great service in the course of our investigations, that we cannot too strongly recommend its use to chemists engaged in spectral analysis. Never-

* Paper read at the Paris Academy of Sciences, Oct. 26, by MM. Delachanal and Mermet. *Comptes Rendus*, t. lxxxi. No. 17, p. 726.

† See the description of the original apparatus in the "Annales de Chimie et de Physique," 5e series, t. iii., 1874.

theless, in some cases, as for example when it is desired to observe the spectrum of ferric solutions, it is preferable to employ the original tube ; * for the flow of the liquid causes solid particles to be given off, which tend to become fixed in the electrode.

* See "Annales de Chimie et de Physique," Third Series, t. iii., 1874.

SCIENCE IN GERMANY

(*From a German Correspondent.*)

In the twenty-fifth volume of the "Zeitschrift für Wissenschaftliche Zoologie," just completed, Ehlers has given some interesting conclusions with respect to the distribution of the Chætopoda which were collected during the *Porcupine* expedition, by Messrs. Carpenter, Wyville Thomson, and Gwyn Jeffreys ("Beiträge zur Kentniss der vertical Verbreitung der Borstenwürmer im Meere"). He finds, in the first place, that of all Chætopoda occurring on the European coasts of the North Atlantic Ocean, only two families show representatives in the greater sea-depths at more than 300 fathoms, and he thinks, therefore, it is not certain that any forms belong exclusively to the deep sea. Further, the conditions of temperature of the water, as they determine the horizontal distribution of Chætopoda, seem also to be of influence with regard to their vertical distribution, seeing the deeper layers of water are also the colder. Accordingly the forms that live in the cold deep sea of that zone of the Atlantic Ocean correspond with those of the coast fauna of the Arctic regions ; and Ehlers thinks that they might even have a direct connection through currents which descend from the Arctic regions to the depths of warmer marine zones. It is also conceivable that the deep-sea forms, at a time when those regions of the Atlantic were warmer than they are now, were frequenters of the coast, and in proportion as the Gulf Stream heated the upper layers, they retired into the depths. For the most part they remain inferior to their Arctic congeners, perhaps because the conditions of existence in the depths are less favourable, and partly, doubtless, on account of the lack of plant life, and also the small amount of animal nutriment for the worms, there provided. Though in the greater sea depths the light is quite excluded, yet in the Chætopoda found there (with some rare exceptions) we miss neither the colours nor the eyes, which are met with in coast regions. Ehlers believes that these colours and eyes are preserved in the lightless depths, in consequence of new animals ever migrating down from the brighter layers of water, and so preventing the disappearance of these body-parts. There is, however, in the same "Zeitschrift" which contains Ehlers' work, a paper by the physiologist Ranke, on the eyes of leeches (*Hirudo medicinalis*), which may explain that phenomenon in the deep-sea Chætopoda in a different way ("Beiträge zur Lehre von der Uebergangs-Sinnes-Organen"). Ranke, on the ground of his observations on living leeches, considers that their very simply constructed eyes have also sensations of touch and taste ; and, further, that they are not eyes proper, which, on occasion, also serve other ends ; they are, rather, neutral organs of sense, which can act in various directions, but in no particular one so specially as sense organs more highly organised, and therefore limited to one specific energy. This appears partly from the fact that organs quite similar to these so-called eyes on the head of the leech occur also in the whole of the rest of its body, quite in the same way as the so-called side organs of fishes and amphibia, which probably afford sensations of touch. We might, then, regard the eyes of the deep-sea Chætopoda as similar indifferent organs of sense, which, even where light fails, do not discontinue their functions. In an appendix to his memoir, Ehlers further describes how the tube-worms (Tubicola) construct their abodes. They use their feelers only for seizing and holding the building materials, then press these to the mouth or side of the abdomen, where they are coated with a cement secreted from numerous skin-glands in these parts of the body. So prepared, the piece has merely to be pressed on a firm bed, or the edge of a tube already formed, and there it adheres. In this way not only are new tubes constructed, but also any damages are repaired.

NOTES

The following are the probable arrangements for the Royal Institution Friday evening meetings before Easter 1876 :—Jan. 21, Prof. Tyndall, F.R.S. : The Optical Deportment of the Atmosphere in relation to the Phenomena of Putrefaction. Jan. 28, Prof. Huxley, F.R.S. : The Border Territory between the Animal and the Vegetable Kingdoms. Feb. 4, W. H. Preece : The Applications of Electricity to the Protection of Life on Railways. Feb. 11, William Crookes, F.R.S. : The Mechanical Action of Light. Feb. 18, Dr. C. William Siemens, F.R.S. : The Action of Light on Selenium. Feb. 25, Lord Lindsay : The Transit of Venus. March 3, Earl Stanhope, F.R.S. : The Ancient Sun Worship, and the Remains of it in England. March 10, Prof. W. H. Flower, F.R.S. : The Extinct Animals of North America. March 17, Sir Henry Sumner Maine, K.C.S.I. : The Later History of the Fief and Manor. March 24, Prof. Odling, F.R.S. (subject not announced.) March 31, Edward B. Tylor, F.R.S. : Ordeals and Oaths. April 7, Prof. Jas. Dewar, F.R.S.E. : The Physiological Action of Light, Part II. The following lecture arrangements have been made :—Christmas Lectures (adapted to a juvenile auditory) by Prof. Tyndall, F.R.S. : Six lectures on Experimental Electricity. In this course the phenomena of frictional electricity will be so illustrated and its principles so explained as to enable the pupil to repeat the experiments, and to pursue the subject further, at school or at home. With this object in view the laws of the science will be elicited from facts obtained with the simplest apparatus. Prof. A. H. Garrod Twelve lectures on the Classification of Vertebrated Animals. Dr. J. H. Gladstone, F.R.S. : Eight lectures on the Chemistry of the Non-metallic Elements. Dr. W. Spottiswoode, Treas. R.S. : Four lectures on Polarised Light. R. P. Pullan : Three lectures on his Excavations in Asia Minor. W. T. Thiselton Dyer : Four lectures on the Vegetable Kingdom ; the Boundaries and Connections of its Larger Groups. Prof. G. Croom Robertson : Three lectures on the Human Senses. Edward Dannreuther : Two lectures on Wagner and his Trilogy (with pianoforte illustrations).

The Stockholm *Nya Dagligt Allehanda* of the 4th inst. contains some account of the return voyage of the *Pröven* from the mouth of the Yenesei, after the departure of Nordenskjöld. The information is sent by Dr. Théel Kjellman, to whom, it will be remembered, Nordenskjöld gave over the command of the *Pröven*. The *Pröven* left Dickson Harbour, at the mouth of the Yenesei, on the 19th August, and set her course towards the north-east part of Novaya Zemlya. On the 23rd August she was found to be already in 75° 24′ N. lat., and 66° 24′ long. E. from Greenwich, and so a little to the south of Cape Middendorf, on the north-east coast of Novaya Zemlya. This peculiar circumstance can only be explained by a very strong north-westerly current going from the Ob and Yenesei out over the Kara Sea. At Cape Middendorf, where ice was met with which extended eastwards as far as the eye could reach, the expedition was becalmed for six days. During this time a considerable amount of dredging work was done, with abundant results. That animal life is here uncommonly rich at the sea-bottom may be inferred from the fact that when a swab was allowed to remain in contact with the bottom for a few minutes it was covered over with animals : sea-stars by hundreds, with

the most beautiful nuances of red, numerous, and colossal bush-like Alectos, Crustacea, and Mollusca stuck fast on its strands. On the 28th a start was again made, and a number of immense glaciers coming down to the sea were passed; the coast was rocky and very wild. The following day anchor was cast in Udde Bay. Marine vegetation was uncommonly abundant here, which is all the more interesting, as it has been stated that the Kara Sea is devoid of all plant life. Vegetation on land, on the contrary, was exceedingly scanty. Some small withered willows met the eye here and there. The fell-poppy (*Fjellvalmon*) alone yet bare flowers, but even these the autumn had almost destroyed. "The whole of nature produced the impression of indescribable desolation." On the 3rd September the *Pröven* sailed into the mouth of Matotschkin Strait, where the expedition remained till the 11th September. They then steered homewards, and after experiencing exceedingly tempestuous weather, the *Pröven* entered the harbour of Tromsö on the 3rd October. "We have," the letter concludes, "during this summer sailed over known and unknown seas more than 6,000 (English) miles; we have visited regions whither expeditions for more than three hundred years have attempted in vain to come; we have made rich collections in all departments of natural science. What more can man desire from such a journey?" In Petermann's *Mittheilungen* for December, along with some account of the expedition, is a map showing the route outwards and home of both parties. Nordenskjöld had reached St. Petersburg on the 17th instant.

IN his will, dated Oct. 16, 1875, Sir Charles Wheatstone bequeaths all his scientific books and instruments, as well as his medals and diplomas, to the Corporation of King's College, London, together with a legacy of 500*l.* for the purchase of scientific instruments. To the Royal Society he bequeaths the portraits of the Hon. Robert Boyle, and of all the other scientific men in his possession, together with a legacy of 500*l.* to be added to the Wollaston Donation Fund.

IT is stated that Prof. Huxley has accepted the invitation of the Senatus of the University of Edinburgh to take charge again of the Natural History Class during next summer session.

THE *Challenger* arrived at Valparaiso on the 19th inst.

THE following gentlemen have been appointed as a Commission to consider the claim of the Scottish Meteorological Society on Government, a claim which we may state has already been reported on by the Duke of Devonshire's Commission:—Sir Wm. Stirling Maxwell, Dr. Hooker, Col. Strachey, Messrs. Francis Galton, Brassey, D. Milne Home, Farrer, and Lingen.

PETERMANN'S *Mittheilungen* for December contains a translation of Mr. Stanley's letters, with a clear map embodying the results of his circumnavigation of Lake Victoria Nyanza, and showing at the same time Speke's route of 1858, and that of Speke and Grant in 1861–62. In an introduction to the letters, Dr. E. Behm discusses the results obtained by Mr. Stanley. The *Daily Telegraph* of Tuesday publishes two letters from the late unfortunate M. Linant de Bellefonds, describing his sojourn at Mtesa's and his meeting with Mr. Stanley.

THE same number of the *Mittheilungen* contains the first part of an elaborate and important paper by Oscar Loew, giving an account of Lieut. Wheeler's second expedition into New Mexico and Colorado in 1874, and pointing out the important scientific bearings of the results obtained. He pays a well-deserved tribute of praise to the enterprise of the U.S. Government, in accomplishing the survey of so large a portion of their extensive territories in so comparatively short a time.

AN interesting letter appears in yesterday's *Daily News* from Mr. Smithurst, the engineer of the steamer which made the voyage up the newly discovered Baxter River in New Guinea, referred to in Sir Henry Rawlinson's address at the Geographical Society last week. The river seems to be a magnificent one, and could evidently be made navigable to a considerable distance inland. The exploring party found the banks to consist mainly of mangrove swamps, though, near the end of the journey, high clay banks with *Eucalyptus globulus* were found. Scarcely any natives were seen, though there were frequent signs of their being about. Mr. Smithurst refers to a very remarkable bird, which, so far as we know, has not hitherto been described. The natives state that it can fly away with a dugong, a kangaroo, or a large turtle. Mr. Smithurst states he saw and shot at a specimen of this wonderful animal, and that "the noise caused by the flapping of its wings resembled the sound of a locomotive pulling a long train very slowly." He states that "it appeared to be about sixteen or eighteen feet across the wings as it flew, the body dark brown, the breast white, neck long, and beak long and straight." In the stiff clay of the river bank Mr. Smithurst states that he saw the footprints of some large animal, which he "took to be a buffalo or wild ox," but he saw no other traces of the animal. These statements are very wonderful, and before giving credence to them we had better await the publication of the official account of the voyage. A very fair collection of rocks, stones, birds, insects, plants, moss, and orchids has been made, which will be submitted to a naturalist for his opinion. The dates of Mr. Smithurst's communication are from August 30 to Sept. 7.

THE long-standing Chancery suit of the King of Portugal *v.* Carruthers has at length been terminated by a compromise. The suit arose out of the will of the late eminent African explorer, Dr. Welwitsch, who had explored a portion of Central Africa at the expense of the Portuguese Government, and had made large and important botanical collections. These collections were left by will to the British Museum; but Dr. Welwitsch's right to so leave them was disputed by the Portuguese Government. The compromise finally arrived at is to this effect:—A declaration that the King of Portugal is entitled to all the collections; the King, as an act of grace and favour, paying the defendants 700*l.* in full discharge of all demands; that the study set (the best) and the next best set of the collections should be separated from the other collections; that the British Museum should have the second best set as a gift from the King, and that the King should have all the other sets, and should distribute them as he may think proper.

WE learn from the *Gardener's Chronicle* that M. E. André, well known as a landscape gardener in this country as well as on the Continent, and also as the editor of the *Illustration Horticole*, is about to undertake a botanical exploration in Brazil, Peru, Ecuador, and New Granada.

M. GABRIEL DE MORTILLET, the learned sub-director of the St. Germains Museum, has been appointed President of the Paris Anthropological Society for 1875-76.

TWO new zoological gardens have recently been established and opened in the United States of America, at Philadelphia and Cincinnati, and both appear to be making good progress. The Superintendent of the former is Dr. Dorner, who was lately scientific secretary of the Zoological Garden at Hamburg, and has quitted Europe in order to inaugurate the new institution in America.

THE meeting of Orientalists to be held in September next at St. Pete sburg is to be accompanied by an exhibition of Oriental manuscripts, coins, arms, implements, and other objects illustrative of the history and industry of the East. The meeting will be directed by an Imperial Commission, presided over by Prof. Gregorieff, the well-known geographer of Central Asia,

and including the names of Peter von Lerch, Victor von Rosen, and Daniel Chvloson. MM. Gregorieff and Lerch are ready to receive objects intended for exhibition.

AT a meeting of the Fellows of the Royal Society of Edinburgh, held on Monday, the 22nd inst., the following were elected office-bearers for the session 1875-76:—President, Sir William Thomson, LL.D. Vice-Presidents: Rev. W. Lindsay Alexander, D.D., the Right Rev. Bishop Cotterill, David Milne Home, LL.D., Prof. Kelland, Lord Neaves, David Stevenson, C.E. Secretary, Prof. H. Balfour. Secretaries to ordinary meetings: Professors Tait and Turner. Treasurer, David Smith. Librarian, Prof. Maclagan. Members of Council: Alexander Buchan, J. Matthews Duncan, M.D., Prof. George Forbes, Andrew Fleming, M.D., Prof. Geikie, Sir Alexander Grant, Thomas Harvey, LL.D., John G. M'Kendrick, M.D., Arthur Mitchell, M.D., Charles Morehead, M.D., Ramsay H. Traquair, M.D., Robert Wyld, LL D.

THE session of the Poitiers Meteorological Congress was opened on the 18th inst. M. Leverrier was present. The future Association is to be composed of sixteen departments: Loire, Loire et Cher, Loiret, Indre et Loire, Maine et Loire, Loire Inférieure, Vendée, Charente Inférieure, Deux Sevres, Charente, Haute-Vienne, Vienne, Indre, Sarthe, Correze, and Creuze. The Gironde, which is to become the centre of another branch of the Association, sent three delegates. The proceedings are to be published, but the sittings were not public.

IT is officially announced that it is the purpose of the U.S. Government to make a complete and representative collection of the mineral products of the United States, which shall illustrate the mineral resources of the country and its mining and metallurgical progress at the forthcoming International Exhibition to be held in Philadelphia.

IN consequence of the time at the Manchester meeting of the Iron and Steel Institute being insufficient to allow of the reading and discussion of several papers that were upon the programme, a supplementary general meeting is being held in London to-day in the rooms of the Council of the Institution of Civil Engineers. Besides discussions on papers read at Manchester, Mr. G. J. Snelus will read a paper on fireclay and other refractory materials; Mr. William Hackney on the manufacture of anthracite coke in South Wales; Mr. C. J. Homer on the North Staffordshire Coalfield, with the ironstones contained therein. Suggestions will be submitted to this meeting for introducing such modifications in the rules and regulations as will in future admit of dealing fully with the various subjects that may be brought before each meeting of the Institute.

AT its last sitting the French Geographical Society broached a scheme for inducing the several French Railway Companies to place at each station a map of the vicinity, with indications of the most notable historical or economical facts connected with the district. It appears that this is the universal practice on Brazilian railway lines.

A THIRD and cheaper edition of the translation of Dr. F. A. Pouchet's work, "The Universe," published by Messrs. Blackie and Sons, has been issued. We reviewed the work in our first volume (p. 259), when we expressed our belief that it would do much to foster a love of pure science in the young. This cheaper edition, though a few illustrations and notes have been omitted, is still a handsome and beautiful work, well adapted for a present to boy or girl.

IT is expected that the buildings for the Yarmouth Aquarium will be completed by the 1st of June, 1876. Mr. Saville Kent has been appointed naturalist and manager of the aquarium.

AMONG recent additions to the Manchester Aquarium are nine examples of the Sterlet (*Accipenser ruthenus*) from St. Petersburg, a species that has hitherto, in this country, been on public exhibition in the living state at Brighton only. The fine Sturgeon obtained from Colwyn Bay for the Manchester tanks some six months since is still doing well.

IT is said that the French National Library is to be opened every evening from 8 to 10. It is an important innovation which has been tried with success at the library of the Conservatoire des Arts et Métiers, and has existed for years at the Bibliothèque St. Génévieve, in the Quartier Latin, for the use of students.

EXPERIMENTS have been tried with success for using locomotive engines on Paris tramways.

THE International Medical Congress, which this year met at Brussels, will hold its next meeting at Geneva, in September 1877.

THE Italian Expedition for exploring the interior of Africa will leave in January next, and will be absent three years.

THE members of the Metropolitan Scientific Association lately paid a visit to the recent excavations in the Surrey Commercial Docks. One of the most important results of the visit was the discovery of what, on further examination, will doubtless prove to be a line of fault hitherto unsuspected, and if further inquiry confirm the accuracy of the engineer's section, another line of fault will have to be added to future geological maps of this district.

A MOVEMENT has been set on foot at Philadelphia, the Society of Arts *Journal* states, since Mr. Cunliffe Owen's visit to that city, for the establishment of a Museum of Science and Art of a character similar to our own South Kensington Museum.

MR. SERJEANT COX will publish, early in January, the first volume of a treatise on "The Mechanism of Man," being a reproduction, re-written, re-arranged, and greatly extended, of his work entitled "What am I?" which has been for some months out of print.

A PAPER was read at the meeting of the Psychological Society on Thursday week, by Mr. G. Harris, LL.D., F.S.A., vice-president, on "Caligraphy as a test of Character," in which, after remarking on the various modes in which character in each person is exhibited, and on the infinite diversities of handwriting, he adverted to the peculiarities which display character, and illustrated his theory by exhibiting a number of original autographs, including those of Napoleon I., Wellington, Nelson, Brougham, Horne Tooke, Southey, Cowper, Sheridan, Cobbett, Bulwer Lytton, and Charles Dickens, commenting on the contrast between the writing of the two latter. A discussion followed, in which Mr. Serjeant Cox, the President, Prof. Leone Levi, and others took part.

THE additions to the Zoological Society's Gardens during the past week include an Arabian Baboon (*Cynocephalus hamadryas*) from Arabia, presented by Mrs. M. A. Moore; a Pampas Deer (*Cervus campestris*) from Uruguay, presented by Capt. Hairby; a Herring Gull (*Larus argentatus*) European, presented by Mr. P. Gipps; a Western Slender-billed Cockatoo (*Licmetis pasinator*) from W. Australia, presented by Mr. W. J. Irving; a Golden Tench (*Tinca vulgaris*), European, presented by Mr. S. C. Hincks; a Capybara (*Hydrochærus capybara*) from S. America, two Central American Agoutis (*Dasyprocta punctata*), two Yellow-winged Blue Creepers (*Cærеba cyanea*), two All-green Tanagers (*Chlorophonia viridis*), two Naked-throated Bell Birds (*Chasmorhynchus nudicollis*), two Yellow Hangnests (*Cassicus persicus*), a Sulphury Tyrant (*Pitangus sulphuratus*), a Silver Blue Tanager (*Tanagra cana*), a Blue Grosbeak (*Guiraca cyanea*), five Pileated Finches (*Coryphospingus pileatus*), from Brazil; five Darwin's Pucras Pheasants (*Pucras darwini*), from China, deposited.

SCIENTIFIC SERIALS

THE *Journal of the Chemical Society* for October contains but one paper communicated to the Society, viz., a lengthy communication on the chemistry of tartaric and citric acids, by Mr. R. Warington. The author has had considerable experience in the manufacture of these acids, having been for some years chemist to the factory of Mr. J. B. Lawes. The author's experiments prove that the citric acid of commerce contains one molecule of water corresponding to the formula $C_6H_8O_7$, H_2O. Some interesting results have been brought to light in the course of some experiments made with a view to determine the water of crystallisation in various samples of the acid. Thus in one determination a specimen of the powdered acid lost the whole of its water over sulphuric acid in a few days, at a temperature of 16°. In another experiment the powdered acid lost but a mere trace of water *in vacuo* over vitriol for some days, while the same acid heated to 100° lost its normal amount of water. Results of an equally contradictory nature were obtained with various other samples of the acid tried at subsequent periods. It has been proved also that a strong solution of citric acid undergoes considerable contraction when mixed with water.—The next section of the paper relates to the acidity and commercial value of the different lime, lemon, and bergamot juices supplied for the manufacture of citric acid. The nature of some of the acids existing in the concentrated juices is to be made the subject of further research; up to the present time, in addition to citric, formic, acetic, and possibly propionic, acids have been detected. It appears, however, that the organic acids other than citric which exist in the juice are chiefly non-volatile, and have soluble calcium salts. Phosphoric acid has also been found, and there is reason to suspect malic and aconitic acids, the latter being produced by the concentration of the juice. With regard to calcium citrate, it has been found that the amount of water contained in this salt varies according to the mode of preparation, a result demanding further investigation. The author next gives details of the method employed for analysing the citric acid liquors. With regard to tartaric acid, it is found that a strong solution contracts even more than citric acid when mixed with water. The author then proceeds to consider the qualitative reactions of tartaric, metatartaric, and ditartaric acids. Contrary to the statement given in books, it has been found that calcium acetate yields a crystalline precipitate of calcium tartrate, even in dilute solutions of tartaric acid. Free tartaric acid also is precipitated by calcium chloride in the presence of alcohol. The reactions with the acetates of lead and barium have likewise been studied. With regard to the amount of water in calcium tartrate, the author concludes that the salt has no definite composition at 100°. A very complete series of experiments upon the solubility of potassium bitartrate has been made, and the remainder of the paper is devoted to the materials used for the manufacture of tartaric acid, viz. lees, argol, and tartar, and the methods of analysis employed in their valuation. Mr. Warington deserves credit for thus contributing to the general store of knowledge from the experience gained in the chemical factory. A great deal of manufacturing chemistry is at present carried on without any regard to the scientific principles involved, and if manufacturers would only be somewhat more free in communicating apparently inexplicable facts to the scientific world, the advantage gained could not but be mutually beneficial. To quote the author's own words:—"A large amount of information is acquired in the laboratories of our great manufacturing concerns; most of this might be published without any injury to the individual manufacturer. Especially is this true of analytical methods, and the publication and discussion of these would do much to remove the disgrace to which science is often subjected from the wide discrepancies of commercial analyses." We cordially echo the hope "that the publication of these notes may lead to many similar communications."—The remainder of this part is occupied by abstracts of papers from British and foreign journals.

Poggendorff's Annalen der Physik und Chemie, No. 10, 1875. In this is given the remaining portion of Prof. Stein's article on the formation of sound; and from his analysis of the motions of tuning-forks he concludes that only displacements of the nature of condensation and rarefaction yield sound: that the strength of the tones depends, among other things, on the size of the sounding mass; and that only transversal or rectilinear excursions produce resonance. With these data he explains a number of phenomena; the disproportionate loudness of forks held near the ear, &c.—MM. Kundt and Warburg give the concluding part of their researches "On friction and heat-conduction of rarefied gases." After discussing the capability of their apparatus for determining coefficients of heat-conduction, they show that these coefficients are independent of pressure within 150 mm. to about 1 mm. for air and carbonic acid, and 150 mm. to 9 mm. for hydrogen. They tried to produce an actual vacuum in regard to heat-conduction, and by drying to 200° they reduced the conduction to a small fraction of its original value. The co-efficient for hydrogen (in accordance with Maxwell's theory and Stefan's experiments) they found to be 7·1 greater than that of air; while that of carbonic acid was 0·082 of that of hydrogen, which is considerably smaller than by Maxwell's theory.—M. Edlund gives an experimental demonstration that galvanic resistance is affected by the motion of the conductor. He made a current pass in two opposite directions from the middle part of a tube, through water that was sent through the tube; and with a galvanometer proved that the resistance was less where the galvanic current went *with* the liquid one.—There is another electrical paper, in which Dr. Bleekrode recommends ebonite as preferable to glass in many ways for the discs of "electro-machines." He gives a *résumé* of the various modifications of the Holtz machine that have appeared, and describes several observations with the ebonite electro-machines.—M. Glan has a paper on the change of phase of light polarised, through reflection, parallel to the plane of incidence.—M. Emsmann describes a curious phenomenon bearing on binocular vision; while M. Vogel gives an account of spectral observations on the Red Sea and Indian Ocean, and in the blue Grotto of Capri.

Transactions of the Royal Society of New South Wales for the year 1874.—This number contains the following, among other papers:—Description of eleven new species of Terrestrial and Marine Shells from North-west Australia, by Mr. John Brazier, C.M.Z.S.—Iron Pyrites, by Mr. J. Latta.—Nickel Minerals from New Caledonia, and Iron Ore and Coal Deposits at Wallerawang, N.S.W., by Prof. Liversidge.—Some of the results of the observation of the Transit of Venus in New South Wales (with diagrams), by Mr. H. C. Russell, Government Astronomer.—The Transit of Venus as observed at Eden, by the Rev. Wm. Scott.

Bulletin de l'Académie Royale des Sciences, tom. xl. No. 8.—The two original communications in the "Classe des Sciences" are a long article on arithmetical operations, by J. C. Houzeau, and a description of some fossil plants from the "Poudingue de Burnot" (Lower Devonian), by Dr. A. Gilkinet. The two species are *Filicites pinnatus* (Cœmans) and *Filicites lepidorachis* (Cœmans), which latter Dr. Gilkinet removes from the Ferns and places among the Lycopods, under the name *Lepidodendron Burnotense*. There are three plates of figures.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Nov. 19.—"On the Physiological Action of Vanadium," by John Priestley, Platt Physiological Scholar, the Owens College, Manchester. Communicated by Prof. Gamgee, F.R.S.

Thirty-one experiments are detailed, in which frogs, a pigeon, guinea-pigs, rabbits, dogs, and cats were made use of. From these experiments it is gathered:—

1. That vanadium is a poisonous substance.

2. That the symptoms of poisoning are, in general, similar, whatever the method of the introduction of the salt into the animal system.

3. That the symptoms of poisoning which appeared in one or other of the various classes of animals above mentioned are: paralysis of motion; convulsions, local or general; rapidly supervening drowsiness, or indifference to external circumstances; congestion of alimentary mucous membranes; discharge of sanguinolent fluid fæces; presence of glairy, fluid mucus in the intestines after death; certain changes in respiration, and, coincidently, a fall in temperature; drowsiness and feebleness of pulse. In addition the heart was always irritable after death; consiousness and sensibility to pain seemed unimpaired; and no diminution could be detected in the powers of muscle and nerve to respond to stimulation.

4. That the lethal dose for rabbits lies between 9·18 mgr. and 14·66. mgr. of V_2O_5 per kilog. of rabbits.

The author details a number of experiments undertaken with

the view to gain more exact information as to the action of the salt of vanadium upon particular functions. The methods of experiment and the precautions observed are fully described.

Chemical Society, Nov. 18.—Prof. Abel, F.R.S., president, in the chair.—The Secretary read a paper by Mr. T. M. Morgan, on ethyl-phenyl acetylene.—The second communication, on narcotine, cotarnine, and hydrocotarnine, Part 2, by Mr. G. H. Beckett and Dr. C. R. A. Wright, is a continuation of their investigations of this subject.—Mr. W. Noel Hartley then gave an account of the presence of liquid carbon dioxide in mineral cavities, in which he proves, from the physical properties of the liquid enclosed in a cavity of a quartz crystal in his possession, that it is carbon dioxide.—The last paper, by Mr. W. H. Perkins, was a preliminary notice on the formation of coumarin, cinnamic and other similar acids.

Meteorological Society, Nov. 17.—Dr. R. J. Mann, president, in the chair.—Sergeant James Conroy, R.E., Morris Jones, L.R.C.P., A. H. Leycester, Sir David L. Salomons, Bart., and James P. H. Walker, were balloted for and duly elected Fellows of the Society. The following papers were then read:—Some remarks on the reduction of barometric readings with a form of table for combining the corrections for index-error, temperature, and altitude, by William Marriott. Readings of the barometer to be of any scientific value must be corrected for index-error, temperature, and height above mean sea-level. There is not much difficulty in applying the first two, but it is a very troublesome thing to obtain the proper corrections for altitude if the station be more than 100 feet above sea-level. The author has found that a great number of observers make some very extraordinary mistakes in applying this correction, and gives a few as specimens. He attributes the difficulty in applying this correction to the unsatisfactory explanation accompanying the tables as given in the different manuals on meteorology and to the fact of the corrections being only given for two pressures, viz., 27 inches and 30 inches. He then submits a table which gives the sea-level pressure on the left hand and the reading of the barometer at the station corresponding to that pressure on the right hand, with the altitude correction between them. In conclusion he submits a form of table in which is combined the corrections for index-error, temperature, and height above sea-level, which is the means of saving much time, besides reducing the liability to error.—On a continuous self-registering thermometer, by W. Harrison Cripps. The thermometer consists of six coils of glass tubing, the first five being wound concentrically round an axis, each coil lying within the other, in such a manner as to form a spiral glass wheel 4 inches in diameter. The sixth coil is moved slightly away from the others, so that it shall form the circumference of a circle 5 inches in diameter, the centre being the axis around which the spiral tube is coiled. Pivots are attached to either end of the axis, which rest on two parallel metal uprights. The tubing is filled with spirit, and mercury and a small quantity of air are enclosed in the large coil. The thermometer works in the following manner: when the spirit contracts on cooling, the expansion of the included air keeps the column of mercury in contact with it; this immediately alters the centre of gravity, and the wheel begins to revolve in a direction opposite to that of the receding mercury. On applying heat, the mercury passes forwards and the wheel moves in the opposite direction. The thermometer is made to record somewhat in the same way as the recording aneroid barometer.—On a self-regulating atmometer, by S. H. Miller, F.R.A.S. After several years' experimenting with evaporating dishes of different forms under various conditions, the author has arrived at the conclusion that none of the contrivances which have come under his own observation are entirely satisfactory. After remarking upon the conditions which a good evaporator should fulfil, he proceeds to describe a self-regulating one which he has devised and which has now worked satisfactorily for several months. The apparatus consists of an open cylinder 8 inches diameter, surmounted by a brass rain-gauge rim which receives the water from which the evaporation takes. This vessel is surrounded by another cylinder 15 inches in diameter and closed at the top, which is divided into two compartments, upper and lower. The upper one is filled with water to keep the level in the inner cylinder always constant, and the lower one receives the overflow rainfall. The amount of evaporation is determined by weighing the apparatus.

Zoological Society, Nov. 16.—Mr. Osbert Salvin, F.R.S. in the chair.—Mr. Sclater exhibited the upper horn of a Two-horned Rhinoceros that had been shot in March last by Lieut.-Col. C. Napier Sturt, in the valley of the Brahmapootra. Mr. Sclater remarked that this seemed to prove conclusively the existence of a two-horned species of Rhinoceros in Assam, which would probably turn out to be the same as that from Chittagong, now living in the Society's Gardens.—Mr. Sclater read an extract from a letter addressed to him by Dr. N. Funck, director of the Zoological Gardens, Cologne, stating that the bird figured in Mr. Sclater's recent article on the Curassows as *Pauxi galeati* var. *rubra*, was the true female of *Pauxi galeata*. —Mr. H. Seebohm exhibited and made remarks on a series of rare and interesting birds and eggs from the tundras and deltas of the Petchora River, North-eastern Russia, collected there by Mr. J. A. Harvie Brown and himself during the present year.—Mr. A. H. Garrod read some notes on the Manatee (*Manatus americanus*) recently living in the Society's Gardens.—Dr. Günther, F.R.S., read a third report on the collections of Indian reptiles obtained by the British Museum, and gave descriptions of several species new to science.—A communication was read from Mr. E. Pierson Ramsay, containing a list of birds met with in North-eastern Queensland, chiefly at Rockingham Bay.—A second communication from Mr. Ramsay gave a description of the eggs and young of *Rallina tricolor*, from Rockingham Bay, Queensland.—A third communication from Mr. Ramsay contained the description of a new species of Pæcilodryas, and a new genus and species of Bower Bird, proposed to be called *Scenopœus dentirostris*, from Queensland.—A communication was read from Mr. Sylvanus Hanley, containing the description of a new Cyclophorus and a new Ampullaria, from Burmah.—A communication was read from Dr. J. S. Bowerbank, F.R.S., containing further observations on *Alcyoncellum speciosum*, Quoy et G., and *Hyalonema mirabile*, Gray.—Mr. Arthur G. Butler read a paper on a collection of butterflies from the New Hebrides and Loyalty Islands, and gave descriptions of some new species.—A second paper by Mr. Butler contained particulars of a small collection of butterflies from Fiji. Mr. Butler also read the descriptions of several new species of Sphingidæ.—A communication was read from Mr. W. H. Hudson, containing remarks on Herons, with a notice of a curious instinct of *Ardetta involucris*.—A communication was read from Dr. Otto Finsch, in which he gave the description of a new species of Crowned Pigeon from the southern end of New Guinea, opposite Yule Island. Dr. Finsch proposed to call this bird *Goura scheepmakeri*, after Mr. C. Scheepmaker, of Soerabaya, who had transmitted a living specimen of it to the Zoological Gardens, Amsterdam.

Entomological Society, Nov. 3.—Sir Sidney Smith Saunders, C.M.G., president, in the chair.—This being the first meeting of the session in the new rooms of the Society at 11, Chandos Street, Cavendish Square, the President delivered an inaugural address, pointing out the advantages which might be expected from the library and meeting-room being brought into juxtaposition on a more central site; and also from the library being open to members during three days in each week instead of one day only.—M. Oscar Lamarche, of Liége, was elected a foreign member.—Mr. W. C. Boyd exhibited mines of *Heliozela sericiella* in oak. He had succeeded in rearing the insects by confining them with a young oak plant, and thus was enabled to discover their habits, which had hitherto been unknown. The mines were situated in the footstalks of the leaves.—Mr. M'Lachlan exhibited a living apterous female of a terrestrial Trichopterous insect, *Enoicyla* (probably *E. pusilla*, Burm.) He had recently bred it, with others, from cases forwarded to him by Mr. Fletcher, of Worcester, the discoverer of the insect in this country. Mr. M'Lachlan gave an account of its structure and singular habits. The perfect insects emerge in November, and the males are furnished with ample wings.—Mr. Champion exhibited several rare Coleoptera captured by him in Kent and Surrey.—Mr. Phipson exhibited a *Catocala nupta*, with several *Acari* on a portion of one of the anterior wings, instead of on the body, as is usually the case.—The Rev. H. S. Gorham read descriptions of some new species and a new genus of *Endomycici*.—Mr. Arthur G. Butler communicated "a list of the Lepidoptera referable to the genus *Hypsa* of Walker's list, with descriptions of new genera and species."—Mr. Edward Saunders communicated a second part of his Synopsis of the British *Hemiptera Heteroptera*.—Mr. Charles O. Waterhouse read descriptions of some new genera and species of Heteromerous Coleoptera (*Helopidæ*), chiefly from Terra del Fuego. The specimens had been brought to this country by Mr. Charles Darwin, and had been described many years ago by Mr. Water-

house, sen., but the manuscript had been unfortunately lost, and the insects had remained unnoticed till the present time.

BERLIN

German Chemical Society, Nov. 8.—A. W. Hofmann, president, in the chair.—J. Landauer described a blowpipe-apparatus consisting of two bottles, one of which contains air, while the other, filled with water, is placed above and is connected by a tube with the air-bottle. The water replacing the air produces the blast.—T. Grabowsky has found amongst the products chlorine forms with acetone, a liquid of the formulæ $C_5H_7Cl_3O$, and another liquid $C_6H_7Cl_3O$ (trichlorinated oxide of mesitylene).—The same chemist has studied anew the transformation of chloral into chloralid and solid chloral.—P. Griess has obtained betain by the action of iodide of methyl on glycocol.—S. P. Sadler appears to have transformed glycerine into tartronic acid by means of diluted fuming nitric acid.—V. von Richter reverted to a reaction formerly observed by him, through which nitrobromobenzol and cyanide of potassium form cyano-bromobenzol, and consequently a bromobenzoic acid, of which the acid group CO_2H is *not* corresponding in position to the nitro-group of the original compound. He has repeated the experiment with bibromo-nitro-benzol, and finds corresponding exchanges to take place in their case. He also described the formation of certain di-tri- and tetra-bromo-benzols.—F. Beilstein and A. Kurbatow, by adding chloride of antimony to nitrobenzol and passing chlorine gas into it, have obtained a good yield of meta-chloronitrobenzol and higher chlorides.—T. A. Roorda Smit prepares acetate of ammonium and acetamide by means of carbonate of ammonium. The same fluids, nitrobenzol and sulphite of ammonium, yield anilosulphite of ammonium $C_6H_5NHSO_3NH_4$. The same chemist has found thioanilide, $C_6H_5NH—S—NHC_6H_5$, a yellow oil, amongst the products of the reaction of chloride of sulphur on aniline.—Ira Remsen communicated researches on the action of potassium on succinate of ethyl and on the action of ozone on carbonic oxide.—The President then read to the meeting an autobiographical sketch by F. Wöhler, not intended for publication, of which the following is an extract:—His father, as well as a friend of the family, encouraged his pleasure in collecting natural objects, and experimenting. In 1814 he was sent to the grammar-school of Frankfort. He was backward particularly in mathematics, partly because he was constantly occupied in collecting minerals. Dr. Buch in Frankfort was his first serious instructor in chemistry. Buch published remarks on selenium conjointly with Wöhler. Hagen's old treatise, based on the phlogistic theory already used by his father, was his first guide, but was soon exchanged against more modern views and books. His room was changed into a chemical laboratory; he learnt to engrave on copper, and collected antiquities; but his great pleasure was the construction of a Volta-battery of 100 couples and the reduction of potassium by means of it, as well as by heat alone. He was fond of bodily exercises, such as swimming and shooting. In 1820 he went to the University of Marburg, but was offended by one of the professors, who forbade his making chemical experiments while he was studying medicine! He therefore continued his studies in Heidelberg. The great physiologist Tiedemann became his friend, and he published researches on the change that organic acids undergo through passing the human body. He obtained a prize for this paper, and used it for his dissertation as Doctor of Medicine. He still had the intention of entering into the practice of a profession. He worked in Gmelin's laboratory, but never heard any lectures on chemistry. The sketch does not enter into his life in Sweden, described in a former paper. After returning from Sweden his friendship with Liebig commenced in Frankfort, to cease only with Liebig's death. In 1825 Leopold von Buch proposed him as teacher of chemistry of the newly founded School of Industry (Gewerbeschule) at Berlin. He accepted the place, and was named Professor in 1828. He derived great benefit from living in friendly intercourse with Magnus, H. and G. Rose, and Mitscherlich. He remembers with enthusiasm the influence of Humboldt and his eloquence. Humboldt was president of the Association of Natural Philosophers at Berlin, and the contrast between his never-ceasing flow of language and the silence of Berzelius is humorously described in the following anecdote. During an excursion of the Association, Wöhler had to take his seat, as he says, on account of his thinness, in a carriage nearly filled already by the stoutest members of the Association, viz. Humboldt and Berzelius. The former held forth with his usual readiness, when Berzelius suddenly broke out in Swedish: "Mr. Wöhler, what eloquence! I cannot stand it any longer!" Fortunately Humboldt's all but universal knowledge did not comprise the Swedish language. In Berlin Wöhler published his text-book (Grundriss) of chemistry, at first anonymously. Soon afterwards he left Berlin for Cassel. In 1829 he visited France together with Magnus; in 1835 England. In 1836 he was named successor of Stromeyer as Professor of Chemistry in Gottingen.

PARIS

Academy of Sciences, Nov. 15.—M. Frémy in the chair.—The following papers were read:—On meridian observations of small planets at the Greenwich and Paris Observatories during the third trimestre of 1875, by M. Leverrier.—On the density of pure platinum and iridium and their alloys, by MM. Sainte-Claire Deville and H. Debray. The numbers obtained (about 21·5 for platinum and 22·4 for iridium) are higher than those found hitherto.—Researches on the composition of dissolved acids and salts, by M. Berthelot.—Memoir on measurement of the affinities between liquids of organised bodies by means of electromotive forces, by M. Becquerel. He studies the electromotive force obtained from the white and the yolk of an egg, from the arterial and venous blood of dogs, and from each of these with albumen, the reactions between plant liquids, and between them and animal liquids, the electro-capillary effects of sulphurous liquids in contact with liquid exuded from the skin, &c.—Examples of the contemporaneous formation of iron pyrites in thermal springs and in sea water, by M. Daubrée.—On the carpellary theory according to the Amaryllideæ (Part I, Alstrœmeria), by M. Trécul.—Fifteenth note on the electric conductivity of moderately conducting bodies, by M. Du Moncel.—M. Janssen presented four cases of natural history specimens from the Japanese Government.—On the representation of figures of geometry of *n* dimensions by correlative figures of ordinary geometry, by Mr. Spottiswoode.—On the development of the fruit of Coprini, and the supposed sexuality of the Basidiomycetes, by M. van Tieghem.—Theory of hail, by M. Cousté.—On the employment of nickel deposited electrically to protect the magnets of compasses against oxidation, by M. Duchenin.—Application of the principle of analytic correspondence to the demonstration of the theorem of Bezout, by M. Saltel.—Observations of the planet Jupiter, by M. Flammarion. He notes (*inter alia*) the appearance of white elliptic spots followed by shadows. Some sketches are given.—On some combinations of titanium, by MM. Friedel and Guérin.—Solution of platinum in sulphuric acid during the industrial process of concentration, by M. Scheurer-Kestner.—On the presence of a new alkaloid, ergotinine, in spurred rye, by M. Tanret.—On the *rôle* of carbonic acid in the phenomenon of spontaneous coagulation of blood, by M. Glénard.—Reply to MM. Mathieu and Urbain's last note on the same subject, by M. Gautier.—On the embryogeny of the flea, by M. Balbiani.—On larval forms of Bryozoa, by M. Barrois.—Note on the storms of November 6 to 11, 1875, by M. Marié-Davy.

THURSDAY, DECEMBER 2, 1875

THE GOVERNMENT AND THE POLLUTION OF RIVERS

Pollution of Rivers. What Means can be adopted to prevent the Pollution of Rivers? A Paper read at the Social Science Congress, Plymouth and Devonport, September 1872, by William Hope, V.C. (London, 1873.)

Food Manufacture versus River Pollution. A Letter addressed to the Newspaper Press of England, by the same Author. (London: Stanford, 1875.)

THE question of River Pollution, one of undoubted importance to the country at large, has been once again raised by Mr. Hope, so well known for his untiring zeal in the cause of sewage farming, in the two above-named pamphlets. As involving questions of science—or at least of applied science—we feel called upon to offer some remarks upon the subject, the more so as it is one having such unquestionable sanitary bearings as to have been made the subject of Select Committees, Royal Commissions, and of at least three Parliamentary Bills.

We shall in the first place give a brief abstract of Mr. Hope's pamphlets, in order to lay before our readers the present state of the sewage question, before proceeding to consider the manner in which the subject has been handled by the Legislature.

In the first-named pamphlet the author passes in review the chief processes which have been proposed for preventing the pollution of rivers by sewage, classifying all systems under two divisions—"those which profess to deal with part only of the sewage, and those which profess to deal with the whole." The inefficacy of the former is summed up in the following words (page 5):—

"But supposing that they really accomplished all they are intended to effect, the sewage question would still be as far from solution as ever, for the part of the total refuse which they profess to deal with is only about a half per cent. of the whole."

Of processes professing to deal with the whole of the sewage the first noticed are those precipitation schemes in which the sewage matter is supposed to be precipitated by the addition of some chemical substance. The so-called "A B C" process is considered at some length, and its not very creditable history traced; analyses of the various precipitating mixtures employed by this company are given, beginning with that first employed which the author distinguishes as "Moses" (because stated by the patentee to have been first revealed to Moses in the wilderness and communicated by him to the children of Israel!), and concluding with that in use at Leeds at the time of reading the paper.

When we state that this mixture consists of alum, blood, clay, and charcoal refuse from Prussian blue works, our readers will at once perceive the justice of the sentence pronounced by Mr. Hope—that none of the ammonia in solution is precipitated, but runs away in the effluent water. We may furthermore recall to mind the fact that the process as carried on at Leicester and Leamington, with a mixture containing the same ingredients in different proportions, was made the subject of an exhaustive inquiry by the Rivers Pollution Commission, and justly condemned by that body in their second Report, on the grounds of its failing to remove the organic polluting substances in the state of solution. The same objections are applicable to Forbes' phosphate of alumina process, and to Anderson's process, which are the next considered. Mr. Whitthread's phosphate of calcium process is spoken of somewhat more hopefully, although at the time of reading the paper it was in a very early stage of development, while Weare's peat charcoal process is unhesitatingly condemned—"the effluent water resulting from it is, as a matter of fact, still sewage."

General Scott's hydraulic cement process, which consists in precipitating lime and clay in the sewage, is effective in clarifying and to a great extent deodorising the sewage by the removal of suspended matters in the form of "sludge," but from a sanitary point of view the sewage question is untouched, as the inventor does not profess to deal with the effluent water.

The purification of sewage by its direct application to land as effected by irrigation next receives consideration, the author pointing out that this is really an effective means of disposing of sewage—a statement fully borne out by every scientific authority who has examined into the method. Without at present entering too fully into details, we may state that the author's experience has led him to the conclusion that the successful treatment of sewage as a manure depends upon its thorough intermittent downward filtration through the soil, with due precautions against overflooding the land. By those who have followed the question from the beginning, it will be remembered that the chemical principles of "downward intermittent filtration" were first discovered in the laboratory of the Rivers Pollution Commission, and its efficiency made known in their first Report. The chemistry of the process, it is scarcely necessary to add, is accelerated oxidation, and Mr. Hope had been independently led to adopt this principle as applied to irrigation on an experimental sewage farm at Romford. The remainder of the pamphlet is chiefly devoted to what we cannot but consider as a fruitless discussion upon the precise meaning of the terms "irrigation" and "intermittent downward filtration," it being contended that the two processes are really identical—an opinion in which we feel constrained to differ from the author, since, although the involved principles are most probably the same, the methods of application are essentially different. The results of the early experiments upon the Romford farm were made known to the British Association Committee at the Brighton meeting, and are thus summarised by the author:—

"Although the soil is exceedingly siliceous, and ill-adapted for the retention of manure, yet out of every 100 parts of nitrogen applied in the sewage, no less than 40 were actually converted into crops, 50 parts were unaccounted for (remaining chiefly in the soil), and only 10 parts escaped in the effluent water, of which again only a fraction was still in an organic form."

The second pamphlet is a spirited appeal to the press to take up the sewage question, but as it relates chiefly to the financial aspect of the matter, it is not well adapted for abstracting in these columns. It may be stated, however, that the author therein admits that he has met with heavy losses in the working of the Romford farm, because, in his own words, "he has not had the sewage of Romford to convert." The original outlay, it seems, had been based

upon the assumption of his receiving the sewage from a population of 8,000, instead of which the amount actually received was that due to a population of about 3,000.

Mr. Hope has thus done excellent service in continually directing attention to and practically demonstrating, often at great pecuniary sacrifice, the applicability of the irrigation scheme to the disposal of sewage. It is true that the Towns Sewage Commission of 1865, in their third Report, did not speak favourably of the process, stating that their analyses proved that the effluent water from the Rugby works contained about the same quantity of dissolved organic impurity as the raw sewage, but it is now known that the process of analysis employed by them gave fallacious results, and analyses by the Rivers Commission (First Report) show that the process removes an average of 81·7 per cent. of the nitrogen, and 68·6 per cent. of the carbon contained as *dissolved* organic impurity, and 97·7 per cent. of the *suspended* organic pollution.

So much for irrigation. The other plan recommended by the Commission, Frankland's "downward intermittent filtration," is equally if not more effective. An average of 87·6 per cent. of nitrogen and 72·8 per cent. of carbon contained as *dissolved* organic pollution is removed by the operation, and *all* suspended impurities. We may further state that the plan has been applied by Mr. Bailey Denton to the sewage of Merthyr Tydvil, and has been in successful operation at that town for a period of three years.

Two effective schemes for the treatment of sewage—either of which might be employed according to the locality—are thus offered, so that, the sewage question being practically settled, let us now consider the action of the Government in the matter.

It is at least fifteen years since the efficacy of irrigation was first made known, and seven years since the discovery of intermittent filtration. In a letter on the sewage question published in 1865 by Mr. Hope, it is stated that "there have already been six Select Committees and two Royal Commissions on the question, independently of the Main Drainage Committee of the Metropolitan Board of Works, which has investigated the subject for five long years, and these Committees and Commissions have published no less than ten reports." A Rivers Pollution Commission was formed in 1865 and replaced by another in 1868, which continued its work down to 1874. These Commissions have cost the country from 40,000*l.* to 50,000*l.*, and in their laboratory the various processes devised for the purification of sewage and other foul liquids have been quantitatively examined and the results made known in no less than nine consecutive reports. Remedies for the different forms of pollution have been clearly and consistently pointed out, and various recommendations suggested for legislation. The standards of polluting liquids proposed by the Commission to be fixed by Act of Parliament have been substantially approved of both by English and Continental chemists of eminence. Now the members of a Royal Commission are presumably appointed because specialy qualified for the inquiry, a presumption which has been amply testified in the case of the Rivers Commission. Notwithstanding this—notwithstanding that a code of standards has been proposed for legislative enactment—in spite of the fact that practical and efficient remedies do already exist for the disposal of sewage, down to the present time nothing whatever has been done by the Government. The Duke of Northumberland's Bill of 1873 embodied, it is true, all the recommendations of the Rivers Commission, but, most wonderful to relate, in the Rivers Pollution Bill brought in last session, the whole of the work done by that Commission is totally ignored; and the Bill moreover shows that its framers were totally unacquainted with the advancement of science in this direction during the last twenty years.

Confronting these facts with a statement in Mr. Hope's second pamphlet, that "the Registrar-General's returns, confessedly incomplete from various causes, show that 'sanitary authorities' have been killing by means of enteric fever no less than 14,000 persons per annum," we now leave the subject to the serious consideration of the Legislature.

THE MANCHESTER SCIENCE LECTURES

Science Lectures for the People, delivered in Manchester. First, Second, Third, Fourth, Fifth, and Sixth Series. 1866-74. 3 vols. (Manchester: Heywood.)

IT is now nine years since Prof. Roscoe made the bold experiment of ascertaining whether the working men of Manchester would appreciate the value of scientific instruction given in a plain but correct manner, and illustrated by suitable experiments and diagrams. The magnificent success that attended the early efforts of Prof. Roscoe has led the experiment to be repeated yearly until it is now, we hope, a settled institution. In the preface to one of the series we learn that each lecture, on an average, has been attended by nearly 1,000 persons, and an additional and wider audience has been secured by the verbatim reports of the lectures which are bound together in the volumes before us. Published at a penny each, from 5,000 to 10,000 of each of these lectures have been sold, and the demand for back numbers still continues.

Certainly it is to be hoped, as Prof. Roscoe remarks, "that the example of Manchester may be followed by other large towns, for surely nothing can at the present time be more important than to infuse into the minds of the people an idea of that scientific truth which is rapidly being recognised as not only lying at the foundation of our material welfare, but also of our social and moral well-being." We are aware that many of our large towns are doing good work in this direction by the lectures regularly arranged in connection with some local institution; witness, for example, the immense audiences attracted by the admirable lectures yearly given in connection with the Midland Institute at Birmingham. But the lectures at these and similar institutions are chiefly frequented by the middle classes, whereas we are assured that at the Manchester lectures the class of persons present was chiefly working men, for whom the lectures were designed, and who by their marked attention and interest invariably showed how keenly they appreciated the information that was given. It is said that to make working-men lectures a success, a very low entrance fee must be charged, and this involves a pecuniary loss that must be met by local subscriptions. This must necessarily be true of the first course or two, when the people will not pay for that of which they have had no experience. But

we question the wisdom of not allowing these Manchester lectures to be self-supporting. Working men are now absolutely better paid than the great majority of clerks and *employés* in the Civil Service, and their expenditure is less heavily taxed than those who esteem themselves in a higher social scale. Mechanics and others can therefore well afford to pay whatever is necessary for these lectures, and we cannot but think it is an unwise thing to establish the idea that fustian can have for a penny what is charged sixpence or a shilling to cloth. If a penny entrance-fee is too firmly rooted to be dislodged with impunity, boxes might be put in the room for contributions by the audience, who might be urged to make the lectures self-supporting. Moreover, the profits on the sale of these reports of the lectures must be large and ought to go some way towards meeting the expense of the lectures themselves. After all, the main secret of success in any popular lecture scheme is to have some one responsible person, like Prof. Roscoe, who, year after year, has unsparingly used his influence and his time in this good cause.

We must add a few words about the books before us. When upon opening our parcel we found the editor of NATURE had sent us these lectures with a request for a review of them, we felt he had set us to a hopeless task. What sane solitary reviewer dare venture to criticise the collective wisdom of Professors Huxley, Tyndall, Roscoe, Gladstone, Geikie, Balfour Stewart, Odling, Clifford, W. C. Williamson, Wilkins, Ward, Jevons, Drs. Carpenter and Huggins, Mr. Spottiswoode, Sir John Lubbock, and other famous men who make up the brilliant array of Manchester lecturers?

It is hardly needful to say that all the lectures in these volumes are good, and some well repay careful perusal. Many of the lectures are so fascinating that it is difficult to put the volumes aside. What, for instance, can be more charming than Prof. Geikie's lecture on the Ice Age in Great Britain, or Sir John Lubbock's lecture on Modern Savages, or Prof. Stewart's on the Sun and Earth? And we envy those who were present at such experimental lectures as Prof. Tyndall's on Crystalline Forces, Prof. Abel's on Gun Cotton, or at Prof. Roscoe's or Dr. Huggins', and others we have not space to name. The books before us are therefore well worth preserving, for though the lectures are popular they are in no instance claptrap; and whilst within the comprehension of all classes, they will also be found not unworthy of perusal by men of culture.

Mr. Pitman, who reported the lectures, has evidently done his work faithfully and well, and Mr. Heywood who publishes them has clothed the volumes in a new and attractive dress.

We would venture, however, to suggest to Prof. Roscoe—whose name at the foot of each preface is the only editorial mark—that it would be desirable to have a responsible editor when such permanence, as these volumes indicate, is given to the lectures. Reading one of Dr. Carpenter's lectures, for example, there is a continual reference to diagrams and maps which, though present to the audience, are not so to the reader; and to some other lectures the same remark applies. Moreover, before binding up the lectures, the authors, we think, ought to have been informed that a volume was to be issued, and so the opportunity afforded them of making any corrections or additions to their lectures they might find necessary. Then a better table of contents of each volume would be an advantage, and the names of the lecturers should be attached to the titles of the lectures in the contents. In the first series the names of those who gave the short courses on Chemistry, Zoology, and Physiology are entirely omitted both in the index and in the lectures themselves. A reader opening on p. 119 of the first volume finds the course on physiology beginning, "The subject, my friends, upon which I am going to speak to you this evening, &c.," but who the speaker is he will be perplexed to find. Incidentally the omitted names happen to be mentioned by Prof. Roscoe in the preface. Such little matters as these might readily be amended by proper care on the part of the publishers.

W. F. B.

RECENT AUSTRALIAN EXPLORATIONS

Explorations in Australia; with an Appendix on the Condition of Western Australia. By John Forrest, F.R.G.S. (London: Sampson Low and Co., 1875.)

DURING the last three years there has been an admirable activity among the Australian colonists in the exploration of the great tract of unknown land in the centre of the southern continent. It was long ago surmised that this interior was either occupied by a great lake or lakes, or was in the main a barren desert, but only within the last two years has its real condition been conclusively demonstrated. The most prominent names in recent exploration are those of Giles, Gosse, Ross, Lewis, Warburton, and Forrest. The first two were baffled in their attempts to cross the country; even though Gosse was provided with camels, he only reached close on the 130th degree of E. long. when he had to return eastwards. Ross, in 1874, explored a considerable previously unvisited tract to the S.W. of the Neale River, while Lewis explored, in 1874-5, the region to the W., N., and N.E. of Lake Eyre. Col. Warburton has the honour of having been the first to cross the country, starting from Alice Springs on the telegraph line in April 1873, and eight months after, reaching the west coast. His narrative we noticed in vol. xii. p. 46. Mr. John Forrest though yet a young man, has perhaps done more than any recent explorer to make known the real nature of the hitherto unknown or imperfectly known regions. He is, we believe, a native of West Australia, a member of the Colonial Survey, and well qualified in every respect for the trying task of Australian exploration, and the Colonies would do well to make liberal use of his services in order to obtain a satisfactory idea of the resources of their country.

The volume before us contains an account of three separate exploring journeys made by Mr. Forrest. The first of these was a comparatively short trip to the north-east from Perth, as far as the 123rd degree of E. long., accomplished between April and August 1869. The object of this journey was to endeavour to find some traces of the unfortunate Leichardt, who twenty-seven years ago quitted Moreton Bay to cross the continent, but whose fate is still a mystery. We need hardly say that Mr. Forrest's journey was in vain, so far as this

object is concerned, though he brought back much valuable information concerning the country traversed. The latter portion was over comparatively unknown ground; and Mr. Forrest discovered a remarkable series of salt lakes extending from about 119° to 122° E. long., and between 28° and 29° S. lat. The country is somewhat hilly along the 29th parallel, with granite and sandstone rocks. Here he was on the edge of the dreary spinifex desert which has daunted so many explorers.

Mr. Forrest's second journey was a much more important and extensive as well as hazardous one; it was indeed along the same route as that in which the dauntless Eyre suffered so terribly thirty-five years ago. With a small party, and after making excellent arrangements with a vessel to meet them at a certain point, he set out from Perth on March 30, 1870, came S.E. to the coast, and travelled along the great Australian Bight, reaching Adelaide on Aug. 24, without loss. He kept considerably more inland than did Eyre, and was in every respect more fortunate, though there was frequently considerable suffering from want of water. His report of the country traversed is much more favourable than Eyre's; large grassy tracts, extending many miles inland, being found along nearly the whole length of the Bight. Water is the great want, yet, since Forrest's journey, settlers have been attracted to the region, and we believe preparations are being made to connect West Australia with the eastern colonies by means of the telegraph.

Mr. Forrest's third journey was a much more formidable undertaking, and in all respects of more importance than either of the two previous ones. Its object was to discover decisively the real nature of the mysterious interior, and thus make an important contribution to scientific knowledge, as well as to let the Australians know what are the resources of their immense continent, not much less in area than continental Europe. The expedition was carefully organised, though it did not cost much above 600*l.*, and consisted of four white men, two blacks, and a large number of horses to carry provisions, equipment, &c., as well as for riding. The party set out from Perth on March 18, 1874, and after reaching 26° S. lat. in 117° E. long., proceeded in a generally eastward direction along that parallel, until on Sept. 27 the telegraph line was struck in 27° 7′ 50″ S. lat. Mr. Forrest's route was thus on an average about 400 miles S. of that of Colonel Warburton. After the first few entries in his journal, Mr. Forrest's narrative becomes somewhat tedious from its sameness, though the intelligent and energetic leader is not to blame for this. As has been the case with nearly all previous inland Australian expeditions, the daily occupation of the present one was to hunt for water; this is the burthen of every day's entry in the journal. Mr. Forrest has the same tale to tell as Colonel Warburton had of the more northerly route—apparently endless spinifex plains, varied with sand-hills, sandstone cliffs, granite rocks, a few trees, and, in Forrest's case, with rare grassy plains, but with scarcely enough of water all the way to fill a fair-sized mill-pond. Forrest's party, however, notwithstanding that they had no camels, fared much better, both in the matter of food and drink, than did Warburton's; only one of the horses actually died, and comparatively few had to be abandoned. Once only were they attacked by the natives, who were dispersed by a shot or two that did little damage. Not many natives were met with, though signs of them were frequently seen, and they seem to have been watching the expedition along most of the route.

Mr. Forrest sums up the results of his third journey as follows:—

"The whole of the country, from the settled districts near Champion Bay to the head of the Murchison, is admirably suited for pastoral settlement, and in a very short time will be taken up and stocked; indeed, some already has been occupied.

"From the head of the Murchison to the 129th meridian, the boundary of our colony, I do not think will ever be settled. Of course there are many grassy patches, such as at Windich Springs, the Weld Springs, all round Mount Moore, and other places; but they are so isolated, and of such extent, that it would never pay to stock them. The general character of this immense tract is a gently undulating spinifex desert—*Festuca* (*Triodia*) *irritans*, the spinifex of the desert explorers, but not the spinifex of science. It is lightly wooded with acacia and other small trees, and, except in a few creeks, there is a great absence of any large timber.

"The prevailing rock, which crops out on the rises and often forms low cliffs, in which are receptacles for holding water, is *light red sandstone* (desert sandstone, tertiary). The only game found in the spinifex is a kangaroo rat, commonly called the 'wirrup;' but in the grassy openings there are many kangaroos, and often emus, also a rat known as the 'wurrung.' These animals are very good eating, and formed a valuable addition to our store department. At the permanent waters there were always myriads of bronze-winged pigeons, and also the white cockatoo with scarlet crest, called the 'chockalott;' also the 'beaccoo,' or slate-coloured parrot. Generally, however, with the exception of the crow and hawk, birds were not very numerous except round water. Whenever a sheet of water was found we found ducks, and in Lake Augusta swans and ducks were innumerable."

Though the expedition became ultimately a race for water and life, yet Mr. Forrest found opportunities of carefully noting some of the principal features and productions of the country passed through, and the geologist and botanist especially will find a good deal in all the three narratives to interest them. There are a few spots on the cross-country route of Forrest where a well-provisioned expedition could encamp for months; and if the Colonial Government were to follow the advice recently given by the German Commission in reference to Arctic exploration, and send out a properly equipped scientific expedition to a suitable centre from which varied observations could be made, the scientific, and therefore the practical results, would, we believe, be of great value. This, we think, is the method that ought now to be pursued, at least in conjunction with ordinary exploring expeditions.

Mr. Forrest has made in his three narratives a contribution of high value to the literature of Australian exploration. We are glad to see he has met with so much honour in his own country, though there was no occasion to increase so largely the bulk of his work by newspaper reports of the various meetings held in his honour. Appended are a scientific list, by Baron von Mueller, of the plants collected in the third expedition; a report, by Mr. Brough Smyth, on the geological specimens; and General Weld's report, of September 1874, on the condition of Western Australia, with three pages of statistics.

The maps of the three routes deserve a word of praise. They have been plotted with great care, and the notes along the route are so numerous and full of information, that they form an admirable epitome of the whole work. The few illustrations are interesting; that especially of the Spinifex Desert gives one a good idea of this horror of Australian exploration.

OUR BOOK SHELF

Official Guide-book to the Manchester Aquarium. By the Curator, W. Saville Kent, F.L.S., F.ZS. Third edition. Twentieth thousand. (Michaelmas, 1875.)

THE Manchester Aquarium, situated in the Alexandra Park of that city, has now been opened to the public for more than two years, and has attained considerable success, although we believe it has not quite realised the expectations formed of it by its original promoters. Next to the Brighton Aquarium, that of Manchester is the largest amongst the six principal institutions of this kind existing in the country. The series of tanks, including the deep sea, shallow, and fresh-water groups, is sixty-eight in number, surpassing that of any other aquarium, while their linear frontage falls little short of 700 feet, which is but slightly less than that of the well-known establishment at Brighton. The building itself is of the plainest possible design, and at first sight seems as if it had been originally destined for a church of some kind. It consists of a high central oblong nave and two narrow side aisles. Being lofty and well lighted, however, it affords excellent accommodation for the smaller tanks which line it on both sides, as well as for the two fine large tanks, upwards of forty feet in length, which are situated at the two extremities. The proprietors of the Manchester Institution have been moreover fortunate in securing the services of a competent scientific naturalist as its director, an advantage shared by few if any of the sister establishments. Mr. W. Saville Kent transferred his services from Brighton to Manchester some two years ago. One of the last things he did at Brighton was to prepare the excellent Handbook to the Aquarium there which has been already noticed in this journal. We have now before us a copy of the third edition of the same author's "Guide-book to the Manchester Aquarium," prepared somewhat after the same fashion. After a few words of introduction describing the building and the general management, the sixty-eight tanks and their contents are discussed successively. A large amount of information upon the various fishes and other animals which they contain is thrown together in a very popular and readable form, and woodcuts are introduced illustrating the more attractive and noticeable objects exhibited. The Guide-book is concluded by a chapter on the principles of management of aquaria generally, which cannot fail to be of service to those who are interested in such matters, and which proves that Mr. Kent is fully master of the subject of which he treats.

Elementary Science Manuals. Botany for Schools and Science Classes. By W. J. Browne, M.A. Lond. (Belfast: W. Mullan, 1875.)

AN unfavourable impression of this little book is created at first sight by the obvious imitation, in the style in which it is got up, of Macmillan's series of "Science Primers." Such a plagiarism may generally be taken as a confession on the part of author or publisher that the work has not sufficient merits of its own to stand without adventitious assistance. This, however, is not the case in the present instance; and our depreciatory criticisms are almost exhausted. We had, it is true, marked certain passages in the margin for correction; but they are but few. The most important is the resurrection of the old blunder (twice over) of the existence of "spongioles" at the extremities of the root-fibres; and this is the more remarkable as the work from which the illustrative woodcut is copied does not make this mistake. The statement in the preface, however, that the book "contains all the subjects required for the First B.Sc. Examination in the University of London," must be taken *cum grano.* There is no index; and the deficiencies have therefore to be made out by careful inspection; but we find no description whatever of the process of fertilisation (although there is a diagram to represent the entrance of the pollen-tube into the embryo-sac), and no adequate one of that of respiration, this term being erroneously applied, as is so often the case, to the process of assimilation. But what can you expect for eightpence? You get, at all events, a great deal for your money; and the morphological and structural portion is on the whole so well done as to render the little book of great use to the beginner. Indeed we do not know any purely elementary work in which this part is more satisfactory. A few technical errors will doubtless be noticed and corrected in future editions. The illustrations, seventy-six in number, though not new, are very good and serviceable.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Hoffmeyer's Synoptic Weather Charts

WILL you kindly draw the attention of your readers to the fact that the second year of Capt. Hoffmeyer's synoptic charts of the weather in Northern Europe and Atlantic, commencing with Dec. 1874, is now about to be issued?

The subscription, as before, will be 12*s.* 6*d.* per quarter, including postage of the monthly parts.

I shall be glad to receive names of gentlemen who are willing to encourage the undertaking, which is carried on at Capt. Hoffmeyer's own expense. ROBERT H. SCOTT, Director

Meteorological Office,
116, Victoria Street, London, S.W.

Collomia

ON reading Mr. Duthie's communication (vol. xii. p. 494) on the capsules and seeds of *Collomia*, I presumed that some one would be ready to indicate the use of the mucilage and threads of the seed-coat; but I now notice that Mr. Bennett (vol. xii. p. 514) supposes that it "still remains to be discovered." An obvious and sufficient explanation will be found in A. Gray's "Structural and Systematic Botany," as far back as the edition of 1845. In the later editions, all of them now old, it is twice referred to. On p. 40, after mentioning that these gelatinous threads, or the like, occur on many seeds or seed-like fruits of various orders, it is said: "They may subserve a useful purpose in fixing light seeds to the ground where they lodge, by means of the moisture of the first shower they receive." And on p. 321, where forms of this apparatus are described, it is added: "This minute mechanism subserves an obvious purpose in fixing these small seeds to the moist soil upon which they lodge, when dispersed by the wind."

The seed of a *Collomia* or *Gilia*, when wetted, forms a *limbus* of three or four times its diameter; this would involve a multitude of grains of sand, and ballast the seed most effectually in the situations where or at the time when alone it could germinate. A. GRAY

Sir Thomas Millington and the Sexuality of Plants

IN your article last week on the Oxford Botanic Garden, reference is made to Sir Thomas Millington, the Savilian Professor of Botany, as having in 1676 "first divined the fundamental fact of sexual reproduction in flowering plants." In a review in the columns of the *Academy*, of the English edition of

Sachs's "Text-book of Botany," by Prof. E. R. Lankester, the Savilian Professor is also spoken of as having "discovered the sexuality of plants." It would interest students of the history of botany to know to what extent the writer of either of these articles is able to corroborate this statement by reference to Sir Thomas Millington's writings. In his recently published "History of Botany," Prof. Sachs gives the following account of this alleged discovery:—"In all histories relating to the subject of sexuality, a certain Sir Thomas Millington—otherwise unknown in the history of botany—is mentioned as deserving of the credit of having first indicated the stamens as the male sexual organs. The only information, however, which we have in support of this is contained in the following statement by Grew in his 'Anatomy of Plants,' 1682, p. 171, ch. 5, § 3:—'In conversation on this subject'—viz., on the part played by the stamens (termed by Grew the 'attire') in the formation of seeds—'with our learned Savilian Professor, Sir Thomas Millington, he gave it as his opinion that the 'attire' serves as the male organ for the production of the seed. I at once replied that I was of the same opinion, gave him some reasons for it, and answered some objections which might be made to it.'"* In the first edition of Grew's work, 1671, he attributes no sexual function to the stamens; but in the edition of 1681 he thus continues, in substance:—It appears firstly, that the "attire" serves to separate certain superfluous portions of the sap in order to prepare for the production of the seed. Just as the foliature (floral leaves) serves to carry away the volatile saline particles of sulphur, so the "attire" serves to diminish and adjust the atmospheric portions, in order that the seed may become more oily and its principles better fixed. The flowers have therefore usually a more powerful odour than the "attire," because the saline is stronger than the atmospheric sulphur, which is too subtle to affect the senses. An analogy drawn from the animal kingdom follows, which is hardly quotable; but Sachs points out how wonderfully any germ of truth in Grew's hypothesis was corrupted by the chemical theories and strivings after a false analogy of the day. It is difficult to see that there was really any advance in this hypothesis upon the state of knowledge in the time of Theophrastus (B.C. 371–286), who distinctly recognised some individual plants as male, others as female. Whatever merit also is due to Millington must, unless there is other record of his services, be at least equally shared with Grew.† It does not appear, however, that either of these botanists even attempted to confirm their conclusions by experiment. The merit of the first discovery of the true function of the stamens is assigned by Prof. Sachs to the German botanist Camerarius, in his "De sexu plantarum epistola," published in 1694. This tract closes with an ode, reminding one of Darwin's "Loves of the Plants," beginning thus—

"Novi canamus regna Cupidinis,
Novos amores, gaudia non prius
Audita plantarum, latentes
Igniculos, Veneremque miram."

ALFRED W. BENNETT

6, Park Village East, London, Nov. 29

The Late Eclipse

ON my return from India I should like to say a few words about some letters which appeared in the *English Mechanic* during my absence. Mr. Proctor, and a writer signing himself "A Fellow of the Royal Astronomical Society," comment in these letters on the result of the late Eclipse Expedition. It would be better if these discussions were postponed until the results are published by the Royal Society, but if writers who have not heard anything beyond a few short telegrams take it upon themselves to enlighten the public as to the value of photographs which they have not seen, a few remarks of one who has seen them become necessary.

If the telegrams written by me have given rise to the misunderstanding, I am sincerely sorry for it. I have had no personal interest either in the success or the failure of the expedition. The Royal Society has done me the honour to entrust me with the task of carrying out a programme sanctioned in detail by the Eclipse Committee. This I have done to the best of my ability, and in wording the telegrams in question I avoided, carefully any expression which might have raised expectations, not to be fulfilled on the arrival of the photographs. If the impression has been propagated that the expedition has not obtained any results of great importance, it is the fault of those who, thinking I had an interest in exaggerating the importance of the results, have taken away from the meaning of my words, which in reality remained far below the truth.

There cannot be the slightest doubt that the photographs obtained by the prismatic camera are full of interest and importance. They solve the question in which part of the spectrum the chief photographic rays of the corona are situated. They open out almost an entirely new field of inquiry, answering questions which could never have been answered by any other method, and suggesting new questions to be answered hereafter.

I should have liked to postpone the question whether it is possible to photograph in all its details the spectrum of the corona in the time available during eclipses, until Mr. Proctor's long-promised mathematical solution has appeared. As, however, we have had to wait for it already a considerable time, I venture to submit to your readers the following considerations:—The prismatic camera is a spectroscope without collimator. It has given us photographs after one minute's exposure, and would have done so in less time under more favourable atmospheric conditions. If we add a collimator and telescope to this camera, we shall have an arrangement similar to that which actually was employed for the photographs of the spectrum. If the lens of the telescope is, as regards diameter and focal length, like that of the camera; if, further, the focal length and diameter of the collimator lens is such that it would collect all the light which passed through the objective of the telescope, if the slit plate was removed, the only diminution the intensity of the light would be caused by the absorption through the two additional lenses and by the diffraction of the slit. The influence of diffraction can be reduced to a minimum by suitably altering the aperture of the collimator lens and by using a slit not too narrow. We should thus have an instrument capable of photographing the spectrum of the corona in one minute.

This is not the place to discuss whether the failure of the spectroscopic cameras was due to atmospheric causes, to the instruments employed, or finally, to my own fault. It will, I believe, be found hereafter, that the experience gained by even these failures will prove useful on future occasions.

In enumerating the results of the expedition the photographs of the corona and the sketch taken by the Hon. H. N. Shore ought not to be forgotten. The time observations were conducted with as much accuracy as the instruments permitted.

Sunnyside, Upper Avenue Road, N.W., Nov. 20 ARTHUR SCHUSTER

Lommel's Optics

I AM indebted to Prof. W. N. Hartley for a correction in my review of Lommel's Optics, the proof-sheets of which did not reach me in time for revision. The translator of the work is evidently right in using the term napthalin red for the body which exhibits the fluorescent spectrum depicted in Fig. 6 in the article. The substance in question, Prof. Hartley states, is also called Magdala red, and has the elegant chemical name of Azotrinaphthyldiamine. I am also obliged to my friend Prof. H. M'Leod for pointing out that the mode of exhibiting the formation of the rainbow described by Prof. Lommel, is to be found in Jamin's "Cours de Physique" (tome 2, p. 782), although the substitution of a spherical flask filled with water for a solid glass globe, as described by Jamin, is more appropriate and convenient. Pouillet (tome 2, p. 769) also gives, I see, a somewhat similar experiment, using a cylindrical glass vessel filled with water.

W. F. B. ("the Reviewer of Lommel's Optics")

The Rainfall

IN NATURE, vol. xiii., p. 70, under the head of "The Rainfall," you allude to the extraordinary rainfall for 1875 in Great Britain, and call it a plague of rain; you further call attention to the astonishing fall of 1·287 inches for each of the three hours between 4 and 7 A.M. on the 1st of September last, at Sikawei, in China; and to the total quantity that fell there during the twenty-four hours that elapsed between 4 P.M. on August 31 and the same hour on the day following, viz. 8·59 inches.

I believe that a very heavy rainfall indeed was registered in South Devon in September last, the fall in one hour and in a total of twenty-four being unprecedented; but I have mislaid

* I have not Grew's work at hand, and am therefore retranslating Sachs's translation.

† Grew was born in Coventry in 1628, and died in 1711; in 1677 he was appointed Secretary to the Royal Society.

the record. It would be interesting to have this accurately stated, and more widely published.

At Bangalore, in the Mysore Province, I once registered an inch and a quarter in twenty minutes; and seven and eight, and more inches have been occasionally gauged during a heavy twenty-four hours' fall, notably so in 1856, when disastrous floods occurred. Somewhere about that period a most extraordinary fall of rain occurred at Madras. I regret that I have not the record by me, but I am right in saying that more than twenty-three inches fell in twenty-four hours! and that more than seven inches fell within six hours! This was gauged at the Madras Observatory, and registered every hour; the statement can therefore be easily corroborated by a reference to the superintendent at that place. A coffee planter on the western Ghauts of Mysore told me that at Hoolikul he had gauged, in August 1874, 13¾ inches in one day, and 10¼ the next. He described it as a sullen, intermittent, continuous downpour, the monotony of which was very depressing. At Mahableshwar, on the same line of Ghauts, the average fall is 240 inches, chiefly in the four or five months, from May to September inclusive; while at the Cherrapoonji Hills, not very far from Calcutta, the average fall is over 600 inches, or (say) seventeen yards of rain! My notes are in a book that I left in India, but I am within the mark in what has been stated above.

The meteorology of India would furnish many startling incidents. It has not hitherto been sufficiently attended to, or recorded, and much valuable time has been allowed (like the rainfall) to run by; but attention is now, I believe, being paid to its systematic registry, and to the publication of accurate results. I have some interesting records, however, of the Province of Mysore, which I would gladly place at your disposal should you desire to have them.

J. PUCKLE

A New Palmistry

IT is the old story—"In striving to be concise, I have become obscure." If Mr. Mott will refer to my abstract of Prof. Ecker's paper, he will find directions as to procedure, very briefly stated, I will grant; for I, and others too, more competent to judge than myself, had no idea that the subject would attract the attention which it has done. At Mr. Mott's desire, however, I give him a literal translation of Prof. Ecker's directions (*op. cit.* p. 73) in full:—

"With regard to the method of measurement on living individuals, I will merely remark that the hand must be simply laid, with the fingers closed together, upon a board or a piece of paper, upon which a well-defined perpendicular line has been drawn. With this latter the axis of the middle finger and its metacarpal bone is made precisely to coincide. Every lateral movement of the middle finger naturally alters also the position of the other fingers, and every movement of the fingers upon the metacarpal bones towards the pollex turns to the advantage of the position of the index, while that toward the little-finger-edge of the hand to the advantage of that of the ring-finger. The tips of the fingers (without nails *à la Chinois*) are then outlined with a pencil, halved longitudinally; its cut surface being applied against them."

JOHN C. GALTON

Nov. 29

I HAVE made a number of determinations of the relative lengths of the "index" and "ring" fingers of both hands, the results of which, I think, very decidedly show that there is a great dissimilarity between the two hands. The hands of twenty-two persons were examined; in ten there was similarity between the hands as regards the relative lengths of the two fingers in question; in twelve there was dissimilarity. In the case of eight out of the ten the "ring" was longer than the "index;" in one case the "index" was the longer, and in the remaining instance the two fingers were of equal length. Of the twelve cases which exhibited dissimilarity, six had the "ring" longer than the "index" in the left hand, and five in the right hand; four had the "index" longer than the "ring" in the left hand, and in three the same relation existed in the right hand.

Faye on the Laws of Storms

M. FAYE'S paper on cyclones and waterspouts, of which you have lately published a full abstract, seems very unsatisfactory. The statement in NATURE, vol. xii. p. 401, of the laws of the cyclone's motion is no doubt true, but it is avowedly not original. But the succeeding parts, where the dynamics of the subject are treated of, cannot be sufficient—I think I may say cannot be sound—because they take no account of the very remarkable facts of the geographical distribution of cyclones. If M. Faye's theory were true and complete, cyclones ought to be equally common in all equatorial and tropical regions, except perhaps that they ought to be commonest in the hottest parts. So far is this from being the case, that they are strictly local phenomena. They are formed in the West Indian seas, but not in the South Atlantic; in the Indian Ocean, both north and south of the equator, but much oftener on the eastern than on the western side of India; and, I believe, off the coast of California, but not that of Peru. Their periodicity is equally remarkable. In the West Indian and in the Chinese seas they occur chiefly at the end of summer, but in the Bay of Bengal after the equinoxes.

All these facts point to the origin of the cyclone, not, as M. Faye seems to think, in eddies formed in the upper currents of the atmosphere—how could eddies be formed in currents so totally free from obstructions?—but in eddies formed by the meeting and conflict of the two trade-winds where one of them is drawn across the equator. This hypothesis agrees with observation, and harmonises all the geographical facts relating to cyclones.

This simple and true theory is stated in a paper on the Law of Storms by Prof. Maury, in NATURE of June 12, 19, and 26, 1873. It had previously been stated for the Bay of Bengal, as the result of an examination of particular storms, by Mr. Meldrum, in a paper read before the Meteorological Society of Mauritius, and reported in NATURE, vol. ii. p. 151; and a letter of mine in NATURE, vol. iv. p 305, maintained the probability of all cyclones so originating.

I think M. Faye is as unsatisfactory on waterspouts as on cyclones. I hope to follow this by a letter on waterspouts.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, Nov. 16

OUR ASTRONOMICAL COLUMN

SATELLITES OF URANUS.—There are many amateurs in this country who possess instruments quite competent to show the two larger or exterior satellites of the planet Uranus. With the view to facilitate the identification of these objects, their angles of position and distances from the centre of Uranus are given below for 14h. Greenwich mean time for the last ten days of the present year, with the intention of continuing them while the planet is most favourably placed for observation as regards position and distance from the moon's place. They are deduced from the very convenient tables appended by Prof. Newcomb to his discussion of the observations of the satellites with the 26 inch equatorial at Washington, forming Appendix I. to the Washington Observations for 1873:—

At 14h. G M.T.		Titania. °		"			Oberon. °		"

31 ...	,,	311·3	,,	17·0	...	,,	142·2	,,	25·5

The above angles are reckoned as is usual in measures of double stars, *i.e.*, from the N. point round by the east. The apparent diameter of Uranus by the Malta determination of Lassell and Marth will be 3″·87 on December 25th. With this value, should it be found more convenient, the arc values may be reduced to distances in diameters of the planet.

THE MINOR PLANETS.—No. 156 is announced as having been discovered by Herr Palisa, at Pola, on Nov. 22, in R.A. 2h. 54m., and N.P.D. 70° 23′: it is of

the twelfth magnitude.—From observations on Nov. 2 and 7 Herr Palisa has calculated circular elements of No. 153, which place the ascending node in longitude 228° 31′, with an inclination of 6° 57′. The mean diurnal motion assigned on this hypothesis (447″), if it were reliable, would make the period of this planet considerably longer than that of any other member of the group, but it will be necessary to wait till elliptical elements on a fair extent of observation are in our hands, before attributing to No. 153 a revolution so much in excess of the rest.

PUBLICATIONS.—(1) P. A. Hansen. *Ueber die Störungen der Grossen Planeten inbesondere des Jupiter.* A posthumous memoir published in vol. xi. of the "Proceedings" of the Mathematical Class of the Royal Saxon Society of Sciences. The analytical developments forming the subject of the first part of this treatise are applied especially to the case of the planet Jupiter; the perturbations of latitude by Saturn, and the perturbations by Uranus, Neptune, Mars, the Earth, Venus, and Mercury are exhibited numerically; and from Herr v. Glasenapp, who was engaged in this part of the work up to the time of Prof. Hansen's decease, may, it is announced, be expected the complete calculation of the perturbations of longitude and radius-vector of Jupiter by Saturn.

(2) J. N. Stockwell. *Theory of the Moon's Motion.*—This is a republication in an extended form of an investigation which appeared in the *Astronomische Nachrichten*, Nos. 2,024—2,026, wherein the mathematical developments are given in greater detail, with the addition of those applying to the formulæ for latitude. The author hopes to find time to continue his investigations in the same direction, so as to complete the developments of the perturbations of the moon's motions by means of the differential equations given in this first chapter. In the author's introductory remarks on the labours of those eminent mathematicians who have taken up the lunar theory, in referring to Prof. Hansen, there is no mention of his "Fundamenta nova investigationis orbitæ veræ quam Luna perlustrat," Gotha, 1838; or his "Darlegung der Theoretischen Berechnung der in den Mondtafeln angewandten Storüngen," the first part of which appeared in 1862, and the second in 1864.

(3) Dr. Franz Melde. *Theorie und Praxis der Astronomischen Zeitbestimmung*, &c. (Tübingen, 1875).—The author, Professor in the University of Marburg, explains that in the course of lectures on the determination of time by astronomical observations, he had found the want of a work in which the subject should be treated both in a theoretical and practical point of view, and in the present volume of 500 pages he has presented a very detailed discussion of time-determinations after the methods generally employed. The transit-instrument, its arrangement, mounting, and errors, with the methods of regulating it; the sextant, more particularly as regards its use for ascertaining time by corresponding altitudes of sun or stars, time by occultations, refraction, aberration, precession, &c., are explained at length. The volume, it will be seen, is one of a special character, and will be a desirable addition to an astronomical library.

DR. R. VON WILLEMOES-SUHM

IT is with the deepest regret that I have to intimate the death of Dr. Rudolf von Willemoes-Suhm, at sea, on our passage from Hawaii to Tahiti. He had not been in his usual robust health for some months, having suffered occasionally from indolent boils on different parts of the body. On Sept. 6 he applied to the surgeon for advice. He had had a rather severe shivering fit the day before, and an inflamed spot on the face began to show symptoms of erysipelas. The swelling and inflammation of the face increased during the next week; it extended over the forehead; and the fever and delirium attending erysipelas became more pronounced. On the morning of Sept. 13 he sank into a state of collapse, and died at three o'clock in the afternoon.

This sad occurrence has of course thrown a heavy gloom over our little party. From the commencement of the voyage Dr. v. Willemoes-Suhm devoted himself with unremitting industry and zeal, and in the best possible spirit, to the objects of this expedition. He has already published, in connection with our work, a paper in the *Annals and Magazine of Natural History*, "On a terrestrial Nemertine from Bermudas;" a long paper in Linnean Proceedings, on the deep-sea Crustacea of the cruise; "On the development of *Umbellularia*," in the *Annals and Magazine*: "On the Development of *Lepas fascicularis*," a paper sent to the Royal Society from Honolulu; and the notes on Crustacea which have been incorporated from time to time in my letters and reports. He has also written some interesting letters to Prof. von Siebold, describing the general zoological results of the cruise, which have been published in the *Zeitschrift für Wissenschaftliche Zoologie*. He leaves a fine series of drawings, with full descriptions, chiefly illustrating the development of surface Crustacea. For example, the development of species of the genera *Euphausia*, *Sergestes*, and *Amphion* is traced through all its stages. He leaves also an ample official journal in two large volumes. The loss of his valuable assistance in working up the final results of the expedition must, I fear, seriously affect their completeness.

Rudolf von Willemoes-Suhm was a native of Schleswig-Holstein; his family now reside in the neighbourhood of Rendsburg, where his father holds a high official appointment. He was about twenty-eight years of age when he died. He studied in the Universities of Göttingen and Bonn; he showed very early a strong taste for natural history in all its branches, and when quite a boy he published papers on the habits of European birds. Shortly after he left the University, he was appointed Privat-Docent in Zoology in the University of Munich, where he was associated with Prof. von Siebold, with whom he was extremely intimate, and whose place he frequently took in the lecture-room when the professor was prevented from teaching by indisposition. In 1868 he visited Italy and made zoological observations at Spezzia. In the summer of 1870 he made a series of observations on various marine animals, *Halicryptus*, *Balanoglossus*, &c., which formed the subject of his thesis on being appointed Privat-Docent in Munich.

In the summer of 1872 he went to the Faeroe Islands. He published some of the results of his investigations there in NATURE and elsewhere, but unfortunately a large series of zoological drawings which represented the greater part of his work was lost *in transitu*. It was from the accident of his calling upon me in Edinburgh, on his return from Faeroe, while there was still a vacancy on the staff of the *Challenger*, that he joined the expedition.

Among the more important of his publications are—

"Helminthologische Notizen," I. (Zeitschrift fur Wissenschaftliche Zoologie, Bd. xix., 3 Heft.)

"Helminthologische Notizen," II. (Ibid. Bd. xx., 1 Heft.)

"Zur Entwickelung von *Schistocephalus dimorphus*" (Ibid. Bd. xix., 3 Heft.)

"Biologische Beobachtungen über Niedere Thiere" (Leipzig, W. Engelmann, 1871) contains: "On a young calcareous sponge;" "On the development of an appendiculate Distoma;" "On *Balanoglossus kupferi*;" "On *Halicryptus spinulosus*;" "On *Priapulus caudatus*;" "On the development of some Polychæte Annelids, *Etone*, *Terebella*, and *Spirorbis*;" "On the natural history of *Polystoma integerrimum* and of *P. ocellatum*."

Dr. von Willemoes-Suhm was a man of unusual acquirements and culture; besides having a wide and accurate knowledge of the literature of natural science, he

was a good classical scholar, and could converse with perfect fluency in English, French, German, Danish, and Italian; and could read with ease nearly all the modern European languages. He made some strong friendships among his colleagues, and his acknowledged ability and his manner and address, which were eminently those of a polished gentleman and man of the world, won for him universal respect and esteem.

Altogether I looked upon Rudolf von Willemoes-Suhm as a young man of the very highest promise, perfectly certain, had he lived, to have achieved a distinguished position in his profession, and I look upon his untimely death as a serious loss not only to the expedition in which he took so important a part, but also to the younger generation of scientific men among whom he was steadily preparing himself to become a leader.

C. Wyville Thomson

H.M.S. *Challenger*, Tahiti, Oct. 1

THE PENIKESE SCHOOL

Our readers will regret to hear that the Anderson School of Natural History in Penikese Island, U.S., has come to an untimely end, and will no doubt regret still more that it has done so amid much unpleasant feeling between those chiefly concerned. We shall endeavour to state fairly the facts of the case.

Mr. Anderson, who is a wealthy merchant, made a gift of Penikese Island and 50,000 dollars in cash to the late Prof. Agassiz, in order to enable him to start a school for the practical teaching of natural history. This sum, it may well be believed, was only sufficient to start the school, erect buildings, furnish apparatus, and other necessaries. No one can complain that Mr. Anderson did not also endow the school, and during the life-time of the elder Agassiz there seems to have been no difficulty as to funds. On his death, his son, Mr. Alexander Agassiz, undertook to carry on the school. This he did, we believe, very unwillingly, as he knew there were no funds available for the daily business of the school, and he did not consider the island a suitable location for such an institution unless largely endowed. Moreover, it was his father's earnest wish that he should devote most of his time and energy to the Museum at Cambridge. However, he consented to conduct the school on condition that Mr. Anderson would contribute the sum of 10,000 dollars towards its support for the next three years. The first intimation of any dissatisfaction on the generous donor's part seems to have been made to the trustees at the end of 1874, when he sent them 1329·60 dollars to pay off debts which had been incurred, announcing at the same time that this was the last contribution he would make. The trustees seem, nevertheless, to have made every effort to carry on the school. A member of Prof. Agassiz's family contributed a guarantee fund of 3,000 dollars, and appeals were made in all directions, but without anything like success. Clearly the trustees and the teachers themselves could not be expected to carry on the school at their own expense, and all that they had any right to look for from Mr. Anderson was the balance of the 10,000 dollars which he promised; why he failed to contribute this, we are unable to say. Had he done so, those interested in the success of the school would have had time to set about raising something like an endowment fund, and a fine opportunity would have been afforded to the U.S. Government to show their appreciation of practical scientific teachers and scientific research. As it was, the only course which seemed left to the trustees, when everything is taken into account, was to close the school and sell off the furniture and aquaria. Mr. Anderson seems to have considered himself ill used and insulted by the trustees, and Mr. Agassiz in particular; but so far as the facts are known to us, we certainly believe he is mistaken. Mr. Agassiz has duties of the highest importance to attend to in connection with the Cambridge Museum, and he could not possibly be expected to waste his time and energy on an undertaking in whose success no one seemed to be interested. He seems to us to have acted in a straightforward and honourable manner, and only to have given up the school when he saw there was no possible hope of getting funds to carry it on. Mr. Anderson, for some reason which does not appear, seems to have lost his temper, and may naturally have been annoyed that the public did not come forward in support of the school which he so generously founded. The result is certainly to be regretted, but we hope that Mr. Agassiz and Mr. Anderson may come to a better understanding, and that even if the school be not again started, the latter will see that the former has acted all along in the interests of science, whose servant he is. To have touched the Agassiz Memorial Fund, now 347,000 dollars, as some one suggested should have been done, was simply impossible; it was collected for a special purpose.

Mr. Agassiz took two of the most promising Penikese pupils into his laboratory at Newport, and intends, we believe, as soon as the necessary means can be collected, to establish a school at some more suitable locality.

THE THEORY OF "STREAM LINES" IN RELATION TO THE RESISTANCE OF SHIPS *

II.

It might at first sight appear that I have now the materials for the proof of my chief proposition, the assertion of the unresisted progress of a submerged body; for such a body might be assumed to be surrounded by a system of imaginary pipes, as shown in Fig. 8; and each of these pipes being in equilibrium

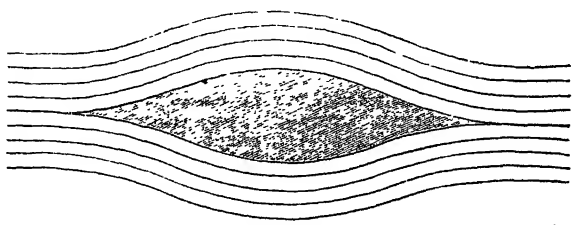

Fig. 8.

endways, that is to say, the flow of fluid through it not tending in the aggregate to move it endways, neither, it might be said, would the flow of fluid tend to move the submerged body endways. But this reasoning would not be sound. The pipes we have hitherto been considering have been of uniform sectional area throughout their length, an assumption which has been necessary to the treatment pursued, as the velocity has in each case been assumed to be uniform throughout the pipe. The section of the pipe may have been square, circular, trapezoidal, or any other form; but the area of the section has been assumed to be the same throughout the length of the pipe.

But pipes of uniform sectional area do not truly represent the flow of a fluid past a submerged body. I shall presently ask you to consider the fluid as flowing past the body through a system of imaginary pipes; but to render the assumption admissible, the sides of the imaginary pipes must not be so placed as to interfere with the established course of the fluid, whatever that may be; in other words, if, for the sake of illustrating the behaviour of the fluid, we assume that it is divided into streams or filaments flowing through imaginary pipes, we must accept such a form for those imaginary pipes that their sides exactly follow the paths of the adjacent particles of fluid.

Now such a rule may, and probably will, require the imaginary pipes to be of varying sectional area throughout their length. Therefore, before we can apply the analogy of the flow of fluid through pipes to the flow of a fluid past a submerged body, it is necessary to consider the behaviour of fluid in pipes of varying sectional area.

It is, I think, a very common but erroneous impression, that a

* Address to the Mechanical Section of the British Association, Bristol, August 25, 1875; by William Froude, C.E., M.A., F.R.S. President of the Section. Revised and extended by the author. Continued from p. 52.

fluid in a pipe exercises, in the case of its meeting a contraction (see Fig. 9), an excess of pressure against the entire converging surface which it meets, and that, conversely, as it enters an enlargement (see Fig. 10), a relief of pressure is experienced by the entire

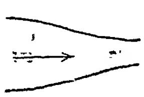

FIG. 9.

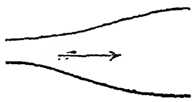

FIG. 10.

diverging surface of the pipe. Further, it is commonly assumed that, when passing through a contraction (see Fig. 11), there is

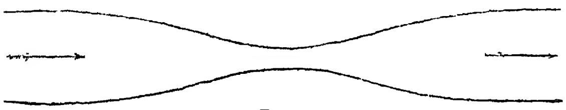

FIG. 11.

in the narrow neck an excess of pressure due to the squeezing together of the fluid at that point.

These impressions are in no respect correct; the pressure at the smallest part of the pipe is, in fact, less than that at any other point, and *vice versâ*.

If a fluid be flowing along a pipe which has a contraction in it (see Fig. 12), the forward velocity of the fluid at B must be

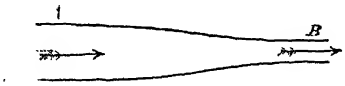

FIG. 12.

greater than that at A, in the proportion in which the sectional area of the pipe at B is less than that at A; and therefore while passing from A to B the forward velocity of the fluid is being increased. This increase of velocity implies the existence of a force acting in the direction of the motion; that is to say, each particle which is receiving an increase of forward velocity must have a greater fluid pressure behind it than in front of it; for no other condition will cause that increase of forward velocity. Hence a particle of fluid, at each stage of its progress along the tapering contraction, is passing from a region of higher pressure to a region of lower pressure, so that there must be a greater pressure in the larger part of the pipe than in the smaller, and a diminution of pressure at each point corresponding with the diminution of sectional area; and this difference of pressure must be such as to supply the force necessary to establish the additional forward velocity required at each point of the passage of the fluid through the contraction. Consequently, differences of pressure at different points in the pipe depend simply upon the velocities at those points, or, in other words, on the relative sectional areas of the pipe at those points.*

It is simple to apply the same line of reasoning to the converse case of an enlargement. Here the velocity of the particles is being reduced through precisely the same series of changes, but in an opposite order. The fluid in the larger part of the pipe moves more slowly than that in the smaller, so that, as it advances into the enlargement, its forward velocity is being checked; and this check implies the existence of a force acting in a direction opposite to the motion of the fluid, and each particle being thus retarded must therefore have a greater fluid pressure in front of it than behind it; thus a particle of fluid at each stage of its progress along a tapering enlargement of a pipe is passing from a region of lower pressure to a region of higher pressure. As is well known, the force required to produce a given change of velocity is the same, whether the change be an increase or a decrease. Hence, in the case of an enlargement of a pipe, as in the case of a contraction, the changes of velocity can be satisfied only by changes of pressure, and the law for such change of pressure will be the same, *mutatis mutandis*.

In a pipe in which there is a contraction and a subsequent enlargement to the same diameter as before (see Fig. 11), since the differences of pressure at different points depend on the differences of sectional area at those points, by a law which is exactly the same in an enlarging as in a contracting pipe, any points which have the same sectional area will have the same pressures,

* See Supplementary Note B.

the pressures at the larger areas being larger, and those at the smaller areas smaller.

Precisely the same result will follow in the case of an enlargement followed by a contraction (see Fig. 13).*

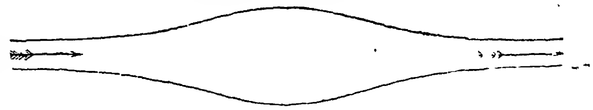

FIG. 13.

This proposition can be illustrated by experiments performed with water.

Figs. 14, 15 show certain pipes, the one a contraction followed by an enlargement, and the other an enlargement followed by

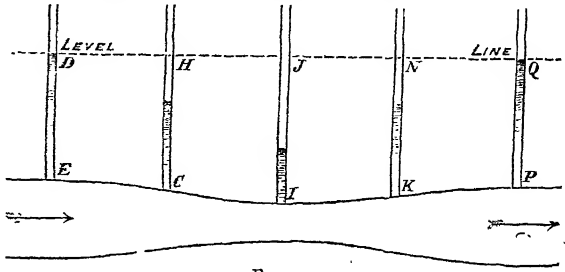

FIG. 14.

a contraction. At certain points in each pipe, vertical gauge-glasses are connected, the water-levels in which severally indicate the pressures in the pipe at the points of attachment.

In Fig. 14 the sectional areas at P and E are equal to one another. Those at C and K are likewise equal to one another, but are smaller than those at P and E. The area at I is the smallest of all. Now, if the water were a perfect fluid, the pressures P Q and E D would be equal, and would be greater

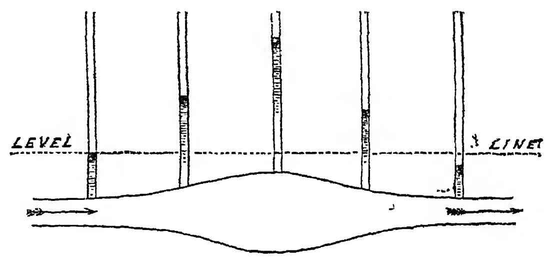

FIG. 15.

than C H and K N. C H and K N would also be equal to one another, and would be themselves greater than I J.

The results shown in Fig. 15 are similar in kind, equal pressures corresponding to equal sectional areas.

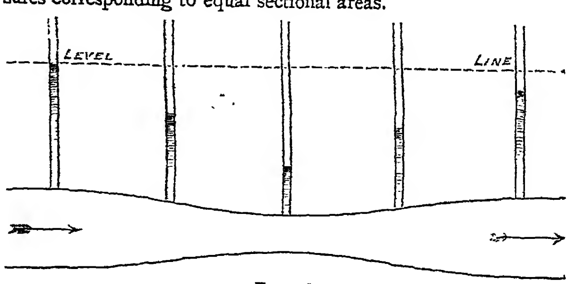

FIG. 16.

As water is not a perfect fluid, some of the pressure at each successive point is lost in friction, and this growing defect in pressure is indicated in the successive gauge-glasses in the manner shown in Figs. 16, 17.

* In a perfect fluid, we may say in a sense, the *vis viva* of each particle remains constant. If the particle is stationary, the *vis viva* is entirely represented by the pressure; if it be under no pressure, the *vis viva* is entirely represented by the velocity; if it be moving at some intermediate velocity, the *vis viva* is partly represented by the pressure and partly by the velocity.

As the pressure of the perfect fluid in the pipe at any point depends upon the sectional area at that point, it follows that the amounts of the pressures are independent of the distance, as

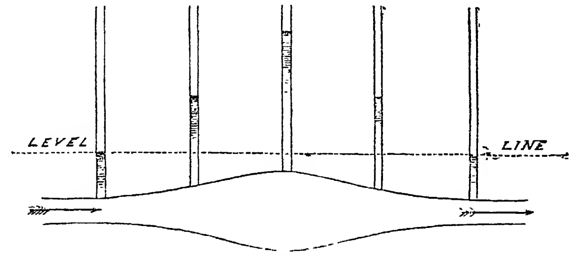

FIG. 17.

measured along the pipe, in which the area of the pipe alters; so that if in the pipe shown in Fig. 18 the areas at all the points marked A are equal, if also the areas at all the points marked B are equal, and so also with those at C and D, then the pressures at all the points A will be the same, the pressures at all the points B will be the same, and so with those at C and D.

Since, then, the pressure at each point depends on the sectional area at the point and on that only, it is easy to see that the variations in pressure due to the flow are not such as can cause any total endways force on the pipe, provided its sectional area at each end is the same.

Take the pipe shown in Fig. 19. The conical portion of pipe A B presents the same area of surface effective for endways pressure as does the conical portion H I, only in opposite directions. They are both subject to the same pressure, being that appropriate to their effective mean diameter J. Consequently the endways pressures on these portions are equal and opposite and neutralise one another. Precisely in the same way it may be seen that the endways pressures on B C, C D, D E, exactly counteract those on G H, F G, E F; and in precisely the same way it may be shown that in any combination whatever of enlargements and contractions, provided the sectional area and direction of the pipe at the two ends are the same, the total endways effect impressed on the pipe by the fluid flowing through it must be *nil*.

In the experiment I am about to show you, the several propo-

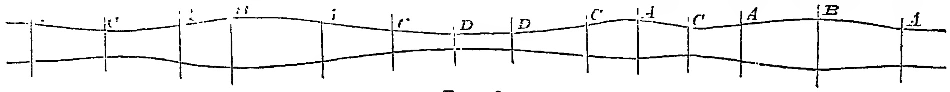

FIG. 18.

sitions which I have been elucidating will be seen to be verified step by step, if due allowance be made for the effect of friction.

A cistern (see Fig. 20), in which a definite head of water is maintained, discharges itself through a continuous series of pipes, which in the local changes of diameter exhibit the several characteristic features which have been under consideration.

From *a* to *b* at the outlet end we have a contraction followed by an enlargement; from *e* to *g* the diameter is uniform, from

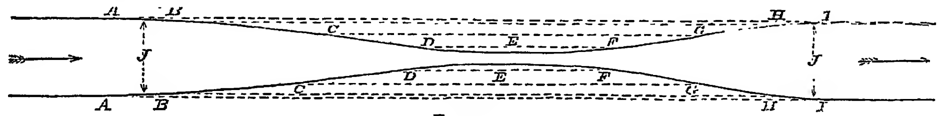

FIG. 19.

h to *l* we have an enlargement followed by a contraction. At the various critical features are fitted gauge-glasses such as have been described, so that the level at which the water stands in each indicates the pressure in the pipe at the point of attachment.

The series of pipes is laid out on an inclination which represents the mean resistance due to friction, or the "head" lost by friction, between the cistern and the outlet, in other words, the hydraulic mean gradient.

The mean diameter of the contracted part between *a* and *b*

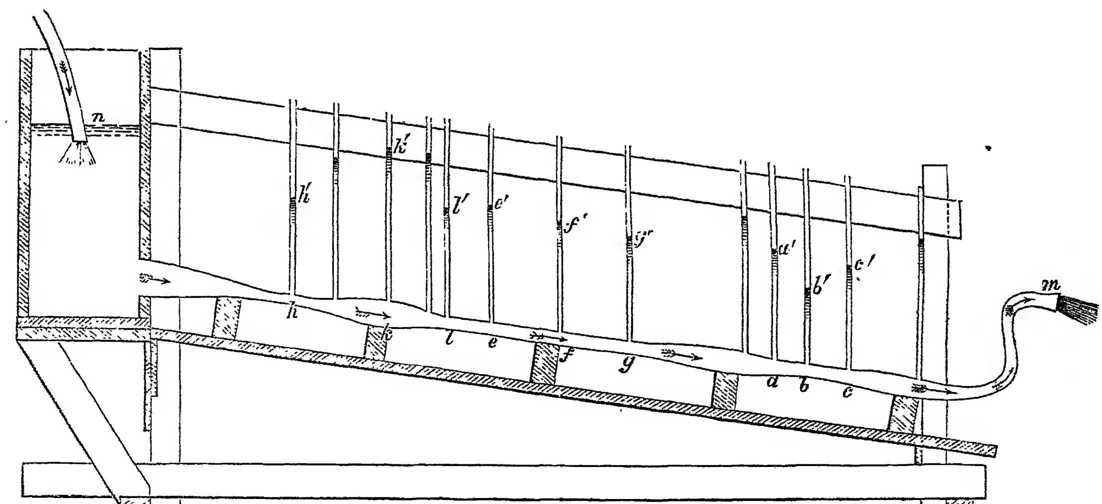

FIG. 20.

has been so determined by well-known hydraulic rules, that when it is compared with the adjoining parallel pipe, the hydraulic gradient shall be the same in each.

You observe that while the levels at which the water stands in the several gauge-glasses corresponds from end to end with the gradient from the head in the cistern to the head at the outlet; when examined in detail, they verify throughout the propositions I have been establishing. Broadly speaking, where the diameter is smallest, the pressure falls most below the mean gradient; at the points where the diameters are equal, the pressures allowing for the gradient are equal, and what is a quantitative verification, the gradient, or loss of head per foot between *a* and *b*,

as indicated by the gauge-glass levels a' and b', is identical with that indicated by $e' f' g'$, the gauge-glass levels connected with the parallel pipe.

In dealing with pipes of varying sectional area I have hitherto treated only of the modifications caused in the forward motion of the particles of fluid; for I have limited the argument to cases where the alteration in sectional area of the pipe is so gradual that, practically, the only alteration in the motion of the particles is that in their forward velocity; but I have previously shown that tortuosity in a pipe of uniform diameter does not introduce endways pressure, provided the initial and terminal directions are the same; and it is easy to see that an elongated system of such gradually tapered pipes as we have been considering, may be also tortuous without introducing endways pressure. Now tortuosity of flow is but another word for sideways deviation of flow.

This leads us up to the case of more sudden contractions or enlargements in pipes, where the particles next the sides of the pipes have to follow their surfaces and must therefore be moved rapidly sideways in their course.

We will, for simplicity, consider the case of a contraction (see Fig. 21), and one in which the pipe resumes the same diameter beyond the contraction.

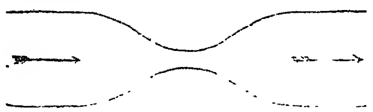

Fig. 21.

The particles along the central line pursue a straight course, and are subject only to the changes of pressure necessary to induce the changes of velocity.

To consider the behaviour of the other particles, let us assume that we insert a number of perfectly thin partitions (see Fig. 22), which we lay in such a manner that they exactly follow the paths of the particles of fluid at each point, so as not in any way to affect their motion; these partitions are quite imaginary, and merely assist us in looking upon the entire fluid in question as divided into a number of small streams. These streams are generally curvilinear, and vary in sectional area; and at the point beyond the contraction where the pipe resumes its former sectional area, we shall naturally find these minor streams occupying the same sectional area as before, and moving with the same velocity as before.

Now each of these small streams is exactly represented by a stream of fluid flowing within a pipe, that pipe being curvilinear and gradually varying in sectional area, and its two ends being of the same sectional area and in the same straight line. We have seen that in the case of such a stream, the sum total of all the forces due to its motion has no resultant longitudinally; and this will be equally the case, whether the envelope of the stream

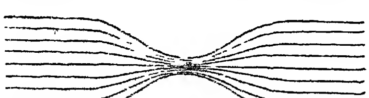

Fig. 22.

be an actual pipe or the mutual pressure of adjacent streams; this envelope will not be moved endways by the flow of the fluid. What is true of each stream is true of all put together; and thus it follows that the whole body of fluid which these separate streams constitute does not exert any endways force; or, in other words, there will be equilibrium of fluid forces throughout the passage of the fluid through a local contraction in a pipe such as we have been considering. The same line of argument evidently holds good in the case of an enlargement, where the pipe beyond the enlargement regains the same diameter as before.

In illustration of the conclusions which have been thus far established, if we had a perfect fluid with which to try the experiment, we might exhibit a very instructive and striking result.

Assume a perfect stream of fluid flowing through a pipe of very large diameter, A B C, with a contraction in it at B, as shown in Fig. 23, and that the equal pressures at A and C on either side of the contraction are indicated by the head of fluid in pressure-gauges A D, C E—the pressure at B, which will be less, being represented by the height B F. Now, the condition of the pipe at A will be just the same if we suppose the pipe supplied from a large cistern G, as shown in Fig. 24; and the appropriate pressure at A will be maintained, if the fluid stands in the cistern G at a height H, equal to the head A D in the pressure-gauge. So, again, the condition of the pipe at C will be the same if the pipe discharges into a cistern, I; and the appropriate pressure at C will be maintained, and can only be

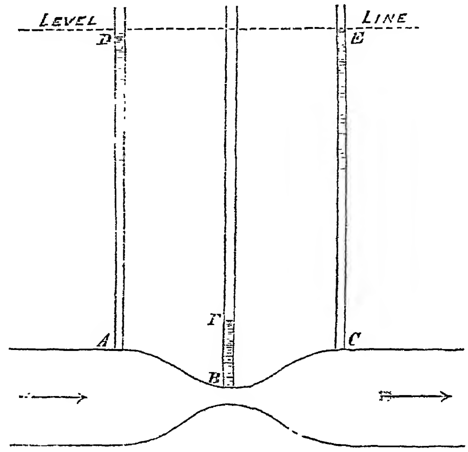

Fig. 23.

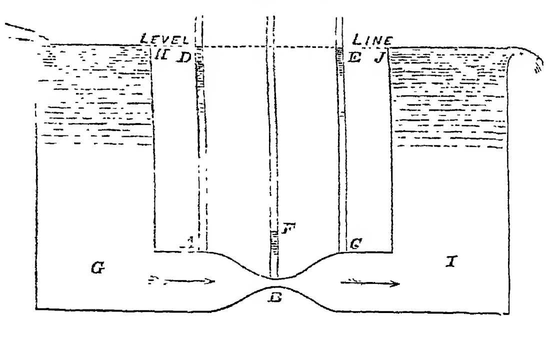
maintained, if the water in the cistern stands at a height J, equal to the head C E in the pressure-gauge, which is, in fact, the same level as H in the cistern G; so that if we once establish the motion through the pipe A B C, and maintain the supply of fluid, we shall have the fluid running rapidly, and continuing to run with unabated rapidity, from one cistern into another, though both are at the same head.

If we take such a condition of things that the pressure at B is zero, or, in other words, if the velocity at B is that due to the head A D, then we might cut the pipe at B and separate the two cisterns as shown in Fig. 25, and we should find the fluid issuing at B in a jet, and re-entering the pipe again at K, and rising as before in the cistern I to the same level with a perpetual flow.

The experiment here suggested is, if rightly understood, only a specialised instance of the properties of what in the previous experiment was termed a contraction followed by an enlargement; it is in fact as if in that experiment the diameter of the contracted part had been so far reduced that the pressure within it would have sunk apparently to zero, that is to say, in reality to the pressure of the atmosphere; in that case, of course, the pipe which enclosed that portion of the stream would have become simply an inert envelope, and might have been removed without affecting the dynamic properties of the stream. Theoretically indeed with the frictionless fluid the contraction of jet might be carried so far as not merely to obliterate all positive pressure, but to produce a negative pressure equal to that of the



atmosphere. For in fact the conditions thus brought into operation would be in effect identical with those which would exist were the experiment performed *in vacuo*, and the head in cistern and at the outlet were both increased by 34 feet; but the theoretical possibility thus indicated is greatly curtailed by friction, and the illustrative experiment I am about to exhibit deals only with the case in which the pressure at the contraction is reduced

apparently to zero, or in reality as I have said to that of the atmosphere.

In the apparatus as here arranged, consisting of the discharging and the recipient cistern, with the intervening jet-orifice and recipient-orifice, the overflow of the recipient cistern is at 18 inches above the centre of the orifices.

As I continue to fill the discharge cistern, you observe the jet shoots across the open space between the orifices, and the water-level continues to rise in the recipient cistern; and so long as the head in the former is maintained at a moderate height above that in the latter, the whole of the stream enters the recipient orifice, and there is no waste except the small sprinkling which is occasioned by inexactness of aim, and by the want of exact circularity in the orifices.

When the head in the recipient has reached the overflow, and thus remains at a steady height of 18 inches above the orifices, the complete reception is insured by maintaining a head of 20½ inches in the discharging cistern, or an excess of head of 2½ inches on the discharge side; and this excess, in effect, represents the energy wasted in friction.

You observe that as I diminish the supply of water and allow the excess of head in the discharger to become reduced, a steadily increasing waste becomes established between the orifices; and it is interesting to trace exactly the manner in which the friction operates to produce this result.

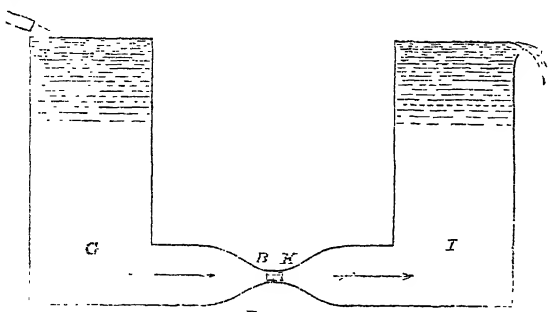


FIG. 25.

If the conoids of discharge and reception are tolerably short as they are here, it is the outer annule or envelopes of the stream which are in the first instance affected, that is to say retarded, by friction, and the escape or waste between the orifices implies that this surface-retardation has reduced the velocity of those envelopes below that due to the head in the recipient; thus an annular counter-current is able to establish itself, and in fact constitutes a counter discharge from the recipient.

As the quantity of water which actually enters the recipient, or in other words the speed of the inflow, is reduced, the friction which belongs to that part of the stream is reduced also, but that which belongs to the issuing jet is unabated, and this circumstance virtually magnifies the waste; it is probable, however, that to the last the velocity of the central zones of the jet remains equal to that due to the head in the discharger, and hence you will observe that unless this is reduced below the level of the overflow, the head in the recipient is fully maintained to that level, though the whole quantity discharged is wasted between the orifices.

When the supply is altogether cut off, both cisterns simultaneously empty themselves, the two jets meeting between the orifices, and becoming spread into a beautiful plane disc or film of water at right-angles to the line of discharge; but you will notice that from some inequality in the commencement of the action, and to some extent probably from a quasi-instability in the equilibrium of the double discharge, one of the jets will presently for a moment get the better of the other and drive it back so as almost to arrest its flow, and thus for the moment arrest also the waste of head on that side; but the momentary excess of head thus occasioned almost instantly asserts its superiority, producing a jet of superior force, and thus driving back for a moment the opponent by which it had just before been mastered. Thus a curious oscillation of discharge ensues, which is to a large extent a true dynamic phenomenon somewhat analogous to that which becomes established in an inverted syphon partly filled with water, if for a moment the head is increased in one of the legs; the reaction which in the syphon is furnished by its continuing through the bend, is, in the case before you, furnished by the dynamic reaction of the jets, but the circumstances here involve an instability which does not exist there, so that the small initial disturbance presently magnifies itself into one of considerably greater range.

This curious corollary phenomenon of the alternated retardation of discharge, though not strictly relevant to the main object of the experiment, is nevertheless highly interesting in itself and tends to enlarge our apprehension of some of the characteristic features of fluid dynamics.

(*To be continued.*)

NOTES

TUESDAY being St. Andrew's Day, the anniversary meeting of the Royal Society, as required by their charter, was held. The President, Dr. Hooker, began his address with a few remarks on the large number of eminent Fellows whose names appeared in the death-list of the past year, and then gave a summary of the numerous measures for "the improvement of natural knowledge" undertaken by the Society. These comprise the publication of papers in the "Philosophical Transactions," in a separate form; preparation of additional volumes of the catalogue of scientific papers; the labours of committees in connection with the Transit of Venus Expedition, and the researches of naturalists in Kerguelen and Rodrigues; the Eclipse of the Sun Expedition to Siam, the Polar Expedition, the voyage of the *Challenger*, and of the Committees appointed to consider the suggested modification of the regulations under which candidates are elected into the Society. The auditors' report showed that the pecuniary resources of the Society were in a satisfactory condition, and Dr. Hooker mentioned the bequests made to the Society by the late Sir C. Wheatstone and Mr. H. Dircks. The medals were then presented, the Copley medal to Dr. Hofmann, a Royal medal to Mr. Crookes, and a Royal medal to Dr. Oldham (at present in India), through Prof. Ramsay. The proceedings terminated with the election of council and officers (comprising the list of names already published) for the ensuing year. We hope to refer at length next week to the President's address. The anniversary dinner was held at Willis's Rooms, Dr. Hooker in the chair, supported by the Marquis of Salisbury, Lord Cardwell, Mr. W. H. Smith (of the Treasury), the Right Hon. Robert Lowe, Mr. Farrer, Admiral R. Hall, Mr. Lyon Playfair, Dr. Hofmann, Mr. Crookes, and a large number of the Fellows of the Society and their friends.

ON Monday night there was a pleasant and lively meeting at the Royal Geographical Society, over Mr. Stanley's work on the Victoria Nyanza. The paper read was by Col. Grant, C.B., the old companion of Speke, and he awarded hearty praise to Stanley, whose work he estimated as of high geographical importance. At the same time he showed that Stanley's discoveries seemed to confirm the discoveries of Speke as far as these went. The former estimates the circumference of the lake at 890 geographical miles, which coincides essentially with Speke's estimates. Sir Samuel Baker spoke much to the same effect as Col. Grant, both as regards Stanley and Speke, as did also Capt. Burton, while Mr. Edwin Arnold acted the part of Stanley's representative. It was announced that the Church Missionary Society are to take advantage of King Mtesa's invitation to send out missionaries; Sir Samuel Baker believes that the good Mtesa mistook Stanley for Livingstone, whom he had been informed might be expected from the south. Sir H. Rawlinson read some extracts from Col. Gordon's letter on the Albert Nyanza, which he trusted would also be explored by Mr. Stanley.

THE Queen has conferred upon Dr. W. B. Carpenter, F.R.S., the honour of the Companionship of the Civil Division of the Order of the Bath.

THE Royal Academy of Sciences of Berlin has elected Dr. Frankland and Prof. A. W. Williamson, of London, corresponding members of the section of Physics and Mathematics.

Many of the readers of Nature will be grieved to hear that Prof. Friedrich Albert Lange died at Marburg, after severe suffering, on the 21st of November. A great career was opening before him when he was smitten by the illness which killed him. His principal work is the "History of Materialism," a second edition of which he had completed shortly before his death. This work will long remain a monument of honour to his memory—an ensample alike of comprehensive learning and of profound and elevated thought.

The three vacant seats on the Senate of the University of London have been filled by the appointment of Dr. Hooker, Pres. R.S., and the Dean of Lincoln (Dr. Blakesley), directly by the Crown, and Mr. J. G. Fitch on the nomination of Convocation.

With reference to Dr. Acland's late pamphlet on the future site of the Oxford Botanic Gardens, in the form of a letter to Dr. Hooker, the Professor of Botany (Mr. Lawson) draws attention to the fact that the question of retaining them upon their present site or of removing them to the Parks is now *sub judice*, and that till Council deems fit to announce the result of their deliberations it would be highly inexpedient for the Professor of Botany to enter into any discussion on the matter, and he requests members of the University to suspend their judgment until such time as the question can be placed before them in all its bearings.

Dr. L. S. Forbes Winslow has been appointed to the chair of Psychological Medicine at Charing Cross Hospital.

Telegrams from Prof. Palmieri state that the interior of the crater created by the last eruption of Vesuvius has given way. A dark smoke issues from the volcano, and he thinks an eruption is consequently to be expected, but perhaps not immediate.

From additional notes on the Meteorological Congress at Poitiers which we have received, we learn that nineteen departments surrounding Poitiers are formed into a permanent meteorological union called "Ouest-Oceanien," for the purpose of organising weather forecasts in the interests of agriculture, and of tracing the paths of thunderstorms. Another similar association will be established at Bordeaux for the south-western provinces. Next year the "Ouest-Oceanien" will hold its second yearly meeting at Tours. It has been decided that a barometer, constructed on an improved plan by M. Redier, shall be sent to each chief town of an arrondissement, as also the telegrams from the Paris Observatory giving the meteorological news transmitted by the international service. The resident meteorologists are to take advantage of these general warnings in issuing special predictions. These efforts will promote the meteorological investigations and multiply the number of observers. It is expected that the Paris Observatory will commence to issue daily bulletins and maps similar to those which for a long time have been issued by the U.S. Signal Service, showing up to what extent their predictions have been warranted by facts. M. Alluard, Director of the Puy de Dôme Observatory, was present at the Congress, and gave interesting details as to the state of the works, which are progressing favourably. In the course of a few months the observations will begin at the top of the mountain, and by the month of May next the works will be opened for inspection by men of science of all nations. The presence of a large number of delegates from various parts of France enabled the Congress to pass resolutions of so general a character as to insure everywhere uniformity of action, and the establishing, on a satisfactory basis, of an *Atlas Météorologique de la France*.

The *South Australian Register* contains a short account of the exploration of the large river in New Guinea referred to in our last number. The details are given in connection with the report of the return of Mr. Macleay's expedition in the *Chevert*, which became disorganised, Mr. Macleay and Capt. Edwards having disagreed. The scientific portion of the expedition proceeded to New Guinea in a missionary vessel, probably the *Ellangowan*, the same which is reported to have sailed up the Baxter River. The details, evidently supplied by some one who had been on board the *Ellangowan*, published in the *Register*, are substantially the same as those given in Mr. Smithurst's letter. Large cloven hoof tracks are reported to have been seen, as also the monstrous bird referred to by Mr. Smithurst. Lieut. Robert H. Armit, R.N., writing to the *Daily News*, states that the position of the supposed newly-discovered river in New Guinea, as given by Mr. Smithurst—lat. 8·38 S., long. 141·59 E.—clearly proves it to be none other than the one discovered by the officers of her Majesty's ship *Fly*, and which to this day bears the name of that vessel.

Prof. Henry's Smithsonian Report for the year 1874, the New York *Nation* states, gives a good account of the management and varied usefulness of the Institution. Among the publications in progress or contemplated are a "complete index to all the species of plants of North America, with their synonyms and all descriptions and important references to them;" a new and enlarged edition of Schott's "Tables of Rain and Snow in the United States;" a general discussion of the winds of the globe; a discussion of all the observations made on the temperature of the U.S. from the earliest times; and a work on the geographical distribution of American thunder-storms. The papers which usually accompany the Report and give it a permanent value are in this case Arago's eulogy on Laplace, Mailly's on Quetelet, and Dumas's on De la Rive; Prof. Hilgard's interesting lecture on tides and tidal action in harbours; De Candolle's notable chapter advocating the English as a dominant language for science; a translation (continued from the previous report) of Morin's elaborate treatise on warming and ventilation; and a letter, by Prof. Warren du Pré, on the so-called North Carolina earthquakes, which literally "made so much noise" in February and March of last year. Prof. du Pré attributes the shakes and explosions to volcanic or earthquake energy, but Prof. Henry inclines to think them caused by either a gradual depression or elevation of the mountain. The stories of issuing smoke and flame were fabulous. The last sixty pages of the Report are given up to Ethnology, with a view to presenting as complete information as possible concerning the location and character of ancient earthworks in America. The accounts here given range from New York to Oregon in one direction, and to Florida and Mississippi in others.

M. Bonnat, a French explorer of the Gold Coast, who had been taken prisoner by the Djuabin, has managed to escape, and is continuing his work along the banks of the Volta, under the protection of Ashantees, amongst whom he is said to have become a favourite.

The Auricula is said to be the only Alpine plant which has come into general cultivation in the gardens of the rest of Europe. In a pamphlet entitled "Die Geschichte der Aurikel," Prof. Kerner traces the history of the discovery and cultivation of this plant, from the time of L'Escluse (Clusius), who first transplanted this species and the hybrid *P. pubescens*, Jacq., in 1582 from the Tyrolese Alps to Belgium. The latter species, and not the true *P. Auricula*, L., which quickly disappeared from cultivation, is believed by Prof. Kerner to be the real ancestor of the cultivated auriculas of our gardens. The two were known at the time of Clusius under the names of "Auricula-ursi I." and "Auricula-ursi II.," from the supposed resemblance in the shape of the leaves to that of the ear of a bear. The hybrid *P. pubescens*, which had been lost from the German and Austrian Alps for nearly three centuries, was rediscovered by Prof. Kerner in 1867 in a single locality in the Tyrol.

A VERY severe shock of earthquake occurred at Gisborne, New Zealand (east coast), on Sept. 14. Strong shocks were also experienced at Wellington and Blenheim.

A NEW monthly magazine is to be started at Dunedin, of the same character as the *Contemporary Review.*

ACCORDING to a letter published in the *East Anglian Times* of Nov. 24, it would appear that the Corporation of so important a town as Ipswich still authorises the use of local mean time within its liberties, and the business of the place is actually regulated by its edict. Railway time has there a distinct meaning, being 4 min. 40 sec. later than that in general use. We believe that Norwich is in an equally unscientific state as regards time-keeping. It is quite time that an end was put to this absurdity, and we hope some pressure may be brought to bear upon the authorities to effect the long-delayed and desirable introduction of Greenwich time.

IN the October number of the *Quarterly Journal of the Meteorological Society of London*, appear several papers of interest, including one by Dr. Mann, the President, on some practical points connected with the construction of lightning conductors, one by Mr. Symons on a white rain or fog bow, and two very valuable and suggestive papers by the Hon. Ralph Abercrombie, on certain small oscillations of the barometer, and on barometrical fluctuations in squalls and thunderstorms. It may be suggested that the printed "Discussions" on the several papers, however interesting to the members, might be curtailed with great advantage.

THE tri-daily Weather Maps of the United States for the first six months of the present year, issued under the vigorous direction of Brigadier-General Myer, have been received. They show with admirable clearness and distinctness, by the style of printing in colours adopted, the outstanding features of the weather thrice a day. These truly magnificent maps give in every case the weather probabilities for each of the great divisions into which the States have been grouped for this purpose, that are likely to follow within the twenty-four hours then *next ensuing*, and also the actual weather which has been experienced during the *past* twenty-four hours. This method is deliberately adopted by the Office for the express purpose of exhibiting equally its successes and its failures in issuing the weather probabilities, and with the further view of receiving assistance from scientific men, who are thus put in possession of materials for studying the subject, by which the rules that have led to the successes may continue to be followed, and those which have caused the failures may be avoided.

MR. STANFORD has published a handy map of India, showing the route originally sketched for the Prince of Wales's tour. Its moderate price and clearness will recommend it to many who wish to follow the Prince in his wanderings.

THE *Bulletin de la fédération des Sociétés d'Horticulture de Belgique* for 1874, published under the authority of the Ministry of the Interior, gives evidence of the extent to which horticulture is made a scientific study in that little kingdom. It contains the reports of no less than twenty-five horticultural and agricultural societies affiliated to the Federation; and a list of twenty-one practical questions, for the best solution of which prizes, varying in value from 100 to 500 francs, are offered. There is also appended Prof. Morren's biographical notice of Clusius, to which we have already alluded, and a third edition, completed to October 1875, of the list of the Botanic Gardens, chairs of Botany, and Botanical Museums, throughout the world.

AN admirable epitome of our knowledge respecting the vegetable palæontology of the United States is contained in M. Leo Lesquereux's reprint, "A Review of the Fossil Flora of North America," printed under the authority of the Department of the Interior. An idea will be conveyed of the wonderful advance of this knowledge in recent years, by the statement that in 1850 Brongniart described in his "Végétales Fossiles" eighteen species of land-plants from North America, whereas upwards of 1,000 species are now known. Of the numerous fossil plants brought by Dr. H. F. Hayden from his exploration of the Western Territories, and found in strata belonging to the Cretaceous formation, by far the majority are remains of Dicotyledons, and included within all three sections, of Apetalæ, Gamopetalæ, and Polypetalæ; and as far as reliance can be placed on characters derived from the foliage alone, a large number belong to genera widely distributed at the present time. The Lower Lignitic flora, on the contrary, belonging to Tertiary times, presents far less resemblance to that at present prevailing in the northern part of North America, but is of a much more southern type.

A BELGIAN practitioner has published a work on the "Maladies which are special to Mystics," the purport of which is to show that Louise Lateau and other persons of the same description might be really total abstainers from food for a lengthened period. The *Revue Scientifique* announces that the Belgian Society of Medicine has ordered that work to be published in its *Comptes Rendus.* M. Charbonnier, the author, advocates the theory that people may subsist without food because the nitrogen from the air can be admitted into the circulatory system, when the body has been emaciated by long abstinence. Feeding on air is an economical way of keeping soul and body together.

AT the opening of the Belfast Natural History and Philosophical Society, the president, Prof. Hodges, delivered an address, in which he reviewed the industrial progress of the North of Ireland. The address was fully reported in the *Northern Whig* of Nov. 11, and has since been separately reprinted.

WE have received the programme of the Cambridge Higher Local Examinations for 1876, for all who have completed the age of eighteen years before January next. The examinations are for both men and women, and the successful candidates are divided into two groups, those who obtain honours and those who do not. The subjects of examination are divided into six groups, one of which includes botany, geology, zoology, and chemistry. The programme seems to us carefully drawn up; an excellent selection of text-books is given.

PROF. NORDENSKJÖLD ON THE JENISEI

THE following extract from a letter from Prof. Nordenskjöld to Mr. Oscar Dickson, dated Tomsk, Oct. 13, appears in the *Göteborgs Handels Tidning.* It describes his exploration of the river Jenisei after the departure of the *Pröven* on its homeward journey. Nordenskjöld, Lundström, and Stuxberg left the mouth of the Jenisei on August 19, in a boat built for the purpose, and well provisioned and equipped:—

"The course was taken along the shore within the multitude of low bare rocky islands which bound the mouth of the Bay of Jenisei on the north, and are named in the Russian maps, Severo-Wostotschnoi Ostrow (North-east Islands). The sounds between these islands were thought to be sufficiently deep even for large vessels, though perhaps a little fouled by rocky ground. With a favourable wind and smooth water we sailed without any considerable rest in forty-two hours without a break to Cape Schaitanskoj, arriving there the night before the 21st, thoroughly drenched and worn out with our long watch. During this time we landed only at two places, the first time at a point within Jewremow Kamen, the last rocky promontory which occurs on the eastern bank of Jenisei for a distance of 100 Swedish (upwards of 600 English) miles.

"Jewremow Kamen itself consists only of a peculiarly formed dolerite rock fifty or sixty feet high. At the bank were still collected, but for the last time during our passage up the Jenisei, true marine animals; an Appendicularia, Clio, large Beroïdæ, various Medusæ, &c. By a land excursion here we

had already obtained a Harpalus, two species Staphylini, a number of Acaridæ and Poduridæ, a species of dew-worm,* &c., and as at the *Pröven's* anchorage, the vegetation has a stamp deviating very much from the flora of Novaya Zemlya. Large bush plants, even the dwarf birch, were completely absent, and the ground was in no case covered with a true mat of grass.

"The other place where we landed for a little was Krestowskoje, a now deserted *simovie* (a place inhabited both summer and winter), which, however, to judge by the number of the houses and the way in which they were fitted up, must once have had its flourishing period. All household articles were removed, and literally there was not to be found an iron nail in the wall; a proof that the inhabitants had not died out, but migrated. The vegetation in the neighbourhood of the huts was extraordinarily luxuriant, the grass and plants forming a real obstacle in walking, certainly occasioned by the quantity of fertilising animal matter which had been collected here during the time when fishing and hunting were carried on.

"The surface temperature of the water was, on our arrival at the mouth of the Jenisei + 7·8° C., but sank during the storm of the following days to + 1·5° C. At Jewremow Kamen it was + 2·5° C., but rose afterwards in the neighbourhood of Krestowskoje to + 11° C., a temperature which it afterwards retained during the whole of our journey. The water was brown in colour, but was often at the sides coloured by clayey streams.

"A little south of Jewremow Kamen the eastern side of the Jenisei is occupied by sand-banks twenty to thirty feet high, and sloping steeply towards the river. At the river bank the tundra commences, an endless, inconsiderably undulating plain, full of low marshes and small shallow pools of water, and overgrown with a sparse vegetation, whose flowering time was now almost completely over. Instead we found at our first night quarters (Cape Schaitanskoj) great quantities of ripe cloud-berries, the taste of which, excellent in itself, was on this occasion heightened by the circumstance that they were for us the first fruit of summer. The red whortleberry (*Lingon*) and the cranberry (*Odon*) were also found here, if in small quantity. Cape Schaitanskoj was the most northerly point on the Jenisei, where we found the dwarf birch; and the same place, by Dr. Stuxberg's discovery of a species of *Physa*, becomes the *most northerly locality for land and fresh-water mollusca.*

"After having rested at Cape Schaitanskoj we sailed on with a favourable wind to Sopotschnaja Korga, where the hard wind and a shallow lying off it, the extent of which it was impossible to distinguish during the dusk of the evening, compelled us to lie to earlier than we otherwise intended.

"Sopotschnaja Korga (the toe of the boot) forms a low promontory projecting far out into the Jenisei, which, as numerous ruins of houses show, was formerly inhabited, but is now deserted.

"A great part of the promontory was occupied by heaps of drift-wood, large stems, with branches and roots broken off, thrown up over each other in an endless chaos, it being possible to go forward between them only with difficulty and care. The trees that lie nearest the water are quite fresh and in good condition. Other tree stems lying farther from the bank and cast up there a century or centuries ago, are in all possible intermediate states from fresh to completely decayed wood. Between the stems there frequently occur deep holes filled with black stinking water. Heaps of drift-wood like those at this place, though perhaps somewhat smaller, are found almost everywhere farther down towards the mouth of the river, but higher up there occur only scattered pieces of drift-wood, and at some places these are entirely wanting. The point was, besides, bestrewn with a number of other fresh-water ponds, more or less grown up with water mosses, and full of sticklebacks, Branchiopoda, and other fresh-water Crustacea, and giving the botanist an opportunity of collecting various grasses and water-plants not found farther north (*Carex chondrorhiza*, *Hippuris vulgaris*, *Juncus castaneus*, &c.) Higher up, on drier places, the ground was sparingly covered with *Empetrum nigrum* and *Andromeda tetragona*, and on the steep slopes with which the ground terminates towards the promontory, there is a luxuriant vegetation a couple of feet high, consisting of grass and other plants. The locality was, on the contrary, extremely poor, as well in Mammalia and birds as in insects, and even the holes and paths of the lemming, by which the land on the coast of Novaya Zemlya is crossed in all directions, are found here only in limited number.

* Its occurrence is remarkable on this account, that the ground here, with the exception of an inconsiderable stratum which thaws in summer, is constantly frozen all the year round.

"We sailed on until we finally succeeded in finding a convenient landing-place in the neighbourhood of a little river, Mesenkin, which there falls into the Jenisei on its right bank." Here they obtained a Cossack, Feodor, as guide. While waiting for the guide, the party employed themselves "in examining the natural history of the locality, in making solar observations to determine the position of the place, &c. It appeared by these that our resting-place was situated only about four Swedish (over twenty-four English) miles south of our former landing-place. Mesenkin's low river valley is, however, much better protected from the winds of the polar sea than the low promontory at Sopotschnaja, and the influence of this was plainly recognisable by its much richer vegetation.

"What first meets the eye on landing is a thicket of dark green bushes about four feet high, which are found to consist of alder (*Alnus fructicosa*). Between the alder-bushes, and protected by them, our botanist found a number of well-grown plants—Sanguisorba, Galium, Delphinium, Hedysarum, Veratrum, &c. The Salix bushes were also higher here than at former places, the mat of grass more abundant, and the slopes of the sandhills in the interior of the country were adorned with a number of new types—Alyssum, Dianthus, Oxytropis, Saxifraga, Thymus, &c.

"As has been mentioned in a former letter, we found at the part of Jalmal visited by us neither small stones nor sub-fossil shells in the fine sand. East of the mouth of the Jenisei the sand is coarser, and contains both sub-fossil shells and large and small stones. The sub-fossil shells, according to information given to me at Dudinka, occur in some places in so large masses that they form true shell banks. At the places visited by us the shells were found not in proper layers, but only scattered through the sand. Immediately at the first glance it appeared that the shells collected by us here belonged in preponderating number to species with which we had become acquainted in the living state during our dredging in the seas of Kara and Obi-Jenisei.

"A sample of the stones which occur in the sandy strata of the tundra was always found at the river bank where we lay, when the lighter particles of sand were washed away, and many important contributions towards a knowledge of the way in which the tundra is formed, and of the nature of the rocks which afforded material for the masses of sand here collected together, were to be obtained. No erratic blocks comparable in size to the erratic blocks in our country occur here, a circumstance which I regard as a proof that the sandy strata of the tundra, at least in these regions, are not of glacial origin. I ought, however, to remark that on a small stone here and there there could be observed striæ and scratches completely resembling those found on moraine blocks. But in such cases these scratches have clearly been formed either by the sliding of the earthy stratum or by the action of the river ice.

"In the northern part of the tundra I could never discover among the stones washed out from the sand any blocks of granite or gneiss, but they consisted for the most part of different kinds of basalt with numerous cavities containing lime and zeolites. Besides there occurred, especially at Cape Schaitanskoj, in not inconsiderable number, blocks of marl and sandstone, containing fossils partly of marine origin, partly containing rolled tree stems, more or less carbonised or petrified. Pieces of brown and pit coal were also found here in not inconsiderable number.

"On Aug. 26, early in the morning, our guide joined us, accompanied by five other Russians settled in that region. . . . After having talked for some time with our friendly guests, who were exceedingly interested in our expedition, we continued our journey, during which we had splendid calm weather, to Cape Gostinoi, where we took our midday rest.

"After resting a little at midday at this place, we sailed on, and came after various wanderings in dusk and mist during the night before Aug. 27, to land at a low promontory, at the mouth of the river Jakowiewa.

"Our next resting-place was a specially attractive fishing station at a small sound between the Briochowski Islands, the most northerly of the labyrinth of islands which occupy the channel of the Jenisei between $69\frac{1}{4}°$ and $70\frac{1}{3}°$.

"On Aug. 28 we rowed on between a number of islands covered with a luxuriant vegetation, and commonly terminating towards the river with a steep slope, down which large masses of peat tumbled here and there. At such places we could see that the island originally consisted of a sand-bank cast up by the river, which in the length of time was covered first with masses of drift-wood, and afterwards with a luxurious vegetation which gradually gave origin to a thick stratum of peat, of which the

part of the island above the surface of the water is mostly formed.

"Towards evening we lay to at the Nikandrow Islands in the neighbourhood of a fishing-station still inhabited. Jenisei is renowned for its richness in large eatable fish-species. . . . I hope some months after our return home to be able to exhibit to those among us who are interested in fishing, specimens of most of the varieties of fish occurring here. During our sailing up the river between Dudinka and Jeniseisk, I caused specimens of all the species of fish which we could procure from the river to be carefully deposited in a cask filled with spirit. This collection will be sent to Stockholm *viâ* St. Petersburg, by a merchant settled in Jeniseisk.

"Like most of the settlers on the lower course of the Jenisei, the inhabitants at Nikandvow fishing-station kept a number of dogs which are believed to be of the same race as the dogs used on Greenland, for draught. The dogs are employed in summer to tow boats up the river, and in winter for all sorts of carriages. Yet the dog, for reasons stated in the introduction to Middendorff's 'Sibirische Reise,' is considered quite unfit for long journeys over uninhabited tracts, if several hunting or fishing stations are not to be met with in the course of the journey. In such cases reindeer are always employed.

"Early next day we sailed, or more correctly, rowed on, the weather being calm and beautiful. We rested at midday in the neighbourhood of a now deserted *simovie* on the southern part of Sopotschnoi Island. Hence we continued our journey first to Cape Maksuninskoj, where we visited a Samoyede family that had set up their skin tent here in order to collect the necessary stock of fish for winter; afterwards to Tolstoj Nos, a still inhabited, well-built *simovie*, where the people living there received us in a very friendly way, and received the account of our journey with great interest and astonishment."

From here the party made haste to catch the last steamer at Saostrowoskoj, in the neighbourhood of Dudinka, which they did on Aug. 31.

"We were yet far north of the Arctic circle, and as many imagine that the region we had now passed through, the so little-known tundra of Siberia, is a desert waste, either covered by ice and snow or by an exceedingly scanty moss vegetation, it is perhaps the place here to declare that this by no means is the case. On the contrary, we saw, during our passage up the Jenisei, snow only at one place, a deep valley cleft of some fathoms' extent, and the vegetation, especially on the islands which are overflowed during the spring floods, was remarkable for a luxuriance to which I had seldom before seen anything corresponding.

"The fertility of the soil and the immeasurable extent of the meadow land and the richness of the grass upon it had already called forth from one of our hunters, a middle-aged man, who is owner of a little patch of ground between the fells in Northern Norway, a cry of envy of the splendid land our Lord had given 'the Russian,' and of astonishment that no creature pastured, no scythe mowed the grass. Daily and hourly we heard the same cry repeated, though in yet louder tones, when we some weeks after came to the lofty old forests between Jeniseisk and Turuchansk, or to the nearly uninhabited plains on the other side of Krasnojarsk, covered with deep *tschornosem* (black earth)—in fertility certainly comparable to the best parts of Scania, in extent exceeding the whole of the Scandinavian peninsula. This direct expression of opinion by a veritable if unlearned agriculturist may perhaps not be without its interest in judging of the future of Siberia.

"During this very summer three separate Russian expeditions have travelled through Siberia with the view of ascertaining the possibility of improving the river communication within the country. These expeditions have, according to unofficial communications made to me in Jeniseisk, come to the conclusion that it is possible for a sum of 700,000 roubles to make the Angara (a tributary of the Jenisei) navigable to Lake Baikal, and to connect the Obi with the Jenisei and the Jenisei with the Lena. How great an extent of territory the proposed river communication will embrace is best seen by considering that the territory drained by the Obi-Irtisch and the Jenisei alone is of greater extent, according to Von Baer's calculation, than the river areas of all the rivers (the Danube, Don, Dnieper, Dniester, Nile, Po, Ebro, Rhone, &c.), which fall into the Black Sea, the Sea of Marmora, and the Mediterranean. Part of this territory indeed lies north of the Arctic circle, but here too are found the most extensive and finest forests of the globe; south of the forest region proper there stretch out territories, several hundred leagues in extent, level, free of stones, covered with the most fertile soil, which only wait for the plough of the cultivator to yield the most abundant harvests; and farther to the south the Jenisei and its tributaries run through regions where the grape ripens on the bare ground: just now, as I write this, I have before me a bunch of the finest Siberian grapes. May the future show that sea communication between these lands and Europe has now been fairly inaugurated.

"A. E. NORDENSKJÖLD."

SCIENTIFIC SERIALS

Der Naturforscher, October 1875.—In this number is given an observation by M. Coulier, that while a cloud was formed in a vessel containing a little water, when an attached caoutchouc balloon was first compressed, then allowed to expand, no cloud was thus produced if the vessel had stood some time at rest, or if the air had been filtered; and the author's view was confirmed that small particles in the air were what caused the formation. M. Mascart has found that strongly ozonised air is not robbed of its cloud-forming action by filtering.—There are two valuable papers in meteorology, one by M. Hann, on the variability of daily temperature, and another in which M. Kerner offers an explanation of the fact that there is, in the Swiss valleys, in late autumn and winter, a middle warm region limited both below and above by a colder.—In physiology we note some interesting researches by M. Bernstein as to what is the highest pitch of tone a muscle may be made to give by electric stimulation. Above 418 vibrations per second of the spring contact, the muscle tone (the same as that of the spring) was distinct, though weaker; at 1,056 vibrations no distinct tone was observed, only a noise. But if the *nerve* were stimulated to the latter degree the muscle gave a tone, not indeed the same as the spring, but a fifth, sometimes an octave, lower. The upper limit beyond which the muscle ceased to give the same tone with the spring (in this arrangement) seemed to be about 933 vibrations. Under chemical stimulus of a nerve, the connected muscle gave a tone like that in natural contraction.—There is also a suggestive paper by M. Delbœuf on the theory of sensation, and M. Hirschberg describes observations on a boy who acquired sight at seven years of age; they favour, he considers, the empiristic theory of sight-perceptions.—In a paper on the origin of the deep-water fauna of the Lake of Geneva, M. Forel thinks the entire fauna of the Swiss lakes are descended from forms which have migrated (up the rivers) since the melting of the glaciers, and have afterwards been differentiated.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Oct. 1.—Dr. Wild, Director of St. Petersburg Observatory, relates the circumstances which led to the Imperial assent being given in June last to the scheme for the establishment at Pawlowsk, distant about an hour by railway from St. Petersburg, of an observatory to be affiliated to the central institution for terrestrial physics over which he presides. The Central Observatory was built twenty-six years ago in an open and quiet space outside the capital. Houses and streets have, however, rapidly been constructed around it, masses of iron are in proximity, and noise and smoke disturb physical measurements, magnetic and meteorological observations. Herr Wild knew that there were serious objections to the removal of the whole establishment into the country, as has been done at Vienna, and determined to recommend a separation into two divisions, one observing and the other administrative, in imitation of the London Meteorological Office and Kew Observatory, the relations to the public of the Russian being similar to those of the English Meteorological Department. On his making this proposal at the Academy of Sciences last autumn, Prince Nicolajewitsch generously presented for the purposes of the new observatory a large piece of ground in his park at Pawlowsk. There will be no reduction in the estimate for the Central Observatory, in order that local observations may be continued, and the accumulated records of former years worked out.—Dr. Hellmann contributes a paper on the physical conditions of the higher atmospheric strata, in which he discusses the observations made in May 1872 by the U.S. War Department at the summit (1,915 metres high), and at the base of Mount Washington, New Hampshire. It appears among other results that the mean difference of temperature for 100 metres of ascent between the hours of 6 A.M. and 6 P.M. and 9 P.M. and 12 P.M. at night was ·69° C., and that the difference between 4 and 5 P.M. was ·83 and at 6 A.M. only ·48° C.; that in 17·4 cases per cent. the wind at the top was the same in

direction as that below; and that the diminution of temperature with increasing height was greater in clear than in cloudy weather. This last result is in agreement with that of Herr Hann, derived from observations taken at Praya West and Victoria Peak.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Nov. 19.—"On some Elementary Principles in Animal Mechanics. No. VII. The Law of Fatigue." By the Rev. Samuel Haughton, M.D. (Dubl.), D.C.L. (Oxon), F.R.S., Fellow of Trinity College, Dublin.

The approximate law of muscular action, which I have called the law of fatigue, is thus expressed:—"*When the same muscle (or groups of muscles) is kept in constant action until fatigue sets in, the total work done multiplying by the rate of work done is constant.*"

The following experiments, in illustration of this law, were performed in Trinity College during the spring of the present year.

I instructed a number of medical students, chosen at random, to raise dumbbells of varying weight, one in each hand, in the transverse plane, with hands supinated, raising and lowering the weights in equal times regulated by the beat of a pendulum. This process was continued until the distress of the fatigue produced became intolerable, and the number of times each weight was lifted was noted. The students were required to count "one-two," in time to the beat of the pendulum, so as to prevent them from counting the total number of lifts of the weight. Prof. Macalister assisted me in these experiments; and one of us counted the number of lifts, while the other compelled the experimenters to observe the conditions of the experiment, which were:—

1. To keep time with the pendulum.
2. To raise the weight in the transverse plane.
3. To supinate the hands.
4. To abstain from all bending of the knees or spinal column.

For each experiment I chose twenty students at random, using altogether about fifty different students; and no individual was experimented upon again, until an interval of forty-eight hours had elapsed. The object of this arrangement was to avoid the effects of "training." In my first Table I give the mean result of twenty different students; and in my second Table I have selected one student, set aside for the purpose, and experimented upon, once a week, so as to prevent the influence of "training."

Let W denote the total work done, and T the time of doing it; then, by the law of fatigue,

$$\frac{W^2}{T} = \text{constant} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If w be the weight held in the hand, and a be half the weight of the arm, and n the number of times the weights are lifted; since the time of raising and lowering the arms is constant, n is proportional to T, and the law of fatigue gives the formula

$$(w + a)^2 n = \text{A} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where A is an unknown constant. In the following Table I give the values of w and the mean value of n for twenty distinct persons. The time of lift is in all cases *one second*.

TABLE I.—*Mean of Twenty Experiments.*

No.	w.	n (obs.)	n (calc)	Diff.
	lbs.			
1.	2·56	131·80	128·0	+3·8
2.	4·25	87·55	78·3	+9·2
3.	5·87	47·35	53·5	−6·2
4.	6·87	40·25	43·7	−3·5
5.	7·75	34·60	37·1	−2·5
6.	9·75	27·15	26·8	+0·3
7.	14·00	17·20	15·4	+1·8

The column containing the calculated values of n was obtained from equation (2) by using the values

$$a = 3·50 \text{ lbs.}$$
$$\text{A} = 4699.$$

These values were obtained by finding the value of a, which renders A most nearly a constant, or

$$\frac{\delta \text{A}}{\text{A}} = \text{minimum}.$$

This Table gives 7 lbs. for the mean weight of the arm of all experimented on, a result which accords with the known facts.

In Table II. I give the results obtained from a single student, as already described, each value of n being a mean of several experiments, closely concurrent.

TABLE II.—*Mr. Samuel Warren.*

No.	w.	n (obs.)	n (calc)	Diff.
	lbs.			
1.	2·56	140·0	137·5	+2·5
2.	4·25	91·0	86·4	+4·6
3.	5·87	63·0	60·1	+2·9
4.	6·87	43·0	49·0	−6·0
5.	7·75	40·0	42·5	−2·5
6.	9·75	32·0	31·0	+1·0
7.	14·00	18·5	17·9	+0·6

The calculated values of n were found from equation (2), using the values

$$a = 3·9 \text{ lbs.}$$
$$\text{A} = 5737,$$

which were obtained from the principle of least variation of A, or

$$\frac{\delta \text{A}}{\text{A}} = \text{minimum}.$$

In the accompanying diagrams I. and II., I have plotted the cubical hyperbola represented by equation (2); and also the several observations which lie sufficiently near the curve to justify me in considering the law of fatigue to be a first approximation to one of the fundamental laws of muscular action. I have elsewhere* shown that the law of fatigue corresponds with other experiments based on different data.

If we consider the *useful work* only, we have from equation (2),

$$\text{useful work} = wn = \frac{\text{A}w}{(w + a)^2} \quad . \quad . \quad . \quad . \quad (3)$$

This equation represents a cuspidal cubic, whose ordinate has a maximum value, when $w = a$ = half the weight of the arm.

The foregoing observations are in accordance with this deduction, as may be seen from Table III.

TABLE III.—*Useful Work.*

No.	w.	wn (20 experiments).	wn (Mr. Warren).
	lbs.		
1.	2·56	338	358
2.	4·25	372	387
3.	5·87	277	370
4.	6·87	276	295
5.	7·75	268	310
6.	9·75	264	312
7.	14·00	241	250

It is to be observed, that in the foregoing experiments the muscles in action were not allowed to *rest* during the whole time of work.

Linnean Society, Nov. 18.—Dr. G. J. Allman, F.R.S., president, in the chair.—The following paper was read:—On the organisation and systematic position of the Ornithosauria, Part i., by Prof. H. G. Seeley, F.L.S. The different results obtained by investigators who have written upon Pterodactyles, led the author to propose a method of research in Comparative Anatomy by which the true nature of these animals could be determined. It consists chiefly in an attempt to distinguish between the characters which make animals members of a class of Vertebrata, and the characters which make those animals members of vertebrate ordinal groups. The class characters were regarded as furnished by the soft vital organs, while the ordinal characters are derived from the skeleton. This was illustrated by an argument tending to show that since the form of brain,

* "Principles of Animal Mechanics" (London, 1873).

and the peculiar respiratory organs of birds, are class characters, any animal would be a member of the class Aves which possessed them; and since the form of skull, of vertebræ, of the carpus and tarsus are ordinal characters in the existing sub-class of birds, they will not necessarily be found in an extinct sub-class or order of Aves. He then showed that Pterodactyles have the brain identical with the bird's brain in every detail; and the pneumatic perforations of the bones for the prolongation of air-cells from the lungs into the bones were identical in both types and are found in no other group of animals. Hence it was concluded that, judged by class characters, Ornithosaurs must be placed in the class Aves. The author then gave an analysis of the characters of the Ornithosaurian skeleton. In the skull, he thought that the bone hitherto named post-frontal is the quadrato-jugal, and that although the malar bone meets the quadrate bone, there are no reptilian features in the skull, and nothing which is inconsistent with the Avian organisation. The vertebral column is the most reptilian part of the skeleton in being procœlous, but the fore limb was shown to be constructed on the Avian plan; the carpus being nearly identical in both groups; while the elongated finger for flight was proved by its carpal articulation to be the index finger as in birds; and in one Pterodactyle it contained two phalanges, as in birds. The petagial membranes of the Pterodactyle were also shown to be extensions of the similar membranes of birds. The characters of the pelvis and hind limb were less unlike those of a bird than had been supposed, the tibia terminating distally in a trochlear end formed as in birds by the anchylosed proximal tarsal bone. From the whole skeleton (excluding the evidence of the cerebral and respiratory characters) the author concluded that it is impossible on morphological grounds to exclude the Ornithosauria from the Avian class, and that their resemblances to reptiles are not more important than their resemblances to mammals.

Geological Society, Nov. 17.—Mr. John Evans, V.P.R.S., president, in the chair.—Mr. Robert Elliott Cooper, C.E., 1, Westminster Chambers, Victoria Street, S.W.; Mr. George Fowler, Assoc. Inst. C.E., Basford Hall, Nottinghamshire; and Mr. William Frecheville, Assoc. Royal School of Mines, 51, Scarsdale Villas, Kensington, W., were elected Fellows of the Society.—On a new modification of Dinosaurian Vertebræ, by Prof. Richard Owen, F.R.S. The peculiar modification of the Dinosaurian vertebra noticed by the author occurs in *Tapinocephalus Atherstonii* and *Pareiosaurus bombidens*. In the dorsal vertebræ of the former the centra are nearly flat on both fore and hind surfaces, a structure to express which the author proposes the term "amphiplatyan." The hind surface is very slightly the more concave. The middle of each surface is pierced by a small foramen leading into a cylindrical canal, first slightly expanding and then rapidly contracting to a point, which meets the apex of the similar hollow cone coming from the opposite surface. Similar characters were observed upon the free surface of the anterior sacral and upon that of the posterior of four anchylosed sacrals. The dorso-lumbar vertebræ of the *Pareiosaurus* had centra relatively longer than those of *Tapinocephalus*. Their articular surface is subundulate, convex along a fourth of the periphery, concave at the centre, where there is an excavation corresponding to that in *Tapinocephalus*, but a relatively wider aperture, a rather more constricted canal, a shorter terminal cone, and an interval of osseous tissue separating the apices of the cones from the fore and hind surfaces. In what is probably the first cervical vertebra of the same Dinosaur, the centrum is so concave on both surfaces as to become amphicœlian. In these unossified tracts of the middle of the centrum in the two genera above mentioned the author sees indications of a persistent trace of the primitive "chorda dorsalis;" and he calls attention to the resemblance thus set up between these probably Triassic Dinosaurs and the lower Ganocephalous reptiles of the Carboniferous series, in which, however, the vertebral centra are more widely perforated.—On the presence of the Forest-bed Series at Kessingland and Pakefield, Suffolk, and its position beneath the Chillesford Clay, by Mr. John Gunn. In this paper the author described a section from the cliff at Kessingland and Pakefield, from the examination of which he arrived at the conclusion that the Forest-bed series underlies the Chillesford Clay and sands. At the foot of the cliff there is an estuarine deposit forming the soil of the Forest-bed, consisting of blue clay and gravel, the "Elephant-bed" of the author's former paper. Above this is the Forest-bed, cotaining large stools and stems of trees, but no fossil bones. This is followed by a fresh-water deposit, consisting of black soil with fresh-water shells, corresponding to a similar bed at Mundesley and Runton known as the "*Unio*-bed," and including the "Rootlet-bed" of oozy clay, regarded by Mr. Prestwich as an indication of the forest. The author considers the supposed rootlets to represent brushwood which succeeded the true forest. Above this come Fluvio-marine deposits, in which Cragshells occur, although but rarely. To this division the author was inclined to refer the Norwich Crag, which at Bramerton underlies the next division, regarded by the author as the Chillesford Clays and Sands. Of the overlying deposits the first is supposed to be the "Pebbly-bed" by the author; it has been regarded as Middle Drift, and the uppermost is Upper Boulder-clay. The paper was illustrated by the exhibition of a fine series of bones, chiefly Cervine, from the lowest deposit noticed by the author.

Physical Society, Nov. 27.—Prof. G. C. Foster, F.R.S., vice-president, in the chair.—The following candidates were elected members of the Society:—Prof. Osborne Reynolds, M.A., Prof. H. J. Smith, M.A., LL.D., Prof. R. B. Clifton, M.A., F.R.S., C. Busk, J. Thomson, J. W. W. Waghorn, W. Esson, M.A., F.R.S., F. W. Bayly, and Prof. R. W. Emerson Mac Ivor.—Prof. Guthrie briefly described Dr. Kerr's recent experiments to show that glass, resin, and certain other substances exhibit a depolarising effect when under the influence of powerful electrical tension, and he exhibited the arrangement of apparatus employed in the research. He also showed certain experiments connected with the investigation.—Dr. Guthrie then made a communication on "Stationary Liquid Waves," in continuation of that which he made to the Society in June last. If water in a cylindrical vessel not less than 9 inches in diameter be agitated by depressing and elevating a flat circular disc on its surface at the centre, a form of oscillation is set up which the author terms "binodal." He finds that these fundamental undulations in an infinitely deep circular vessel are isochronous with those of a pendulum whose length is equal to the radius of the vessel, and further, a fact which is extremely interesting, that the motions of the pendulum and water keep together throughout their entire paths. An arrangement was exhibited for experimentally demonstrating these facts. To the upper end of a short pendulum with a heavy adjustable bob is attached a cardboard sector in the plane of vibration of the pendulum. A silk thread, attached to the edge of this sector, carries a small paraffin disc which rests at the centre of the surface of the water contained in a cylindrical vessel. The pendulum-length is adjusted until the motion of the disc is isochronous with that of the water when the two are not in contact. Two other forms of motion may be produced in cylindrical vessels, namely (1), by alternately compressing and extending opposite ends of a diameter as in the motion of a bell—this gives two diametral nodes at right angles to each other; and (2), by rocking the vessel, which gives a single diametral node. Each of these has its own period of vibration, the last being the slowest. They may be superimposed on each other, and a rotation of the water, however great, does not interfere with their formation. In rectangular troughs a binodal and a mononodal wave system may be established. The former is induced by raising and depressing a wooden lath at the middle of the surface, and the latter by tilting. Binodal vibration in a circular trough may be compared with a vibrating pair of triangular laths, and in rectangular troughs to the balancing of two rectangular laths. In this latter case the nodes are at $\frac{1}{4}$ of the trough length from each end. Some discrepancies are met with when we compare times of vibration in rectangular troughs of various lengths, and these are due to a scraping action which takes place against the ends of the vessel. The result of the experiments on binodal motion in rectangular vessels is to show that the undulations are isochronous with the oscillations of a pendulum whose length is $\frac{2}{\pi}$ times that of the trough. The chief points in connection with this subject to which the author referred as still requiring explanation, are: (1) Why are the motions pendular? (2) How is it that in circular binodal motion the times are identical with that of a pendulum of the given length? and (3) What is the mathematical connection between the individual motion of each particle and that of the mass? Mr. Lodge thought that valuable results might be obtained by treating the mass of moving water as a pendulum with two bobs oscillating about the node. This might be specially useful with small oscillations, when the surface is practically plane.

Anthropological Institute, Nov. 23.—Colonel A. Lane Fox, F.S.A., President, in the chair. The President read a full

report, prepared by himself, on the excavations lately made by the Exploration Committee of the Anthropological Institute in Cissbury Camp, near Worthing, Sussex, and illustrated it by a series of diagrams and models and a large collection of flint implements, flakes, &c. The animal remains found in the excavations, including the skeleton of a woman, were exhibited and described by Professor Rolleston, F.R.S.

Institution of Civil Engineers, Nov. 23.—Mr. Thos. E. Harrison, the president, in the chair. The paper read was On experiments on the movement of air in pneumatic tubes, by M. Charles Bontemps, Engineer in the French postal service.

EDINBURGH

Scottish Meteorological Society, Nov. 15.—At a meeting of the council of this society there was read a correspondence between Mr. Archibald Young, Fishery Commissioner, and Mr. T. Stevenson, the honorary secretary, regarding an investigation into the habits of the salmon.—Besides other elaborate investigations of a national character which the society has at different times undertaken, an inquiry, suggested by the president, the Marquis of Tweeddale, into the meteorological conditions which are supposed to affect the migrations of the herring, is being carried out by Mr. Buchan. For this purpose the temperature of the sea is observed at different parts of the coast; and stations where maximum and minimum thermometers are constantly immersed have been established. The investigation into the habits of fishes is now to be further extended to those of the salmon. For some years back observations have been made by Mr. Paulin on the depth and temperature of the water and the takes of fish in the Tweed, and these are being discussed by Mr. Paulin and Mr. Buchan. Observations were also made for some years on the temperature of the Doon in Ayrshire. But the inquiry suggested by Mr. Young has more especial reference to the question of the earliness or lateness of the different rivers, which among other causes may be found to be due to the temperature of the fresh water as compared with that of the salt water into which the rivers discharge. It is hoped that by means of this investigation the causes which produce late and early rivers may be elicited, and the best times for closing and opening different rivers for fishing may be more satisfactorily determined than at present. On the suggestion of Mr. Young, different late and early rivers have been selected for observation, and the necessary arrangements for carrying these on are being established, and those connected with the river Ugie, in Aberdeenshire, are now completed, and the observations will be commenced immediately. At Peterhead the Harbour Commissioners have on the suggestion of Mr. Stevenson established a station for thermometers under continuous immersion, which has for some years been superintended by Mr. Boyd, who is a member of the Committee, and who has kindly undertaken, in connection with the sea-temperatures at Peterhead, to ascertain those of the fresh waters of the Ugie.

DUBLIN

Royal Irish Academy, Nov. 8.—Dr. Stokes, F.R.S., president, in the chair.—Dr. S. Ferguson, V.P., read a paper On the alleged literary forgery respecting Sun-worship on Mount Callan.—The Secretary read a paper by Dr. Doberck, On the binary stars, 44 Böotis, ζ Cassiopeiaæ, and μ Draconis (this paper will appear in an early number of the "Transactions.")—Dr. Macalister read Notes on anomalies in the course and distribution of nerves in man. The following parts of vol. xxv. of "Transactions" were laid on the table:—Part 16, Researches on the Structure of the Spines of the Diadematidæ, by H. W. Mackintosh plates 31* to 33; part 17, on Nine-point Contact of Cubic Curves, by Dr. Hart; part 18, Experiments on the Movements of Water in Plants (part ii.), by Prof. M'Nab, M.D.; part 19, on the Binary Stars σ Coronæ, τ Ophiuchi, γ Leonis, ζ Aqaurii, 36 Andromedæ, and ι Leonis, by Dr. Doberck; part 20, Report on the Superinduced Divisional Structure of Rocks called Jointing, and its Relation to Slaty Cleavage, by Dr. W. King (plates 34 to 38); this part concludes vol. xxv., and is accompanied by a title-page and table of contents; also the July and October parts of the "Proceedings."

PARIS

Academy of Sciences, Nov. 22.—M. Frémy in the chair.—The following papers were read:—Thermal researches on citric acid, by MM. Berthelot and Longuinine.—Remarks on the interpretation of two tables of chemical analyses, by M. Duchartre. This refers to treatment of beet.—On the periodicity of great movements of the atmosphere, by M. Sainte-Claire Deville. From two years' observations he shows a quadruple, dodecuple, and tridodecuple period in recurrence of barometric maxima and minima in the year.—Continued observations of eclipses of the satellites of Jupiter, made at the Observatory of Toulouse, by M. Tisserand.—New observations on the law of expansion in steam-engines, by M. Ledieu.—Remarks on the Balænides of the Japan seas, *àpropos* of the cranium of a Cetacean of this group sent to the Museum by the Japanese Government, by M. Gervais.—M. Pierre exhibited a specimen of fibres of remarkable length and tenacity, obtained by setting a stem of *Lavatera*.—On the mechanism and the causes of changes of colour in the chameleon, by M. Bert. There are two sets of nerves, the one bringing the coloured corpuscles out to the surface (and comparable to vaso-constrictor nerves), the other bringing them under the dermis (corresponding to the vaso-dilator nerves). Each cerebral hemisphere commands nerves on both sides of the body, and is generally excited through the eye on the other side; but it acts chiefly on nerves of the vaso-constrictor type on its own side, and the other kind on the opposite side. Blue violet rays act directly on the corpuscles, bringing them to the surface.—Granitic diluvium in the neighbourhood of Paris; Lithology of the sands of Beynes and St. Cloud, by M. Salvetat.—On the electrolysis of bodies of the aromatic series, by M. Goppelsroeder.—On the fixation of atmospheric nitrogen in soils, by M. Truchot.—Water of the Vanne, and distilled water; examination of the salt of brine, by M. Monier.—On the construction of lightning conductors, by M. Saint-Edme.—On the formation, structure, and decomposition of the swellings produced on the vine by Phylloxera, by M. Max. Cornu.—Observations on the planet Jupiter (continued), by M. Flammarion.—New examples of representation, by geometrical figures, of the analytical conceptions of geometry of n dimensions, by Mr. Spottiswoode.—On employment of marine chronometers in the German navy, by M. Peters.—On coordinated surfaces, such that at every point considered as centre of a sphere of constant radius, the normals to the surfaces, form in this sphere the apices of a spherical triangle of constant area, by M. Aoust.—On the numbers of Bernouilli, by M. Le Paise.—On a reaction of the homologues of ethylene, which may explain their absence in the natural petroleums, by M. Le Bel.—Remarks *àpropos* of the discovery of gallium, by M. Mendeleef. In accordance with a law he enunciated in 1869, he thinks the new metal may be ekaaluminium.—On the saccharification of amylaceous matters, by M. Bondonneau.—On stripping off the leaves of the beet, by M. Violette.—Troïlite; its true mineralogical and chemical place, by Mr. Lawrence Smith.—On certain alterations of agates and silex, by M. Friedel—On explosive compounds; influence of the fuse on compressed gun-cotton, by MM. Champion and Pellet.—Researches on the functions of the spleen, by MM. Malassez and Picard. The increase of globular richness in the blood of splenic tissue is not due to concentration of blood, for the quantity of iron diminishes.—On the ichthyologic fauna of the Isle of Saint Paul, by M. Sauvage.—Examination of rain-water in the udometers of Paris Observatory, Oct. 14 to Nov. 15, 1875, by M. Gerardin.—On the action of monohydrated and trihydrated phosphoric acid on coagulation of blood, by M. Oré.

CONTENTS

THURSDAY, DECEMBER 9, 1875

SCIENTIFIC AGRICULTURE

FARMING is a complex business. It embraces a greater variety of objects and interests than any other industrial pursuit. Its two great ends are the production of crops and the production of animals. It is among the oldest occupations of man. Its history has been very peculiar. In our own day the system of farming pursued by the great bulk of occupiers of land is far behind the state of agricultural knowledge; and many of the practices of the most enlightened of our farmers are based on empirical data. Various agencies have been proposed for promoting agricultural progress. For the instruction of the mass we must look chiefly to the diffusion of agricultural knowledge through the medium of ordinary schools and colleges, as was pointed out some time ago in NATURE. For further progress in the acquisition of accurate knowledge we must look chiefly to experimental investigations.

In Germany they have had in operation for some years a number of experimental stations which are partly supported by the State, and which are said to work satisfactorily. France and other European countries are following the example of Germany. Recently the subject has been ventilated in Great Britain. It has been forced on our attention by a number of persons who are seemingly desirous of giving to the farmer every aid which science can suggest.

British experience of experimental stations is very limited. We happen to have one at Rothamstead in England, which was described in NATURE last year, and which we owe to the enterprise of Mr. John Bennett Lawes, F.R.S., the great manure manufacturer. He has for upwards of thirty years used a part of his estate for experimental purposes. He has published the results in a vast number of papers. The whole is the work of the man himself. He has had no aid from the Government or any agricultural society, and no advice from any committee or public body. He has obtained a larger body of facts in relation to manures and cropping, and the feeding of animals, than all the agricultural societies in the empire put together. It is manifestly desirable to dwell on his labours and to contrast them with the more public system projected elsewhere.

To Mr. Lawes' experiments I hope to be able to devote another paper before long. For the present I shall merely draw attention to the circumstances on which, in my judgment, the success which has attended his labours has depended. Mr. Lawes has not had an unqualified success, especially in drawing inferences from his facts. But his writings afford ample evidence of great earnestness of purpose. His manly, outspoken language shows that he loves truth for its own sake. He has had ample resources; and he has had the motive of self-interest, as well as love of knowledge, to stimulate him in his investigations.

Here, then, we have a private individual who, unaided by the State, or by any scientific body, has made a greater number of useful experiments than all the experimental farms of European Governments put together. Had the British Government established experimental stations before Mr. Lawes commenced, would he have established his? And if not, would British agriculture have derived more useful results from the governmental stations than from his?

These are questions which cannot be answered by direct evidence. We possess, however, data which enable us to throw light upon them. It is notorious that the agriculture of Scotland has made great progress within the past one hundred years. The improvement of agriculture within that period has been greater in parts of Scotland than in any part of England. Yet the demand for means of effecting further progress is greater among the most advanced farmers of Scotland than among the most advanced English farmers. There is no man in Scotland who has come forward, or offers to come forward, to do for Scotland what Mr. Lawes has done and offers to do for England. The friends of agricultural progress in Scotland are endeavouring to effect, by co-operation, what the private enterprise of Mr. Lawes is doing for England. The subject has been discussed in English agricultural classes, more or less, for several years. The discussion has during the past few weeks assumed a practical shape to which it may be useful to refer. A member of the Council of the Royal Agricultural Society of England, Mr. Randell, desires to "prove, by a series of experiments, under every variety of soil and circumstances, how far the accuracy of the estimated value of manures obtained by the consumption of different articles of food as given by Mr. Lawes, is confirmed by practical results." Mr. Randell was supported by the Earl of Lichfield and Lord Vernon, and the matter was referred to the Chemical Committee of the Society. Mr. Randell has so far confined himself to one point, which has been suggested to his mind by the passing of the Agricultural Holdings Act of 1875. If one or more stations be established, the experiments would of course cover a wider field. The question arises at once, how are the experiments to be directed? Could Mr. Lawes be induced to act as Director-General? He could be assisted by a representative council. In due time the best man to succeed him would appear.

In Scotland the movement has of late been agitated with energy and intelligence. The Royal Agricultural Society of that country, better known as the Highland Society, has a large surplus fund, and contains among its members the leading gentry, many enlightened professional men, and a great array of intelligent farmers. It has been suggested that some of this fund should be applied to the maintenance of experimental stations. Several reports and suggestions have been made. It is said that a sum of 700*l.* a year, and no more, is available for the purpose.

One of the reports goes on to state that "considering the advantages which had already been derived from chemistry in its application to agriculture, it was expedient to reorganise a chemical department under the cognisance of the Society, for the purpose of conducting investigations on all subjects relating to agriculture; and that in connection therewith a series of carefully conducted experiments in the open ground be instituted." The directors found that the Society had at its disposal, for the purpose of the chemical department and field experiments, a sum of 700*l.*, which they recommended should be set aside for a period of seven years. In

carrying out these recommendations they suggested that the 700*l.* should be expended as follows:—"Chemist's salary, 300*l.*; agricultural inspector's salary, 150*l.*," &c.

The report must render it plain to anyone who has had experience in experimental work of the kind contemplated that this part of the recommendation is based on imperfect knowledge. What evidence is there in the history of the Society, or elsewhere, which goes to show that the best man to initiate and conduct investigations on all subjects relating to agriculture should be a professional chemist? Such a man should have a good general knowledge of all the sciences relating to agriculture. He should be well known as a man of broad views and great grasp of mind. He should, moreover, be thoroughly conversant with the details of modern agriculture. He should have given evidence of being imbued with an ardent desire to elicit truth, as well as of his taste and fitness for conducting experiments. We submit that a really good chemist, possessing all these qualifications, can seldom be found. If he exists in Scotland, let him by all means be made director of the proposed station or stations; not, however, because he is a chemist, but because he is the best man. There are many chemists who would doubtless be glad to accept such an appointment, and who would be as unfit for it as for the direction of the Channel fleet. It seems incredible that any body of thoughtful men would propose to trust the initiation and direction of experiments on crops and animals to a man who would not necessarily know anything of the habits of either.

A most peculiar part of the report of the committee to which the Highland Society referred the consideration of this question is the remuneration (150*l.* a year) they propose for an agricultural inspector. If the views of the committee were acted on, the *bonâ fide* value of the experiments would depend on this officer. He should be an accomplished agriculturist. He should possess great intelligence, the highest personal character, and the most rigid love of truth, as well as the sternest sense of duty. He would be expected to initiate experiments from which results of national importance would flow. And this is the man for whom the munificent sum of 150*l.* a year is proposed! If a man like Mr. Lawes were to undertake the duty, he would accept no remuneration. In this case 150*l.* a year may be a fair sum to cover travelling and other expenses. But if a competent man is to be employed who cannot afford to work gratuitously, a salary equal to that of the average of intelligent professional men must be offered. This part of the Report has been already denounced in strong and emphatic language; and we understand it has been opposed by leading members of the Society who value science and appreciate the work to be done. The action of the committee has been openly exposed by Mr. David Milne Home, an ardent advocate of the application of science to agriculture, and by Mr. John Wilson, of Eddington Mains, a truly enlightened farmer. These gentlemen contend that the directing head or body should have the power to call in the professional aid of the best chemist or chemists, and such other experts as may be needed. This view is based on common sense. If they prevail in the councils of the Society, we may expect to see ere long in Scotland agricultural stations which in all human probability will give a new stimulus to agricultural progress. If they fail, and the work is entrusted to men who are not in every way equal to it, we may get an annual crop of worthless or misleading results, like those which have formed so large a portion of our agricultural literature.

While the Royal Agricultural Society of Scotland is discussing these matters, a local Agricultural Association formed in Aberdeenshire has actually fixed sites for five stations, at which experiments will be conducted for three years. The Marquis of Huntley is president of the Society, and Mr. Barclay M.P., is among the active members. A sum exceeding 1,000*l.* has been already subscribed. For the present the experiments will be confined to the determination of the best states in which to apply phosphates and nitrogen. Each plot is to be 1-112th part of an acre. It is to be regretted that potash and one or two other constituents of plants will not be tried. In some respects the scheme devised by the Association corresponds with that which I have carried out at Glasnevin for several years, and the results of which I have not, owing to pressure of other work, been able to publish. In the Glasnevin experimental ground the several crops are crossed by the manures; and thus we bring out the results in a striking way, and guard against inequalities in the soil. We also raised three consecutive grain crops without manure before commencing the experiments.

THOMAS BALDWIN

THE NEW GEOMETRY

Syllabus of Plane Geometry (corresponding to Euclid, Books i.-vi.) Prepared by the Association for the Improvement of Geometrical Teaching. (London: Macmillan, 1875.)

THE readers of NATURE are so well acquainted with the genesis and growth of the Association whose syllabus has recently been given to the public, that we are relieved from all necessity of explaining what objects it has in view. The main result of its five years of labour is this Syllabus, and we shall here briefly exhibit some of its chief features. It is a double syllabus, being a syllabus of geometrical constructions and a syllabus of plane geometry. The former is very brief, and contains such constructions as can be made with the ruler and compasses only. This subject of constructive geometry has been tried in many schools of late and has been found generally to answer the end in view. Boys thus obtain some idea of the objects of pure geometry and of what is involved in the postulates of the science. The more important syllabus is prefaced by a Logical Introduction—not that the Association wishes "to imply by this that the study of geometry ought to be preceded by a study of the logical independence of associated theorems." The opinion of the compilers is "that at first all the steps by which any theorem is demonstrated should be carefully gone through by the student, rather than that its truth should be inferred from the logical rules here laid down. At the same time they strongly recommend an early application of general logical principles." The President, in one of his addresses, states that the object of this introduction is "to guide the teacher immediately, and the student ultimately." It contains certain general axioms (as the whole is greater than its part), and taking as its typical theorem, if *A* is *B*

then C is D, it explains what is meant by its *contrapositive* (if C is not D, A is not B), by its *converse* (if C is D, A is B), and by its *obverse* (if A is not B, C is not D). This last term we have heard strongly condemned; it was substituted (see Fifth Annual Report) for the more usual term *opposite* on the ground that, in logic, two opposite propositions cannot be true together. The terminology, however, to our mind, is a matter of no great consequence. For proving converse theorems frequent use is recommended in the work of a "Rule of Identity" here given, *i.e.* if there is but one A and but one B, then if A is B, it necessarily follows that B is A. (De Morgan's illustration is given in Wilson's Geometry.)

The *Straight Line* is the subject of Book i., and takes up five sections, Angles at a point, Triangles, Parallels and Parallelograms, Problems, and Loci. Here, in the definitions, we have two difficulties to meet, What is a *straight line?* what is an *angle?* The former is defined to be "such that any part will, however placed, lie wholly on any other part if its extremities are made to fall on that other part." The latter is stated to be a "simple concept incapable of definition;" its nature, however, is explained and illustrated in some detail. Parallel straight lines are defined as in Euclid, and Playfair's axiom is Axiom 5. Theorem 21 (Euc. i. 27) is proved as the contrapositive of Theorem 9 (Euc. i. 16); Theorem 22 (Euc. i. 29) by Rule of Identity, using Axiom 5. Book ii. treats of *Equality of Areas* (Theorems, Problems); Book iii. is on the *Circle*. Here a novelty is the treatment of Tangents in two sections, directly, then by the method of limits. Some, if not all, of De Morgan's suggestions ("Companion to British Almanac, 1849) on this subject have been adopted here. The Syllabus so far is not a novelty to many of our readers. Those possessed of Mr. Wilson's "Elementary Geometry" (3rd edition) will know that he has in the main, if not altogether, adopted the lines laid down in the Association's work, adding proofs in full, and much interesting illustrative matter. It hardly needs our saying that the method of superposition is freely used, and that alternative constructions are indicated.

We come now to Books iv. and v., which cover pretty much the same ground, except that in the former book we have the subject of proportion and its application treated in a thoroughly rigorous method, which is a simplification of Euclid's mode of treatment by multiples. In the latter book the same subjects are treated in a confessedly incomplete manner (for commensurables only) for the use of students whose capacities or time may be limited.

Similar figures, areas, loci, and problems complete Book v.

We shall conclude our notice by taking a few extracts from the report made by the committee appointed by the British Association "to consider the possibility of improving the methods of instruction in elementary geometry."

"It seems advisable that the requisite uniformity should be obtained by the publication of an authorised syllabus, indicating the order of the propositions, and in some cases the general character of the demonstrations, but leaving the choice of the text-book perfectly free to the teacher. . . . The committee recommend that the teaching of practical geometry should precede that of theoretical geometry, in order that the mind of the learner may first be familiarised with the facts of the science, and afterwards led to see their connection. With this end the instruction in practical geometry should be directed as much to the verification of the theorems as to the solution of problems. . . . It appears that the principle of superposition might advantageously be employed with greater frequency in the demonstrations, and that an explicit recognition of it as an axiom of fundamental assumption should be made at the commencement. . . . The committee think also that it would be advisable to introduce explicitly certain definitions and principles of general logic, in order that the processes of simple conversion may not be confounded with geometrical methods."

The Syllabus now published is under the consideration of this body of distinguished mathematicians, who will report upon its merits and discuss the advisability of giving it the authority of the British Association. In the mean time it will be of considerable service if teachers will practically test it for themselves, and make known their views of its adaptation or want of adaptation for the end proposed. We may remark that Def. 38 (when a straight line intersects two other straight lines, it makes with them eight angles, which have received special names in relation to one another) is not quite correct, for the three lines may cointersect, and then six angles only are formed. Introduce the words "in two distinct points" between "straight lines," and "it makes."

ESKIMO TALES AND TRADITIONS

Tales and Traditions of the Eskimo, with a sketch of their Habits, Religion, Language, and other Peculiarities. By Dr. Henry Rink. Translated from the Danish by the Author. Edited by Dr. Robert Brown. With numerous Illustrations drawn and engraved by Eskimo. (Edinburgh and London: Blackwood and Sons, 1875.)

DR. Rink is probably the greatest living authority on all matters connected with the Greenland Eskimo. The high value of his contributions to our knowledge of Greenland and its people is universally admitted. The English reading public, and English ethnologists especially, will no doubt be grateful to him for having put his "Eskimo Tales and Traditions" into an English dress. The translation is perfectly idiomatic and altogether creditable to the author.

Not the least valuable portion of the work is the introduction, treating of the Eskimo themselves, in which, in a few short chapters, Dr. Rink presents a succinct and clear statement of all that is at present known of these interesting people. For his present purpose Dr. Rink divides the Eskimo into seven groups, groups which, we think, have quite marked enough distinctions to be regarded as convenient for most other purposes; they are as follows:—1. The East Greenlanders; 2. The West Greenlanders; 3. The Northernmost Greenlanders or Arctic Highlanders of Sir John Ross; 4. The Labrador Eskimo; 5. The Eskimo of the Middle Regions, from Baffin and Hudson Bays to Barter Island, near the Mackenzie River; 6. The Western Eskimo, from Barter Island to the west and south; and 7. The Asiatic Eskimo.

Anything like national or tribal union, however, seems untraceable, although at various periods, no doubt, the small communities of particular districts have united against a common enemy. The only communities which Dr. Rink can trace as anything like permanent are—1. The Family, the tie which unites the various members of which seems to be very strong; 2. The Housemates, or inhabitants of a house; for generally, except recently in some parts of Danish Greenland, one house sheltered two or more families which necessarily had many things in common, and many mutual duties and obligations; and 3. Place-fellows, or the inhabitants of the same hamlet or wintering-place, among whom communism in certain matters was distinctly recognised. Dr. Rink describes with some fulness the principal laws with regard to property and gain which are recognised as regulating the life of these three divisions of the various Eskimo groups.

Dr. Rink is strongly of opinion that the Eskimo are an indigenous American people, who have been pushed northwards by the intrusive Indian tribes, who are frequently referred to in the Tales contained in the volume, under the name of "Inlanders." In the frequent reference to conflicts and other dealings with the Inlanders Dr. Rink finds a confirmation of his theory, but we think it would equally well support a theory which maintained that the Eskimo themselves are the intruders. We are inclined to think that the theory broached by Mr. C. R. Markham in the R.G.S. "Papers on Arctic Geography and Ethnology" (1875) is quite as consistent with all the facts as Dr. Rink's, if not more so. Mr. Markham adduces very cogent reasons for believing that at no very remote period the Eskimo entered America from Asia by Behring Straits, driven to do so by the pushing northwards of the hordes from Central Asia. We doubt if these Tales and Traditions will help us much towards a knowledge of the origin and early history of the Eskimo. Indeed we doubt very much if we have yet data sufficient to authorise us to pronounce with anything like confidence on the subject.

The volume contains in all 150 Eskimo tales and traditions, some of which, however, are only fragments. They have been taken down from the recital of natives of South and North and East Greenland and of Labrador. A vast amount of material was thus collected, many of the tales being evidently variants of one original. This material Dr. Rink has redacted, "all the variations being most carefully examined and compared for the purpose of composing a text such as might agree best with the supposed original and most popular mode of telling the same story." For general purposes this method is, no doubt, quite satisfactory, but if these tales and traditions are to be of any service in enabling us to trace the origin of the Eskimo, the investigator should have before him all the supposed variations of the same original. By comparing these with each other, and with similar materials obtained from the Western and Asiatic Eskimo, and with the neighbouring Siberian and Indian tribes, we should think it not unlikely that some valuable hints might be obtained as to the Eskimo migrations. No one is more competent than Dr. Rink for such a task, if undertaken without prepossession in favour of any hypothesis.

Woman with a Child in the amowt or hood (after present fashion). Godthaab.

The tales are roughly divided into ancient and recent The former may be regarded as the property of the whole

nation, and many of them Dr. Rink believes to be far older than a thousand years. Probably they originated when the Eskimo lived together before their migrations began, and while it is not unlikely that most of them took their rise in some actual incident, they have all evidently been much changed and elaborated by the introduction of the mythical and supernatural. The second class are limited to certain parts of the country, or even to certain people related to each other, "thus presenting the character of family records." But the recent, like the ancient, tales have all more or less of the mythical element in them, and indeed it is mainly from the tales and traditions as a whole that a knowledge of the elaborate and intricate Eskimo mythology has been obtained. The Eskimo have peopled the air, the earth, and the sea with a multitude of supernatural beings; they live as much in an unseen, but to them real and populous, world, as they do among the hard realities of their land and seas. It is very characteristic of them that they have placed their heaven where we have placed our "bad bit," as they call it in Galloway, under the earth, as being so much warmer than the ungenial sky, to which their wicked are condemned to freeze eternally. Of the comparatively modern tales a very few relate to the collision which took place in the fourteenth and fifteenth centuries between the Eskimo and the Icelandic colonists who had been settled in South Greenland since the eleventh century. One relates to two Eskimo who were taken to Europe by some of the early explorers of Greenland, and in both cases the mythical has been largely introduced, affording a good example of how these stories have grown, and showing that while a basis of truth exists in the older stories, the older they are the more difficult it would be to get at it.

While many of the stories are really interesting, there is a great deal of sameness about most of them. Many of them relate to feats of strength, which, formerly at least, seem to have been much admired by the Eskimo. Indeed, it is evident that it was no uncommon thing among them for men to go through a regular and well-devised system of "training" in order to develop muscle and endurance. A large number of them relate to the means adopted by the people to carry on the struggle for existence both against the stern powers of nature that everywhere meet them and against the cunning and competition of their fellows. The satisfaction of revenge and spite form the subject of many, as also the sacrifices made by friend for friend and by the members of a family for each other. Altogether they show the Eskimo to be on the whole gentle, hardy, hospitable, capable of strong attachment, but often capriciously revengeful and spiteful, even to his dearest friend. There is very little of the tender element of love in these stories, an element which figures so prominently in the folk-lore of most other nations. These stories also show that the Eskimo have the poetic temperament in a very fair degree, though most of them are artless enough, and many of them quite objectless and tame in the result. They very frequently remind us of the Brownie tales of Scotland, and some fragments of poetry which Dr. Rink gives, have quite an Ossianic ring about them. The best complete stories are much too long to permit of our extracting one here, though the following short one is a fair example:—

"The inlanders and the coast-people in the beginning were friends. A servant-maid called Navaranak used to be sent out by the inlanders to the coast-people in order to fetch back *matak* (edible whale-skin), and in exchange brought them reindeer-tallow; but after a time she grew weary of this work, and resolved to free herself by making them enemies. For this purpose she told the inlanders that the coast-people were going to attack them, and to the coasters she asserted that the inlanders were making ready to invade them. At length she provoked the inlanders to such a degree that they resolved upon attacking the coast-people. They chose a time when they were well aware that the men had all gone out hunting, and, accompanied by Navaranak, fell upon the helpless women and children. In their fright some of the mothers killed their own children, but one woman who was pregnant fled down beneath the ledge; and when Navaranak was sent back by the inlanders to find her out, she promised her all she possessed not to betray her. Some also escaped by hiding themselves among the rocks, but all the rest were killed. When the men returned, those who were left alive ran down and told them what had happened; and on coming up from the beach to their houses and beholding all their dead, the men were almost desperate. When the time came for flensing and cutting up the whale, Navaranak did not arrive as usual; she seemed to have disappeared altogether. When summer had again come round, the men prepared a great many arrows, and set out for the interior to take revenge on the inlanders. On their way they called out, as was their wont, "Navaranak, come on; we have got matak for thee!" but no one appeared. Again they went on a good distance, and then repeatedly called out, "Navaranak," &c. And this time she answered the summons, and went up to them. On noticing their arrows, she was about to take flight. Reassuring her, however, they told her she had no need to do that. When she had ventured quite close to them, they asked her where her countrymen were to be found, and she said, "Further away in the interior of the country;" but now they made her fast to a rope, and dragged her along with them until she perished. At length they arrived at a very large lake, where the tents of the inlanders were pitched all around, and they saw people going out and in. But they waited till all had entered the tents, and then they made their attack. Arrows came flying from both sides; but those of the inlanders soon grew fewer in number, and the coast-people remained all unwounded. When they had done with the men, they went inside, killing women and children; and having thus satisfied their revenge, returned to their homes.

There can be no doubt about the scientific value of this addition to our Arctic literature. To anyone who wishes to have a succinct and trustworthy account of all that is known of the Eskimo, we could not recommend a better work. The tales themselves are perfectly novel, and many of them quite interesting enough and full of queer adventure to become favourites with omnivorous boyhood and even dainty girlhood.

The illustrations, all things considered, are creditable to the native artists who drew and engraved them. By the kindness of the publishers we are able to reproduce a specimen.

OUR BOOK SHELF

A Report on Trichinosis as observed in Dearborn Co. Ind., in 1874. By George Sutton, M.D., Aurora, Ind (Reprinted from the Transactions of the Indiana State Medical Society, 1875.)

THE literature of Trichinosis bids fair to become co-

extensive with that of all the other parasitic diseases rolled together. Whilst one can but admire the energy displayed by our Transatlantic brethren in turning every scientific discovery to practical account, we must at the same time observe that only a very few of the voluminous reports received by us from the various States contain matter sufficiently novel to demand extended notice at our hands. Dr. Sutton's report, admirable as it is in many respects, forms no exception to the general rule. By European helminthologists the recognition of Trichinosis in the human subject is no longer spoken of as a "recent discovery," seeing that Zenker, whose merit in this relation is supreme, diagnosed the "loathsome disorder" in 1860, whilst the antecedent steps in the chain of evidence were long previously established by Leuckart and Vichow (1859), Herbst (1850), and so on backwards, until we come to the date of the original discovery of the worm as a nematoid by Paget, and its subsequent description by Owen (1835). We may go even further back than this, and point to Wormald and Hilton's previous and independent recognition of the calcified trichina capsules, and also to their still earlier detection by Peacock (1828), to say nothing of the evidence in favour of Tiedemann (Froriep's *Notizen*, 1822). We must dissent altogether from the view expressed by Dr. Sutton, that Trichinosis probably caused "the ancient Jew to prohibit the use of pork" as food. On the other hand, we are glad to perceive that our author adds his testimony to the view previously taken by ourselves and others, that there is no connection between trichinosis and the so-called "hog cholera." In this regard Dr. Sutton would have done well to have consulted Prof. Verrill's various papers (*American Journal of Science and Arts; Report of Connecticut Board of Agriculture*, 1870), and, if possible to him, also, our own subsequent contribution on *Stephanurus* (NATURE, vol. iv. p. 508). Lastly, we can only remark that if Germans will not abandon their habit of eating "smoked sausages" they must expect to be trichinised. Clearly, the fault is their own.

T. S. COBBOLD

The Sea. By Jules Michelet. (London and Edinburgh: Nelson and Sons, 1875.)

MICHELET, as our readers know, wrote a number of works on subjects which suggest a scientific treatment—"L'Oiseau," "L'Insecte," "La Mer," and "La Montagne." The present volume is a translation of the third mentioned, and we believe that at least one of the others has been put into an English dress. These works can hardly be regarded as scientific, except in so far as Michelet seems to have taken laudable pains to acquaint himself, before writing, with some of the principal and especially the most interesting facts which science has discovered in connection with his various texts. For really the titles of his quasi-scientific works are only texts, or rather themes, round which he accumulates a vast variety of more or less appropriate facts, reflections, and word-pictures. He might indeed be regarded as the rhapsodist of science, a man of distinctly poetic or imaginative temperament, excited to enthusiasm by reflections on the facts furnished to him by science. Of course no one would think of resorting to Michelet's works to study any of the subjects he thus treats, but nevertheless his works have their uses from a scientific point of view, uses which we have often referred to in speaking of popular scientific works. "The Sea" will no doubt attract many English readers now that it is translated, and notwithstanding its rhapsodical nature it contains a very fair amount of really useful and trustworthy information concerning marine physics and marine life. But, as in his other works, Michelet skips about his subject on all sides, poses it in every possible attitude, sings about it from every possible point of view. The illustrations are charming, and the book as a whole is got up with great taste. The Messrs. Nelson have done well in publishing such a translation.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The Dresden "Gorilla"

IT is a mere chance that I did not see the numbers of NATURE from Sept. 30 till to-day, and I therefore missed the note (vol. xii. p. 482) about the female chimpanzee of the Zoological Garden of Dresden, said to be a young gorilla. In my opinion there can be no question that this ape is not a gorilla. It is only a very fine specimen of a chimpanzee with a darker face than usual, it is true, but this is by no means sufficient in the present state of our knowledge to separate it specifically from *Troglodytes niger*. I only mention here the *one* characteristic referred to in NATURE—"the slight webbing between the fingers." There is no webbing at all between the fingers which deserves to be called so, and there is a fundamental difference from the hand of a gorilla, not only in respect to this characteristic, but also in respect to the proportion of the fingers to each other. The hand of the Dresden specimen is very long and slender; the hand of the gorilla, even of the young one, is known to be broad and short fingered. But there is a long series of reasons which clearly speak against the supposition that this specimen is a gorilla, and I really do not perceive how anyone can advance this opinion after a very insufficient inspection. It is not enough to say, "I take the specimen for a gorilla;" scientific reasons are needed, and that, too, from some one who really understands the question; it was at least very rash to come out with *this* gorilla. As soon as anyone of the supporters of the opinion that this chimpanzee is a gorilla shall have published *scientific* reasons, I will take occasion to report about it, and to discuss these reasons. Till then there is no reason whatever to go deeper into the matter, and to regard this ape as anything other than a *Troglodytes niger*.

The two specimens of Birds of Paradise, about which I wrote to you some time ago (vol. xii. p. 434), are now in the Zoological Garden of Berlin.

A. B. MEYER,
Director of the Royal Natural History Museum of Dresden

Dresden, Dec. 3

Dr. Stoliczka's Collection of Mammals

I SEND you an extract of a paper lately published in the *Journal of the Asiatic Society of Bengal* by Mr. W. T. Blanford, on the mammals collected by the late Dr. Stoliczka in Yarkand, &c., and have italicised one or two of the more important sentences. These show how the value of the fine collection has been materially reduced by the appropriation of the finest heads of ruminants, &c., after Dr. Stoliczka's death. The collection before its arrival in Calcutta was known to contain some splendid heads of *Ovis poli*, and other wild sheep, all of which were carried at the expense of the Indian Government from Yarkand over the Karakoram *viâ* Kashmir to India, a long and costly journey. The finest of these heads, it is well known, have passed into private hands, while the Government Museum in Calcutta cannot show a specimen of decent size. The whole should have passed intact to the above museum, and would have been there examined, and the duplicate specimens sent to the Indian and British Museums here in England. The extract from Mr. Blanford's paper tells its own tale, and I think it would do good to let the fact of the partial destruction of a valuable collection of an able naturalist be more widely known than to the few readers of the *Journal of the Asiatic Society of Bengal*. Every specimen in the collection was as much public property as the munitions in a Government store, and could not be disposed of by any member of the Government or mission.

Extract from the "Journal of the Asiatic Society of Bengal." Vol. xliv. Part II., 1875.

"List of Mammalia collected by the late Dr. Stoliczka when attached to the Embassy under Sir D. Forsyth in Kashmir, Ladák, Eastern Turkistan, and Wakhan, with descriptions of new species. By W. T. Blanford, F.R.S., F.Z.S.

"The collections made by Dr. Stoliczka in Kashmir, Ladák, Kashgar, and Wakhan comprise a very fine series of Mammalia, the description of which has been entrusted to me by Mr. Hume, who has undertaken the general direction, besides a very large share in the details of a work intended to be a memorial of our

late friend. It is of course impossible to supply the place of the naturalist whose collections I shall do the best to describe, for with him has perished much knowledge of the habits and distribution of the animals, and although this want can be partially atoned for by the copious notes he has left behind, much unfortunately can never be replaced. . . . There is always more difficulty in procuring specimens of Mammalia than in collecting terrestrial animals belonging to most of the other classes of vertebrata and invertebrata, and this is especially the case with the larger forms. It is consequently not to be expected that the species represented will be more than a portion of those inhabiting the country. Still the collection is rich in some respects, and especially in kinds of rodents, and it adds largely to our knowledge of the fauna of Western Tibet and Eastern Turkistan. *The larger mammals, indeed, were originally better represented, but after Dr. Stoliczka's death many specimens appear to have been removed from the collection.* Such at least was the case with the ruminants. In a private letter which Dr. Stoliczka wrote to me, he told me he had sent twenty-two skins of wild sheep from Kashgar. Of these only eleven—seven males and four females—are now forthcoming, and not one of these has fine horns. There is not a single specimen of *Ovis poli* from the Pamir, the original locality, although I have reason to believe that Dr. Stoliczka brought away one head at least. Lastly, there are *skeletons* of wild sheep and ibex in the collection *of which the heads have disappeared.* It is highly probable that other specimens besides those of *Ovis poli* have been similarly made over to private individuals. The value of the collection has been seriously diminished by its being broken up, and the finest specimens distributed, before it had been examined," &c.

Glands of the Cherry Laurel

IN NATURE (vol. viii., p. 245) Mr. Thiselton Dyer, in answer to a correspondent, says that he knows of no explanation of the purpose or origin of the nectariferous glands on the back of the leaf of the cherry laurel. Mr. Darwin ("Origin of Species," sixth edition, p. 73) says: "Certain plants excrete sweet juice, apparently for the sake of eliminating something injurious from the sap; this is effected, for instance, by glands at the base of the stipules in some Leguminosæ, and at the backs of the leaves of the common laurel. This juice, though small in quantity, is greedily sought by insects; but their visits do not in any way benefit the plant." Glands cannot be considered very complex modifications of cellular tissue. They exist on all parts of plants, and contain a great variety of secretions. Mr. Darwin and others have shown that they perform the varied functions of secreting nectar to attract insects to flowers, of secreting odorous matter for the same purpose, of absorbing ammonia from rain-water and the products of decomposed or digested animal or vegetable matter, and of secreting acids capable of digesting solids. The existence of free acids in the plant would be injurious to it, so that their excretion would be beneficial to it apart from any digestive function which they may in some cases perform. The glands of the laurel are so far unspecialised that they are by no means constant in number or size. As their attracting insects is of no service to the plant, the nectar must be said to be excreted; but, being what Sachs has termed (p. 629) a "secondary product of metastasis," it should be looked upon rather as a physiologically accidental excretion than as positively injurious, as a substance which, having ceased to take part in the processes of growth, has not acquired an indirect function as has the nectar of flowers. To account for the position of the glands it may be suggested that, as in other evergreens, the leaves of the laurel are "reservoirs of reserve material" in which metastasis, including the separation of the "formative materials" from the "secondary products," mainly takes place (Sachs, p. 627).

Saw-fish inhabiting Fresh Water

I AM not aware if a curious fact connected with the lake near Manila has been noticed by any traveller.

The Laguna de Baij is a large sheet of water some ninety miles in circumference, divided by an island and two peninsulas, from which it is often spoken of as the "lakes." This lagoon receives the waters of the small rivers of the provinces of the Laguna and Morong, and its only outlet is the river Pasig, which flows into the bay between the military city and suburbs of Manila. The volume of water discharged by the Pasig is augmented by that of another river which joins the main stream some eight or nine miles from Manila, and during gales in the S. W. monsoon, which prevent the free egress of the water, the Pasig overflows and covers the flat land round Manila.

The water of the lake is quite fresh, and after settling, perfectly potable. At certain times the waters of the lake of Baij possess an urticating property which makes bathing very disagreeable from the irritation they produce. The natives (who account for everything in some way or other) attribute this to the Pistia, a plant which is so abundant as to fill up small bays and form floating islands of considerable size. Great quantities of this plant are carried down the river into the bay, and are seen sometimes a long way out at sea, killed and yellow from the effect of the salt water. Sections of the leaves are beautiful microscopic objects. The lake is separated from the Bay of Manila by a few miles of very flat land, and there can be little doubt that before this barrier was thrown up it formed part of, or at least communicated with, the bay. One proof that the waters were once salt is the existence of a bank of fossil oysters at the point of Julu-julu, some twenty miles from the outlet by the river. When this barrier was raised the waters of the lake became gradually fresh from the influx of those of a number of small rivers which drain the surrounding provinces, the only outlet for which (as before mentioned) is the river Pasig.

The peculiarity to which I have alluded is the existence of a species of small shark and numbers of Saw-fish (*Pristis*) in the perfectly fresh water of the lake. They are seldom or never met with in the river, but there is a fishery in the lagoon in which numbers of the latter are taken. The flesh is eaten, the livers give a good deal of oil, and the snouts of the larger specimens make very formidable weapons, which the natives use and which are at times sent down to Manila as curiosities. These saw-fish, now living in perfectly fresh water, have no doubt become gradually accustomed to the change, as has been the case with the marine species of Crustacea discovered by Prof. Lóven in the fresh water lakes of Sweden.*

I am unable to describe the sharks, which I think from the account given me are a small species of dog-fish, quite harmless. Very different, however, are a larger kind inhabiting the brackish water of the lake of Bombon, in which is situated the active volcano of Taal (south-east of the great lake, about twenty or twenty-five miles distant by road). This kind of shark is feared by the natives, who avoid bathing at points which they frequent.

Manila W. W. WOOD

Observations on Fish

IN May last the writer dug a tank within the premises at Garden Reach. About the end of July it was stocked with young fish of several kinds, among others a species of carp, called by the natives "Katlah," which abounds in the turbid waters of the Hooghly, within the range of the tides. The fry varied from half an inch to an inch in length, some even smaller. The "Kutlah" does not breed in fresh water, but attains an extraordinary size in a wonderfully short time in ponds. So very rapid has been the increase of the fish in question, that the fact seems worthy of chronicle in the pages of NATURE. On Sept. 22, the tank was swept with nets to catch one or two fish of the pike species that had been introduced accidentally with the others, and attained a size that rendered them dangerous to the fry of other kinds. In the net several dozens of the "carp" referred to were taken; one of the largest weighed 14 oz., and measured 11 inches from the end of the upper lip to the tip of the tail, $1\frac{3}{4}$ inches thick behind the shoulder, and $3\frac{1}{4}$ inches in breadth; the others were only one or two ounces lighter.

The tank (pond) in which these fish throve so marvellously is only 65 feet long by 58 feet broad, and 13 feet deep. The natives, many of whom live within the compound, wash their rice and other food in the water, preparatory to cooking, furnishing the fish with a large amount of food. As the writer saw the tank dug and the fish put in, there cannot be a doubt about their increase in the short space of three months from small fry barely an inch long, to fair-sized fish 11 to 14 oz. in weight, measuring from 10 to 11 inches.

ROBERT U. S. MITCHELL

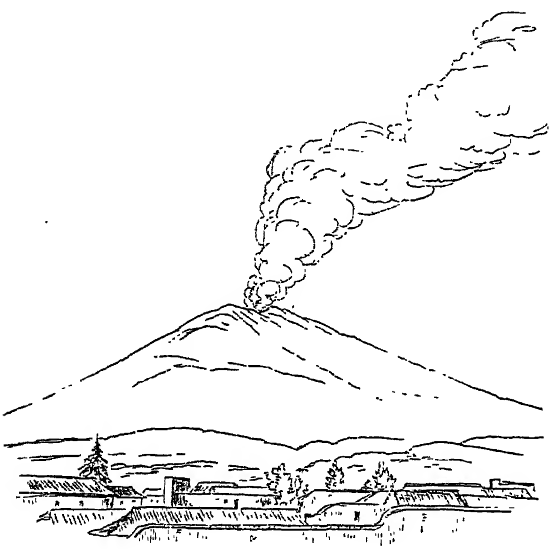
Misti and its Cloud

IN NATURE, vol. xii. p. 487, Mr. Stevenson gives an interesting example of the genesis of clouds, due to hills of about

* See NATURE, vol. i. p. 454.

900 feet high. Something similar is well known to the inhabitants of Arequipa, Peru. The city is built at the base of the extinct volcano "Misti," which rises above the plaza of Arequipa to a height of about 12,500 feet; Arequipa itself being over 7,000 feet above the level of the sea. It is not an uncommon occurrence (during the fall of the year, February and March) in the morning, from sunrise till about ten o'clock, to see a succession of clouds rolling along the summit from N.E. to S.W., much as if huge masses of white smoke were issuing from the extinct crater. These clouds are either suddenly shot upward by meeting the current from the S.W. and lost at a distance of from 30,000 to 40,000 feet to the eastward from the summit, or else, rolling over the summit, they are carried by the easterly breezes till they become absorbed by the dryer and warmer air of the region to the southward of Misti.

It must be remembered that between Arequipa and the sea, at a distance of not more than thirty miles, extends the great sandy desert of Islay, having an average breadth of about twenty-five miles, and before the days of the railroad the great terror of all travellers from the sea-coast to the interior. Of course the winds blowing across this desert (a part of the great rainless belt



of Peru) are greatly heated at all seasons of the year. The eastern slope of Misti, on the contrary, forms the edge of the elevated plateau extending for more than 150 miles to the eastern slope of the Andes, having an altitude of from 10,000 to 14,000 feet, and the amount of rain falling in this district is very great.

The formation of the cloud, seen from Arequipa on the summit only of Misti, is plainly seen from the railroad leading to Puno, which, after leaving Arequipa, makes a gigantic sweep northward round the Chacharni Mountains, and winds its way eastward behind Misti at a height of about 12,500 feet above the level of the sea. There I have several times seen masses of vapour, condensed into huge white clouds rolling along the slopes of Misti, travel up with great rapidity towards the summit, and either follow its crest as described above, or become at once reabsorbed on reaching the top. This shows plainly that the clouds seen from Arequipa are not due to volcanic action; the Indians also all agree in stating that there is no tradition among them of Misti having been active. I enclose a sketch of Misti and its cloud from a photograph obtained during my visit to Peru. ALEXANDER AGASSIZ

Cambridge, Mass., Nov. 6

The Effect of Waves

It is generally believed that at a moderate depth the influence of heavy waves ceases, and that during a hurricane all is quiet a few fathoms beneath the surface. If this be correct, why should a swell show such a marked increase in height when it rolls over the edge of soundings?

On the parallel of Cape Clear, in longitude 15° W., seamen are familiar with this phenomenon, although the depth is nearly five hundred fathoms; at times it is so marked that the dead reckoning may be checked by carefully noting the increase in the depth of the hollow of the waves. Shortly after the edge of soundings is passed the sea becomes more regular, and consequently less dangerous to deeply laden vessels.

Anyone who has watched during a moderate breeze the commotion of the water close to a quay wall can form a good idea of the ocean when it receives its first check against the Irish Plateau; the great waves twist around each other, run up and down in heaps, and then fall suddenly as if bereft, in a great measure, of their forward motion.

Again, it is a well-known fact that during a "norther" in the Gulf of Mexico the frailest vessels weather out the storm if they can cross the edge of the Campeachy Banks; a striking proof that at a depth of over fifty fathoms there is sufficient abrasion to destroy the force of the heaviest wave in a very effectual style. On one occasion the writer witnessed this remarkable fact by running from a turbulent sea into comparative smooth water in this locality.

On George's Shoals, off Nantucket, during a heavy gale, the New York pilots and masters of coasting vessels assert that sand is frequently left on deck after a sea has broken on board, although the depth of water may be twelve or fourteen fathoms. It must require an enormous amount of ebullition at the bottom to raise such dense matter to the surface through such a distance; for a cubic foot of ordinary sea-sand weighs about 100 pounds.

In this wild spot the tide, which frequently runs with a velocity of three miles per hour, would assist the lifting power of the wave if running counter to it. During a winter gale, when the strong springs are thus running, the confusion of the sea is indescribable, although the depth may be thirty fathoms. The shortness of the sea (*i.e.* the distance between the crests of the waves) on the banks of Newfoundland, where the soundings are from thirty to fifty fathoms, is noticed by all the navigators of the Western Atlantic, as it reduces the speed of an ocean steamer more than the heavier waves of deeper water with a similar force of wind will do. It is evident that this can only arise from the friction of the bottom, as the waves increase in height when deeper water is reached a short distance to the eastward.

In the Gulf Stream north of the Straits of Bemine, after a "norther" has blown a few hours, the surface of the sea is covered with lanes of weed, although only a few patches might have been seen before the commencement of the gale. As these lanes are often at a considerable distance from shoal water, which lies at right angles to the direction of the current and wind, it is evident they must have grown near the spot where they float, and been torn from their moorings by the mechanical force of the waves. W. W. KIDDLE

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF 1605, Oct. 12.—Clavius, observing the solar eclipse of April 9, 1567, at its maximum, remarked "a narrow ring of light round the moon which he supposed to be the margin of the solar disc." Kepler, however, maintained that this could not be in reality a portion of the sun, because the moon's apparent diameter at the time must have been greater than that of the sun, and he concluded, as Prof. Grant relates in his "History of Physical Astronomy," that the sun must have been totally covered by the moon while the narrow ring of light was visible, a phenomenon again exhibited in the total eclipse of Oct. 12, 1605, which was observed at Naples. Of this eclipse Kepler says (De Stella Nova in pede Serpentarii)—"Accuratè rectum fuisse totum Solem, quod quidem non diu duraverit; in medio, ubi Luna, fuisse speciem quasi nigræ nubis; circumcirca rubentem et flammeum splendorem, æqualis undique latitudinis, qui bonam cœli partem occupaverit: E regioni Solis, versus Septentrionem, cœlum obscurum planè, et cum profunda nox est; stellas tamen non visas."

Adopting the same system of elements of the lunar motions, employed in previous calculations of past eclipses, the results of which have appeared in this column, we have the following elements of the eclipse to which Kepler refers:—

Conjunction in R.A. Oct. 12, 1605, at 0h. 31m. 44s. G.M.T.

R.A.	197°	41′	51″
Moon's hourly motion in R.A.		35	37
Sun's " " "		2	19
Moon's declination	6	40	28 S.
Sun's "	7	31	33 S.
Moon's hourly motion in Declination ...		10	50 S.
Sun's " " "		0	56 S.
Moon's horizontal parallax		59	21
Sun's "			9
Moon's true semi-diameter		16	10·4
Sun's " "		16	3·9

The sidereal time at Greenwich mean noon Oct. 12 was 13h. 24m. 10·9s., and the equation of time 13m. 29s. additive to mean time. The eclipse would be total and central with the sun on the meridian, in longitude 11° 18′ W., and latitude 52° 26′ N. For Naples, a direct calculation gives a total eclipse, the sun at an altitude of 31°. Beginning of totality at 2h. 18m. 18s., ending at 2h. 19m. 28s., mean time at Naples, or duration 1m. 10s., which appears to correspond fairly with Kepler's statement that the sun was "covered for a short time" only.

The Minor Planets.—M. Stephan, Director of the Observatory at Marseilles, announces the discovery of another small planet by M. Borelly, on December 1. Right ascension at midnight, 65° 31′; north polar distance, 66° 2′; motion towards north-east, thirteenth magnitude. Supposing all the recently detected minor planets to be new, this will be No. 157. The last circular of the "Berliner Astronomisches Jahrbuch," however, has a suggestion by Prof. Tietjen that No. 152, discovered by M. Paul Henry at Paris on November 2, may prove to be the same planet which was found by M. Borelly, 1868, May 29, and which received the name Dike. No. 152 passed the ascending node soon after noon on November 3, the geocentric longitude at the time being 41° 54′, and it was not far from opposition, which is so far favourable to the supposition of identity with Dike, with ascending node in 41° 50′ according to the most probable orbit that could be obtained from the short course of observations in 1868. Dike was estimated of thirteenth magnitude, yet in 1868 was observed within 10° from perihelion; in ascending node the planet would be less than 29° from aphelion; No. 152 is called eleventh magnitude, a difference, considering the respective orbital positions, which is adverse to identity. The unfavourable weather has prevented observations sufficient for a proper calculation of elements for No. 152. Should this planet prove to be identical with No. 99 (Dike), the numbers from 153 onwards will of course require to be diminished by one, and the actual number of small planets, including M. Borelly's late discovery, will stand at 156.

*THE MAMMALS OF YARKAND**

The unfortunate death of the lamented naturalist, Stoliczka—one of the most promising members of the Indian Geological Survey—must be fresh in the memory of many of our readers. After a successful campaign in Yarkand in company with Sir D. Forsyth's late expedition, he did not live to return to India, but perished of exhaustion amongst the snows of the Himalayas. We are pleased to hear that his Indian friends have undertaken the preparation of a work intended as a memorial of him, which will embrace an account of the extensive collections of natural history amassed during his last journeys. Mr. W. T. Blanford has just issued a preparatory list of the mammals of which specimens were obtained in Yarkand and the adjoining countries. They are referable to forty-two species, mostly belonging to groups characteristic of the elevated districts of the Palæarctic region. No new types were discovered, but amongst the novelties are species of Field-voles, Hares, and Pikas (*Lagomys*), all very distinctive of the regions traversed by the expedition, and adding largely to our knowledge of the fauna of Western Tibet and Eastern Turkestan. The larger mammals were originally better represented, but after Dr. Stoliczka's death, many specimens appear to have been removed from the collection. Of a fine series of twenty-two wild sheep from Kashgar, only eleven are now left, and not one of these has fine horns. Moreover there remain skeletons of wild sheep and ibex in the collection, of which the heads have entirely disappeared. Mr. Godwin Austen has invited public attention to these unpleasant facts in another column of this journal. One would have supposed that in the case of a naturalist thus perishing in the performance of his arduous duties, no pains could have been too great to protect the specimens in procuring which he had sacrificed his life. On the contrary, however, advantage appears to have been taken of his untimely death to rob his collection of the choicest specimens. We can only trust that, attention having been called to the fact, restitution will be made, and the missing heads and horns promptly restored to the mutilated specimens now deposited in the Imperial Museum at Calcutta.

* "List of Mammalia collected by the late Dr. Stoliczka when attached to the Embassy under Sir D. Forsyth, in Kashmir, Ladák, Eastern Turkestan, and Wakhan, with descriptions of new species." By W. T. Blanford, F.R.S., F.Z.S. (Journ. As. Soc. Bengal, vol. xliv. p. 105, *et seqq.*)

ARCHÆOLOGICAL RESEARCHES IN KENTUCKY AND INDIANA

In January last Mr. Putnam laid before the Society of Natural History of Boston, U.S., an extended account of his recent archæological researches in Kentucky and Indiana, in which he had examined several rock-shelters, caves, mounds, and circular graves. He called attention to the numerous ancient fortifications in the Ohio valley, and gave a description of two which he had visited in Indiana. These fortifications are generally earthworks, many of them of great extent; but there have been several discovered in which immense walls of stone have been used, extending in one case to several hundred feet in length, and to nearly ten feet in height; whilst in another instance a wall about seventy-five feet in height had been erected to fill a gap in the otherwise nearly precipitous natural wall. The stones of these walls were simply laid, one overlapping another, so as to break joints, without cement of any kind. Mr. Putnam exhibited to the meeting a number of human skulls and other bones found under various conditions, and pointed out that while the skulls of the New England Indians were long and narrow and belonged to the *dolichocephali*, those from the mounds, the circular graves, the stone graves, and the caves were of the short, broad and high type, or the *brachicephali*. In the caves, however, there were two, if not three, classes of burials, and at least two well-marked forms of skull. The skulls he found in graves protected with slabs of stone were all of a form very closely resembling the high, short and broad crania of the mound builders; those of the numerous skeletons from the caves were characterised by the marked depression of the frontal bone and the equally marked concavity on the anterior part of the parietals; and the skulls from the circular graves were distinguished from the others by their decided width and shortness, and the more vertical occipital portion.

A series of shin-bones was also exhibited to show the various degrees of flattening, and to confirm the opinion of Mr. Busk and others that *platycnemism* cannot be taken as an important race character.

Of a number of circular graves which formerly existed on a hill near Glasgow, one, having escaped the plough, had been carefully opened. It was a circle about four feet in diameter, and had been dug to a depth of three feet, where a floor had been formed with pieces of shale brought from a distance of about a quarter of a mile

Around the circumference were placed upright slabs of limestone three feet high, and at least ten bodies had been lodged in the grave, arranged in a sitting posture with their backs against the slabs, and the hole had then been filled up. The teeth showed that the majority were of middle age, whilst the remainder included old persons and children still retaining their milk teeth. The limestone slabs projected a few inches above the present surface of the soil, so that if the grave had ever been covered with an earth mound the latter must have been removed, perhaps washed away. The only artificial object found was one solitary potsherd; hence there is no evidence to prove or disprove any speculation which may be indulged respecting the people whose burial-ground had been thus laid open in the interest of science. It is perhaps safe to conclude that all the bodies found in the grave were placed there at one and the same time.

The Salt Cave, near the Mammoth Cave, and rivalling it in the size of some of its branches, was difficult of access, on account of loose rocks which had fallen from the roof, and of a stream of falling water running off between them. Having effected an entrance, the descent of a steep hill of loose rock led into a large gallery several miles in length, the floor of which was covered with fallen rocks. Small areas were occasionally found, however, where no such masses presented themselves, but where fires had been kindled, and where small piles of stones had been raised around a small central hole having ashes and remnants of burnt sticks at the bottom; whilst on the adjacent rocks there were in some cases found small bundles of sticks tied with bark, and of a convenient size to be placed in the holes, thus indicating that they had been brought into the cave to be used as lights and as firewood.

Further on, in a small chamber never previously visited by a white man, there were seen on the cave earth the imprints of feet shod with peculiar braided mocassins or sandals. In some of the side chambers were found a great number of cast-off sandals, very finely made of the twisted leaves of some rush braided in a careful and artistic way. The manner of braiding was identical with that of the straw sandals from China, but the form of the sandal itself was different. About twenty-five of these sandals, of various sizes and of slightly varying designs, but all worn through at toe and heel, were found in the interior chamber of the cave.

A piece of cloth more than a foot square, and finely and regularly woven, probably from the inner bark of some tree, was also found, and was especially interesting from having been dyed or coloured with black and white stripes, and from having in one place been mended by darning.

Mr. Putnam also exhibited bunches of the bark used to make the cloth, and of different degrees of fineness; a number of pieces of bark, twine, and rope, some made of twisted strands simply, whilst others were of a five-strand braid and of a more pliable substance; a small piece of quite a delicate fringe or tassel of neatly braided fibres; a number of reed "torches," generally burnt at one end; a few small fragments of burnt wood, one of them showing the rough cutting of a flint axe; several fragments of a large gourd, of a species probably not indigenous; two flint arrow-points; a few fragments of shells of the *Unio*; and a few feathers of probably the wild turkey. All the specimens of cloth, &c. from Salt Cave were extremely brittle, and had only been preserved by saturating them with gelatine and afterwards mounting between glass. No bones or other relics indicative of the food of the cave people were found, nor was there any evidence of human interment, though the earth in one of the chambers had been disturbed; the state of Mr. Putnam's health, however, prevented him from making anything like an exhaustive examination. It is encouraging to know that it is intended to continue the work until more is ascertained of the archæology of this large group of important American caves.

The discovery, in 1812-15, of bodies buried with care in some of the caves of Kentucky and Tennessee, and of the numerous articles found with them, was alluded to by Mr. Putnam, who stated that since his return from Kentucky he had examined the body, and what remained of the very large number of articles found with it, that was so widely known as the "Mammoth Cave Mummy" sixty years ago. This body, in reality found in Short Cave, had been taken to the Mammoth Cave, eight miles distant, for exhibition. The relics had been sadly neglected, and many of the articles found in the grave had been lost and others had gone to decay; still enough remained, at the rooms of the American Antiquarian Society at Worcester, to identify the articles found in Salt Cave as the same in material, design, and structure as those found with the body in Short Cave, so that he had thus secured undoubted osteological characters to go with the articles of clothing, &c., of the Salt Cave people, and he thought that we could, with little doubt, class this people among the more highly civilised and agricultural of the prehistoric races of America.

*SCIENCE IN ITALY**

JUDGING from the number of scientific papers that we are in the habit of receiving from Italy, we are glad to infer that the restoration of political unity and freedom has also brought about a revival of that intellectual vigour which we are accustomed to associate with the names of Dante and Tasso, Galileo and Torricelli. When Italy was divided, and each State politically oppressed, her best men were in exile, and their best scientific work was expressed in a foreign tongue. Research was not only not encouraged, it was practically prohibited. It seems incredible, but it is nevertheless true, that the Austrian and Bourbon Governments, in their dread of novelty, would not allow the results of modern research to be taught in the schools. The text-books reproduced the exploded science of the past, in which the modern theory of dew, for example, was ignored; so that Melloni (whose best work was done in Paris, and its results published in French journals), in making a series of observations on the nocturnal cooling of bodies in the neighbourhood of Naples, wished to show that the laws of terrestrial radiation were the same in Italy as in countries where there was more political liberty. We have it on the authority of Matteucci, that he and others, when they revisited their native land, were placed under the surveillance of the police, not from the fear of their meddling with politics, but on account of the scientific reputation which conferred distinction upon them.

Under such circumstances science could not flourish, and the time has perhaps been too short since Italy recovered her freedom to enable her to do much more than revive the glories of the past, and to seek encouragement in the example of the great men who have gone before. Hence it is that in the papers before us, points are discussed in connection with objects of Italian discovery, such as the electrophorus and the condenser, in which old names are curiously mingled with new. Thus Beccaria, Œpinus, Priestley, Volta, and Avogadro are asso-

ciated with Faraday, Tyndall, and a host of modern Italian physicists, whose names we are sorry to say are not so familiar to us. Prof. G. Cantoni's numerous papers, the titles of some of which are given in translation above refer to minute but interesting points in connection with the electrophorus and condenser, in which certain views of Beccaria (1769) and of Volta (1775) are revived and defended and connected with Faraday's theory of electrical induction and the action of the Holtz machine. The title at the head of our list refers, not to papers read before the Lombard Academy, as in the case of the last five, but to a neat little pamphlet which gives an account of forty-nine experiments, and the inference to be drawn from each one, and illustrated by a number of wood engravings representing the arrangement of the apparatus. One portion of the object of these papers is to confirm and extend Faraday's beautiful theory. Indeed, the subject, with the exception of the Holtz machine, has been so extensively investigated by Faraday, Snow Harris, and others, that we do not feel called upon to give an analysis of these ingenious papers. Among the instruments for estimating charge we miss the elegant scale beam electrometer, the hydrostatic electrometer, the electrical balance, the unit jar, and other instruments contrived by Harris and used by him with so much effect. Indeed, Harris's last work on "Frictional Electricity" (1867) seems to be unknown to the Italian physicists. In this work some of the points in question have already been considered experimentally.

Signor Nardi's first pamphlet is a curious exemplification of the dearth of original scientific research to which we refer. When men have but little of their own, they are proud of the wealth of their ancestors. We do not say this is wrong, although its expression sometimes takes an amusing form. Thus, our author, who is Director of the Royal School of Technology at Vicenza, in his visits to the museum of that town, frequently cast an admiring eye on certain cases that contained some of the apparatus of the physicist Fusinieri, who in his own day occupied a respectable position in science, and whose results, when true, have since been absorbed into the great body of science. Hence his name is not much known out of Italy; but, in his native town, his memory is naturally and very properly cherished; so that, when holding a centenary festival in honour of his birth, in February last, the good citizens of Vicenza were naturally grateful to be reminded as forcibly as possible of the genius of their hero. Our author had long regarded these relics with curiosity, until, stimulated by the prospect of this festival, he felt an ardent desire to accomplish something. He says:—"The exquisite politeness of the keepers of this museum, first, that of Monsignor Pietro Canonico Doctor Marasca, and then that of Monsignor Ludovico Canonico Gonzati, threw open to me the sanctuary [that is, they unlocked the cases]. Their encouragement imparted to me the courage to do something, which I now publish in time for the public festival, which I may emphatically term national, in honour of him who is now revered as one of the most eminent physicists of this age."

Guided by the published collected works of Fusinieri, our author examines every article and fragment of the imperfect collection thus thrown open to his inspection. No devotee before the shrine of a saint could display more ardour. If successful in tracing a bit of apparatus to its original use, he is in ecstasy; if unsuccessful, in despair. He has no misgivings as to the originality of his hero, or as to his absolute superiority in all the varied controversies in which he was engaged. Perhaps the most memorable of these (and to which the second pamphlet above cited is devoted) is on some of those obscure catalytic phenomena in which chemical combination is effected by means of certain solids which themselves escape apparently unchanged. Signor Nardi claims for Fusinieri the merit of having refuted Faraday's theory on this point, and of establishing the true theory on a sound basis. And what is this theory? It is, that "platina determines upon its surface a continual renovation of *concrete laminæ* of the combustible substance of the gases or vapours, which, flowing over it, are burnt, pass away, and are renewed: this combustion at the surface raises and sustains the temperature of the metal." Faraday, in his sixth series of "Electrical Researches" (Nov. 1833), in referring to this theory and its author, says:—"I cannot form a distinct idea of the power to which he refers the phenomena." Certainly the revived discussion of the theory has not tended to throw more light upon it.

Considering the wide range of subjects that occupied Fusinieri's attention from the date of his first publication in 1819 to that of his latest in 1850, we must speak in the highest terms of his industry. His works, collected into three large volumes, contain memoirs on Geometry, the Mechanical Sciences, the Electrical Sciences, Terrestrial Magnetism, Optics, Heat, Meteorology, Astronomy, Chemistry, and Molecular Mechanics. But it is surprising how little influence all this labour had on science in general. We seldom meet with Fusinieri's name out of Italy; and the reason is, not that science is unjust, but that she is stern, and requires discovery to be both new and true, before she welcomes the discoverer. Now it must be confessed that Fusinieri is not original. In his best work there is always something reflected from a greater mind than his own. One of his most striking experiments is to show the repulsive force of heat, for which purpose two slightly convex surfaces of glass are screwed together, so as to exhibit Newton's rings, and heat being applied, the rings contract, and the central tint descends in the scale, until the whole vanishes. But in so capital a result as this we are reminded of Fresnel, while the actual experiment was performed by Baden Powell two years before the date of Fusinieri's paper. Fresnel dates from 1825, Powell 1835, Fusinieri 1837; and yet Signor Nardi attaches an inscription to the lenses in the museum to the indefinite effect that "Long before 1837, Fusinieri made with these and other glasses the discovery of the repulsion of heated bodies." In like manner Fusinieri has a long series of researches on the cause of the colour in metals exposed to heat, while Davy decided by a single experiment that it is due to oxidation. He inclosed a bright surface of steel in an atmosphere of nitrogen, heated it, and there was no colour; he raised it to the same temperature in air, and colour was immediately produced. Fusinieri's theories may be more original than his facts, but then they are not accepted. His best known theory is perhaps that which confers a material body on electricity, because it is capable of conveying matter from place to place, and varying its properties with the kind of matter conveyed and acted on. Nor is his theory of dew, in opposition to that of Wells, more favourably received. Our author laments that Wells's theory is the result of a series of illusions, which has seduced many, and he regrets that the latest sad example of this leading astray is in the case of one John Tyndall, who is so infatuated as to believe in Wells; and yet this theory which was so clamorously received and crowned by the Royal Society depends merely on a spider's thread!

Much of the science of Fusinieri arose out of the questions of the day, and it is to his credit, considering the difficulties of his position, that he endeavoured to keep pace with the scientific mind of his time. He is, however, eminently controversial, disputing whenever opportunity offered, and persisting in his views, even though all, his fellow-countrymen included, are against him, his last opponent being Melloni. He is also very sanguine, and fancies he has solved great and difficult questions, should a single experiment turn out satisfactorily to himself. Thus, when by the action of light on an acid solution of ferrocyanide of potassium he obtained

Prussian blue, he fancied he had settled the grand and difficult problems connected with the colouring matter of leaves. While the isolated position of Fusinieri, and the want of contact with better scientific minds than his own, will account for this, we must not forget that the abject political condition of the land and the narrow jealousy of its multiplied rulers made it difficult for a man to work intellectually or to teach properly, so that we may well express our admiration that one so hampered has achieved so much, and set so good an example to his more fortunate countrymen. May their scientific efforts prosper ! C. T.

SCIENCE IN GERMANY

(*From a German Correspondent*)

HERR W. SIEMENS has recently made the following interesting communication to the Academy of Sciences of Berlin :—

It has been shown by Willoughby Smith and by Sale that crystalline selenium conducts electricity better when illuminated than when in darkness. The specific conductivity, however, of selenium rendered crystalline by heating from 100° to 150° C. is very small and extremely variable; and also the increase of the conductivity through illumination is very inconstant, so that it is impossible to establish a determinate dependence of the conductivity on the illumination.

Herr Siemens has succeeded, by continuous heating of amorphous selenium to a temperature of 210°, as also by cooling of melted selenium to 210° (at which temperature, long continued, the selenium passes into a coarse-grained crystalline state), in producing another modification of the crystalline selenium, which has considerably greater conductivity, and retains it, and conducts electricity metallically, so that with increase of temperature the conductivity decreases. The action of light on this modification of crystalline selenium is much greater, and apparently quite constant. By fusing in two flat spirals of wire, about 1 millimetre apart, between two leaves of mica in coarsely crystalline selenium, he has obtained an exceedingly sensitive measure of light. Dark heat rays are *without direct influence* on the conductivity, and heating of the selenium, as already mentioned, *diminishes* the same. Diffuse daylight even doubles the conductivity of this light-measure, and direct sunlight increases it sometimes *more than tenfold*. The increase of conductivity of the coarse-grained selenium through illumination takes place very quickly. And similarly, the diminution of it, on shutting off the light, occurs, apparently, at once; but a longer time is required before the state corresponding to darkness is again fully established. The increase of the conductivity is not proportional to the light intensity, but a function of it, which comes near the proportion of the square root of the light intensities.

Herr Siemens hopes this interesting property of selenium may be utilised for construction of a reliable photometer. W.

NOTES

EVERY one will hear with genuine regret of the proposed resignation by Prof. Max Müller of the Chair of Comparative Philology in Oxford University. He has resolved to take this step on the ground that he begins to feel the need of rest, and that he wishes to be able to devote all his attention to the ancient language and literature of India. He has just finished, he says, the work of his life, the *Editio Princeps* of the text and commentary of the oldest of the sacred books of the Brahmans, the oldest of the Aryan world. It was this which first brought him to England in 1846, and it was in order to be able to stay in England that he accepted the duties of professor. Dr. Müller was appointed to the Chair of Natural Philology in 1868, in which year it was founded and endowed. "I have," he justly states, "satisfaction that I leave the new science of language, to which my work as Professor has been mainly devoted, firmly established in the system of academic studies, and that the University will find among my pupils several quite able to fill my place." It will not be an easy matter, we fear, to find a worthy successor.

THERE has just been placed in Westminster Abbey a marble scroll bearing an appropriate inscription to the memory of Jeremiah Horrocks. The movement for such a memorial was commenced some time ago, and is referred to in NATURE, vol. x. p. 190, and xi. p. 31. The scroll is affixed to the pedestal of the monument of John Conduitt, nephew of Sir Isaac Newton, which is situated at the extreme west end of the north side of the nave, and exactly opposite that of Newton, at the extreme east end. The inscription is as follows :—

In Memory of
JEREMIAH HORROCKS,
Curate of Hoole, in Lancashire,
Who died on the 3d of January, 1641, in or near his 22d year ;
Having in so short a life
Detected the long inequality in the mean motion of Jupiter and Saturn ;
Discovered the orbit of the Moon to be an ellipse ;
Determined the motion of the lunar apse ;
Suggested the physical cause of its revolution ;
And predicted from his own observations the Transit of Venus,
Which was seen by himself and his friend William Crabtree
On Sunday the 24th of November (O.S.) 1639 :
This Tablet, facing the Monument of Newton,
Was raised after the lapse of more than two centuries, December 9, 1874.

The friends of Horrocks are indebted for the inscription to the joint labour of the Dean of Westminster and Prof H. J. S. Smith. It is a simple act of justice to state that the idea of this tablet was suggested by two ladies, Mrs. Orme and Mrs. Patmore, and that upon the latter has fallen the burden and heat of the day so far as the correspondence with subscribers is concerned.

M. LE VERRIER, as President of the Scientific Association of France, has received the handsome sum of 2,300 francs from M. P. Bischoffsheim to meet the balance of the expense incurred during the important and refined experiments conducted by M. Cornu, towards determining with great precision the velocity of light, an expense which otherwise must have been borne by the eminent savant who directed the experiments.

CONSIDERABLE dissatisfaction is felt among the Fellows of the Linnean Society at the delay in the publication of the zoological papers communicated to it. The zoological paper last published in the Journal is dated Dec. 17, 1874, and that in the Transactions, Nov. 19, 1874. It is said that there are at least a dozen awaiting publication, and the number is likely to be increased. There is reason to fear that no zoological paper communicated during the present year will appear before the end of it.

A REPORT is widely circulating in Oxford University to the effect that Lord Salisbury, its Chancellor, is endeavouring to obtain the issue of a Commission for inquiring into the question of University Reform. Another form of the report is that the Commission will have an executive character. A third rumour names Mr. Gladstone as one of the Commissioners. But nothing certain is known upon the subject at Oxford.

THE January number of the *Practitioner* will contain a memoir of the late Dr. Francis E. Anstie, by Dr. Buzzard, with a portrait engraved on steel. This number will also contain some of Dr. Anstie's unpublished researches on alcohol.

DR. BURDON SANDERSON announces that the first of his annual course of Lectures on Comparative Pathology will be given at the University of London, on Wednesday next, Dec. 15. Subject—The Pathology of Inflammation.

We are glad to see that the movement for organising a University College of Science and Literature in Bristol is so far advanced that a meeting of the subscribers will be held in Bristol on Saturday next, to authorise the committee to take the necessary steps to incorporate the College. In a telling article in Monday's *Western Daily Press* the need of such an educational institution in Bristol, as well as in all our other industrial centres, is forcibly shown. The increasing importance of scientific knowledge even in our most trivial manufactures is well pointed out; only by thoroughly training the rising generation can we hope to compete successfully with foreign manufacturers. It is a hopeful sign to find the subject taken up by the newspaper press in the spirit which animates the article referred to.

The Vivisection Commissioners, having now received the evidence of a large number of witnesses, will not meet again for some weeks. They will then assemble to examine a few more witnesses, after which it is announced they will at once proceed to consider their report.

The French Society of Aërial Navigation held its anniversary meeting on the 3rd December, under the presidency of M. Paul Bert. M. Bert delivered, before a full audience, an address reviewing all the scientific ascents executed during the year. The Society, after hearing a lecture by M. Tissandier, illustrated with dissolving views, awarded him a prize. A similar reward was given to the President of the London Aëronautical Society.

The Cambridge Board of Natural Sciences Studies report that the period of three years for which the University agreed to pay 100*l.* a year towards the expenses of Dr. Dohrn's Zoological Station at Naples will expire next year, and they have had under consideration the expediency of recommending a continuance of the grant. For the sum of 100*l.* the University has hitherto had the exceptional privilege of occupying two of the large working tables. Dr. Dohrn is unable to continue the offer of accommodation on the same terms, but offers one or two tables of 75*l.* per table. The Board, considering the claims upon the Worts' Travelling Bachelors' Fund, do not think it right to charge that fund with two tables at the increased price; and, therefore, recommend that one table be retained by the University for five years at the rate of 75*l.* per annum. The Board have reason to believe that very valuable work has been done by nominees of the University at the station, and the Cambridge Museum enriched by important specimens procured from it. Mr. T. W. Bridge, scholar of Trinity, and Mr. J. F. Bullar, of Trinity, have been nominated by the Board of Natural Sciences Studies to study at the Zoological Station, Naples, until July 1876.

There will be an examination at Christ's College, Cambridge, for scholarships and Exhibitions in Natural Science on April 4, 1876. The examination will be open to any one, and there is no restriction as to age. This examination will be held at the same time as similar ones in connection with Sidney Sussex and Emmanuel Colleges, the candidates of either of these colleges being eligible at the other two in default of properly qualified candidates at these colleges.

Dr. Gustavus Hinrichs has written in the *Popular Science Monthly* an interesting account of one of the most remarkable meteors of recent times, which lighted up the entire State of Iowa and neighbouring parts of the States of Missouri, Illinois, Wisconsin, and Minnesota, at 10.20 P.M., on Friday, Feb. 12, 1875. This meteor is stated to have become visible at a height of about 150 miles above Pleasantville, Iowa, to have descended at an angle of about 45°, its course being at first a little to E. of N., but deviating gradually more and more to E. in a curved line. It divided into two in passing over the N.W. township of Keokuk country, and finally exploded at a height of ten miles over a point three miles S.W. of Norway, one of the stations on the Chicago and North-Western Railway. It was the smaller portion of the meteor which produced the meteorite shower in Iowa and Amana townships of Iowa County. Two dollars a pound being given for all meteors collected, a large number have been gathered together varying in weight from 75 lbs. to 2 oz., and amounting in all to upwards of 500 lbs. A woodcut is given, showing nine of the fragments, drawn to one-seventh of their natural size, and a small map with the positions in which the meteors have been found. A map, defining the course of the meteor from all the observations made would have been a useful addition to the paper.

The *Meteorological Bulletin* of the Pyrénées-Orientales for the year 1874, published under the auspices of the department and the town of Perpignan, contains the following:—(1) *Résumé* of the daily observations referring to agricultural meteorology and the state of vegetation collected at Collioure during 1873–74. by M. Ch. Naudin, Member of the Academy of Sciences; (2) Returns of the state of the crops in Roussillon during the same time, by M. Labau, Director of the school-farm of Germainville; (3) Notice of the thunderstorms observed in the department of the Pyrénées-Orientales, by M. Tastu, Chief Engineer; (4) Tables of the rainfall measured at the different stations of the department during each month of the year, with a sketch of the specialities of the rainfall of last year, by Dr. Fines; and (5) Meteorological observations made at fifteen stations in the department. The close union now being drawn in France between meteorology on the one hand, and agriculture and horticulture on the other, as evinced by the Annual Report of the Meteorological Commission of the Pyrénées-Orientales, as well as by the subjects brought under special consideration at the Meteorological Congress of Poitiers, speaks well for the future of French meteorology.

The *Agricultural Students' Gazette* is a small quarterly publication, evidently issued under the auspices of the authorities of the Royal Agricultural College at Cirencester, and which is professedly edited by students of that Institution. Such a publication ought to be eminently useful. It should aid in promoting an enlightened system of agricultural education, which is one of the great wants of the age. If well conducted, the journal cannot fail to assist in making known the merits of the College and of kindred institutions. It does not rival any existing periodical. While edited by students, the chief articles are contributed by professors. To No. 3 Prof. Church contributes a valuable paper on the flesh-forming matter of root-crops. Among the other contributions we would refer to a short but interesting paper from the pen of Prof. McNab, on mould, and another on sewage farming, written by one of the students, Mr. John D. Custance. Prof. Wrightson contributes a paper on the improvement of poor clay pastures, which has evidently been carelessly if not thoughtlessly put together. This periodical merits our best wishes. We see no reason why it should not in due time occupy a leading place among our scientific agricultural journals.

Prof. Kerner, of Innsbrück, has published an interesting pamphlet on the Hybrid Primulaceæ of the Alps. Of these he enumerates no less than twenty-five belonging to the genus *Primula*, four to *Androsace*, and two to *Soldanella*; some of which have been treated as independent species, as that between *P. subacaulis* and *officinalis* under the name *P. brevistyla*, DC., and that between *P. superauricula* and *hirsuta* under that of *P. pubescens*, Jacq. By far the majority (twenty) of the *Primula*-hybrids belong to a single section, *Auriculastrum*, the remainder to *Primulastrum*. Of "derivative-hybrids"—that is, those resulting from the crossing of a hybrid with one of its parent-forms—he knows only one or two certain instances. In two separate reprints, "Floristische Notizen" and "Ueber einige Pflanzen der Venetianer Alpen," Prof. Kerner describes several new plants of the Southern Alps.

ON November 1 a Stenographic Exhibition was opened in a room of the Pedagogic Museum of the College, Rome. Stenography at the present day occupies a very important part in the requirements of public life, and we believe the effort to encourage its study by a public exhibition will lead to useful results. On the walls of the room were a list of the Italian towns that had a school or society for stenography. The only method followed is that of Gabelsberg-Noe. On a table in the centre of the room were stenographic attempts of every kind, from large plates for elementary study to the smallest and most minute works. In one case. Dante's "Divine Comedy" was copied out into a book of Lilliputian dimensions. On a post-card one stenographer had written 3,660 words. The committee who arranged the exhibition wish to reproduce on the historical wax tablet the stenographic marks with which Tiro wrote the speeches of Cicero.

ON November 2 took place the opening ceremony of the scholastic year of the University of Rome. Prof. Scalzi read a critico-historical exposition of a collection of surgical apparatus belonging to lithotomists and oculists of the sixteenth and eighteenth centuries, which he found among families of the province of Umbria. Prof. Scalzi gave some very interesting details, showing that these instruments were invented in Italy, and not by foreigners, as has been supposed. He showed also that the study of the original instruments was of great interest in connection with the history of the progress of the surgical art. On two tables were arranged eighty instruments which had belonged to surgeons of Novicia and Delle Preci in Umbria. Many of these instruments, it was interesting to observe, resembled those found at Pompeii and others found at Ravenna.

A REPORT by Mr. Frank Buckland, on the fisheries of Norfolk, recently issued, states as a remarkable fact that large numbers of sea trout are annually caught off the coasts of that county, though the rivers which flow through it are naturally incapable of producing *Salmonidæ*. The fish thus caught are visitors from the salmon rivers in the north, viz., the Tyne, the Tees, the Coquet, and the Tweed. The object of this visit to the coasts of Norfolk and Suffolk is to find food, which exists in abundance in the shape of the spawn and fry of the many varieties of fish which abound in those waters. The report contains much interesting matter relative to the crab, lobster, and other sea-coast fisheries, and to the fisheries in the fresh-waters of Norfolk and Suffolk.

THE *Comptes Rendus* for October 4 last contains a paper on the interpretation of the sphygmograph trace, by M. Bouillaud. The author gives reasons, which we think peculiarly unsatisfactory, in favour of the sphygmograph trace—a curve now fairly understood—supporting an assumption of his that each cardiac revolution consists of two periods of action and two of repose, instead of one systole and its associated secondary consequences.

OUR readers will find, in the current number of the *Ibis* a short account of the late veteran Swedish ornithologist, Carl J. Sundevall, whose excellent investigations, especially with reference to the Passerine birds, have done much towards the development of sound classificational principles.

WE would direct the special attention of our zoological and geological readers to a paper by Prof. Owen in the current number of the *Quarterly Journal of the Geological Society*, on a fossil Sirenian animal from Jamaica, previously described by him, and named *Prorastomus sirenoïdes*. In this animal the premaxilla of each side gives indications of having supported three not large teeth, at the same time that there were eight teeth of the molar series above and below, on each side. The species was considerably smaller than the Manatee; the skull and atlas vertebra are the only parts known; in conjunction with *Felsinotherium forrestii* it fills an important gap in our knowledge of the pedigree of the Sirenia.

THE *Geographical Magazine* for December contains a paper of great value on the Amú Darya region, by N. P. Barbot de Maruz, who in the summer of 1874 made a journey from Fort Alexandrovski, in the Caspian, to the foot of the Thian-shan. He describes the principal geological features observed along the route, and promises a full report of his researches when he has been able to arrange his abundant materials. Another paper, by Mr. Ravenstein, describes Mr. Stanley's recent discoveries, and is illustrated by two good maps, one of the Victoria Nyanza, principally according to Mr. Stanley, and another of the regions of the Upper Nile, embodying the results of the explorations of Burton, Speke, Grant, Stanley, Baker, Long, and others.

PARTS 10, 11, and 12 (in one), of the well-conducted Italian geographical journal, *Cosmos*, are to hand. The following are the principal papers :—A letter from F. Giordano, giving some account of the condition of New Guinea, in reference to a proposal to make use of some part of it as an Italian penal settlement. Another letter, from Dr. Beccari, describes some results of his investigations into Papuan ethnology. The first of a series of papers on Arctic Geography gives the results of recent Arctic exploration in the Baffin's Bay and Spitzbergen directions.

WE learn from the *American Naturalist* that State Associations of Archæology have been formed in Indiana and Tennessee, similar to that already existing in the State of Ohio. Their field of work is most extensive and important.

ON Thursday, November 26, at 6.35 P.M., an earthquake shock was distinctly felt at Lyons. The commotion, which travelled northwards, lasted from fifteen to twenty seconds.

A SHOCK of earthquake was felt at Naples on Dec. 6, and also throughout the provinces of the Basilicata, Terra di Lavoro, and Salerno.

THE additions to the Zoological Society's Gardens during the past week include a male Prince Alfred's Deer (*Cervus alfredi*), born in the Gardens; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. C. F. Wood; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Miss Kate Symonds; two Alligators (*Alligator mississippiensis*) from North America, deposited; twenty-nine Basse (*Labrax lupus*); a Grey Mullet (*Mugil capito*), and six Cottus (*Cottus bubalis*) from home seas, purchased.

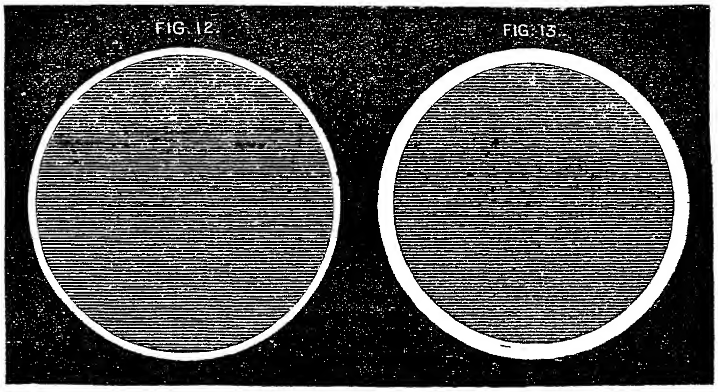
THE DIFFERENCE OF THERMAL ENERGY TRANSMITTED TO THE EARTH BY RADIATION FROM DIFFERENT PARTS OF THE SOLAR SURFACE

THE observations relating to the temperature of the polar regions, referred to in the article (vol. xii. p. 517), at first led to the supposition that the rays projected from the north pole of the sun transmit a perceptibly greater energy to the actinometers than the rays from the opposite pole. Subsequent observations having positively established the fact that the polar and equatorial zones transmit equal intensities, it became evident that some other cause than difference of temperature within the polar regions influenced the actinometers. The only valid reason that could be assigned in explanation of the anomaly being the considerable angle subtended, and the consequent difference of zenith distance of the opposite poles of the sun, my table of maximum solar intensity for given zenith distances (prepared from data collected during a series of years) was consulted, in order to ascertain the influence of zenith distance. The observations indicating a higher temperature at the north pole, it should be mentioned, had been made while the sun's zenith distance ranged between 32° and 33° at noon. Now the table referred to shows that there is a difference of radiant intensity of $63°{\cdot}63 - 63°{\cdot}40 = 0°{\cdot}23$ F. between the stated zenith distances. The mean angle subtended by the sun being fully thirty-two minutes,

it will thus be seen that, owing to the absorptive power of the terrestrial atmosphere, the radiant intensities transmitted from the opposite poles of the luminary differ considerably. The magnitude of this difference, adequate to explain the discrepancy under consideration, need not excite surprise if we consider that thirty-two minutes of zenith distance involves an additional depth of more than half a mile of atmosphere to be penetrated by the rays projected towards the actinometer from the *south* pole of the sun. The foregoing facts show the necessity of taking the difference of zenith distance between the opposite poles into account in making exact observations of the sun's polar temperature, especially at the lower altitudes where the secant of the zenith distance increases rapidly.

Regarding the calorific energy of the radiation emanating from the border of the sun, I deem it proper to present the following brief statement. Several observations during the early part of the investigation pointed to the fact that increased energy is transmitted to the actinometers by radiation from the sun's border. Again, considerable irregularity was observed in the progressive diminution of the force of radiation towards the circumference of the solar disc. It was shown in the preceding article (vol. xii. p. 520) that the radiation from the border zone, 1′ 42″ wide, occupying one-fifth of the area of the solar disc, transmits 0·638 of the intensity transmitted from an equal area at the centre of the disc. Of course it will be supposed that the rate of the diminution of intensity within the zone thus ascertained is much greater near the border of the photosphere than at the middle of the zone. Such, however, is by no means the case, notwithstanding the assumption of phycisists that the heat transmitted by radiation from the border is very feeble. In order to test the truth of the indications referred to showing considerable radiant energy at the border of the photosphere, a very careful investigation was made, Sept. 9, 1875, by means of screens excluding the rays from the solar disc, as shown in Figs. 12 and 13. The diameter of the screen represented in Fig. 12 being 154·06 millimetres, covered nine-tenths of the area of the disc; while the screen shown in Fig. 13, being 145·25 millimetres, covered four-fifths of the disc. It will be well to mention that the dimensions of the screens referred to correspond with the angle subtended by the sun when the earth is in aphelion. Accordingly the distance between the actinometers and the screens was adjusted previous to the observation, viz. shortened, in order to compensate for the increase of the angle subtended by the sun. Agreeable to the stated dimensions of the screens, it will be found that the zone represented in Fig. 13 is 1′ 42″, while the zone in Fig. 12 is 49″·6. The mean width of the latter is consequently situated only 24″·3 from the border of the photosphere.

The following table shows the intensities transmitted to the actinometers from the zones represented in Figs. 12 and 13:—

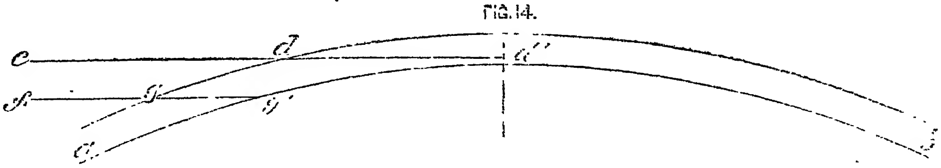


Time	Zone Fig 13. Cent.	Zone, Fig. 12. Cent.	Rate of difference
4′	2°·011	1°·333	$\frac{1·333}{2·011} = 0·662$
5′	2°·248	1°·471	$\frac{1·471}{2·248} = 0·654$
6′	2°·425	1°·583	$\frac{1·583}{2·425} = 0·652$
7′	2°·485	1°·666	$\frac{1·666}{2·485} = 0·670$
			Mean = 0·660

The rate of difference inserted in the last column, it will be noticed, is not quite so consistent as in the table contained in the previous article recording the observations made Aug. 25. The discrepancy is, however, not material, the difference between the lowest and the mean rate being 0·008. It will be seen on inspecting the registered intensities, that the border zone represented in Fig. 12, whose area is only one-half of the area of the zone in Fig. 13, transmits 0·660 of the intensity of the latter. This at first sight indicates an extremely disproportionate transmission of heat from the narrow border zone; but it should be considered that the inflected radiation imparts relatively more heat to the actinometer exposed to the radiation from the narrow zone than from the wide zone. It will be readily understood that since the inflection of the calorific rays is 14″·7 (see preceding article, page 519), the first-mentioned actinometer receives radiant heat from 14″·7 + 49″·6 = 64″·3; while the actinometer exposed to the radiation from the wide zone receives heat from 1′ 42″ + 14″·7 = 116″·7. Consequently, the radiant heat emanating from the narrow zone will be $\frac{64''·3}{116''·7} =$ 0·551 of that transmitted from the wide zone, hence somewhat more than one-half. Our investigation therefore proves that the radiant heat transmitted from the narrow border zone represented in Fig. 12 is 0·660 − 0·551 = 0·109 more intense than that transmitted from the zone represented in Fig. 13, although the mean distance of the latter is twice as far from the border of the photosphere as the mean distance of the former. The singular fact thus revealed can only be accounted for by supposing that internal radiation is not incompatible with the constitution of the photosphere, and by adopting Lockyer's views expressed in the Senate House at Cambridge, 1871, that "the photosphere must be a something suspended in the solar atmosphere." Let *a b*, Fig. 14, represent a section of the "suspended" photosphere, and *d c*, *g f*, rays projected towards the earth. Agreeable to the conditions mentioned, and in view of the fact that the force of radiation from incandescent gases presenting equal areas, varies nearly as their depth, we are warranted in concluding that since the depth *d d′* is greater than *g g′*, the radiant heat transmitted from the photosphere by the ray *d c* will be greater than that transmitted by the ray *g f*. It should be observed that the energy transmitted towards the earth by *d c* suffers a greater diminution than the energy transmitted by *g f* in consequence of the greater depth of the solar atmosphere penetrated. Hence the augmented energy established by our investigation, does not show the full amount of the increase of radiant heat transmitted from the border of the sun.

J. ERICSSON

FIG. 14.



THE GRAPHIC METHOD OF REPRESENTING MUSICAL INTERVALS *

THE object of the paper was to explain a method of representing musical intervals, which was very useful in giving a clear idea to the mind of relations often complex and obscure.

The author pointed out that there was a natural tendency to refer the positions of musical notes to positions in space. It was by no means clear that there was any real physical or physiological relation between the two things, but somehow or other the idea had become so firmly rooted in the mind that it had developed itself in expressions of every-day use. For example, it was customary to call a note with rapid vibrations a *high* note, and one with slow vibrations a *low* note. Few people considered whether there was any natural justification for these terms; probably there was none, but they had existed almost ever since music had taken a definite form, and had given rise to the form of notation employed to express the positions of musical sounds.

It followed from this that the musical idea of distance between two notes, which was technically called a musical interval, might be considered as having an analogy between the high and low positions of the two notes respectively, a greater interval being represented by a greater space, and *vice versâ*; and carrying this idea out to its full extent it became possible to represent musical intervals to the eye in such a way as to convey ideas of comparative magnitude precisely analogous to the impressions which these intervals would make on the ear. This the author called the *graphic* method of representing intervals.

The idea of such a method had been embodied from early times in the word *scale*, which was derived from the Latin *scala*, a ladder, thereby clearly implying an analogy between the spaces of the steps and the intervals of the notes. Mr. Hullah, in some of his elementary books, had actually made use of a diagram of a ladder for this purpose, and he had introduced the improvement of representing the intervals between the third and fourth and between the seventh and eighth steps (of the diatonic major scale) as only half the length of the other degrees, thereby embodying, in a graphic mode, the distinction in magnitude between the whole tones and the semitones. What the author proposed to do in this paper was merely to establish this mode on definite principles, and to give it more capability and more accuracy.

It was well known that the scientific definition of a musical interval was expressed by the ratio which the vibration-number of the higher sound bore to that of the lower one, and it had been shown that the idea of the magnitude of the interval in a musical sense might be expressed by the logarithm of this ratio. Hence, by plotting down this logarithm with a scale of equal parts, and drawing a line of that length, such a line would be a correct graphic representation of the magnitude of the interval.

The author explained the mode of doing this in a simple practical way, which might be put in practice by anyone, with the aid of a small table of logarithms, as easily as working a simple sum in arithmetic; and he calculated and laid down several examples in the presence of the audience. It would be, he said, sufficiently accurate to express the distances in three places of figures, as, for example:—

The interval of an octave would be expressed by a line whose length was—

$= \log. 2$ ... ... $= 301$
That of a major—
Sixth $= \log. \frac{5}{3}$ ... ... $= 222$
That of a minor—
Sixth $= \log. \frac{8}{5}$ ... ... $= 204$
That of a fifth—
$= \log. \frac{3}{2}$ ... ... $= 176$
That of a fourth—
$= \log. \frac{4}{3}$ ... ... $= 125$
That of a major—
Third $= \log. \frac{5}{4}$ ... ... $= 97$
That of a minor—
Third $= \log. \frac{6}{5}$ ... ... $= 79$

And so on for any others.

It would be seen how truly these numbers corresponded to the ideas of the intervals existing in musical practice, for, according to the usual musical rules—

Fifth + Fourth ... ... = Octave.
Major Sixth + Minor Third... ... = Octave.
Minor Sixth + Major Third... ... = Octave.
Major Third + Minor Third... ... = Fifth.
Fourth + Minor Third ... ... = Minor Sixth.
And so on.

The author then, as a more extended illustration of the principle, showed the process of determination of the exact positions of the various notes of the modern musical scale, including all the accidental sharps and flats necessary for chromatic purposes and for modulation; and he proceeded to draw the same on a large diagram, making the octave 3 feet long. This enabled the audience to appreciate clearly many delicate points of intonation, which were difficult to be conveyed to the mind by any process of verbal description, and which the author explained and commented on in their theoretical and practical bearings. He also drew a corresponding scale on the plan of equal temperament, and pointed out the more important differences between this and the true scale, concluding with some remarks on the subject of intonation generally.

* Abstract of a paper read by W. Pole, F.R.S., Mus. Doc., Oxon., at the second meeting of the Musical Association for the Advancement of the Art and Science of Music on Dec. 6, at the Beethoven Rooms, Harley Street, Mr. Bosanquet in the chair.

THE SWEDISH ARCTIC EXPEDITION

THE following extracts are taken from a letter addressed to Mr. Oscar Dickson, of Gothenburg by Dr. F. R. Kjellman, who (and not his brother Dr. Theél Kjellman, as was stated by mistake in NATURE, vol. xiii. p. 75) was in command of the *Pröven*, the vessel of the Swedish Arctic Expedition during the return voyage from the mouth of the Jenesei to Norway. The *Pröven* left the mouth of the Jenesei on the 19th August, fell in with ice on the 23rd in 75° 22′ N. lat. and 66° 30′ E. long. from Greenwich; sailed along the edge of the ice until, a little south of Cape Middendorff, it was found to connect itself with the land so as to bar all passage northwards. The *Pröven* then turned south and was carried by a current twelve miles south of Matotschkin Scharr.

"Before going farther I may perhaps be permitted to make some remarks on the higher vertebrate animals which we found to inhabit or visit the Kara Sea. The walrus occurs here plentifully, and has of late years been the object of exterminating pursuit on the part of the Norwegians. At many places on the Samoyede peninsula and White Island we saw great herds of these beautiful animals. The Kara Sea has three species of seals, *Phoca barbata*, *hispida*, and *Grœnlandica*. The last-named was that which we saw most frequently and in greatest numbers. Off Obi and Jenesei white fish (? dolphins) were very common, and on the east coast of Novaya Zemlya we saw a large fin-whale (*fenhval*). If I add that one day, as we lay becalmed between Udde Bay and Matotschkin Scharr, an ice-bear quite unexpectedly came swimming out to our vessel, where he, of course, soon met his death, I have named all the mammalia we saw during our navigation of the Kara Sea. The bird world was exceedingly poor. I may almost say that it was a great rarity to see a tern or a mew. The alka (*Uria Brünnichii*), which occurs in such immense numbers on the west coast of Novaya Zemlya, is believed to be absent on the east coast. We saw here only one, and it appeared to have gone astray. Only some few species of fish were observed."

The *Pröven* passed through Matotschkin Scharr on the 10th and 11th September, arriving at Hammerfest on the 26th of the same month, and at Tromsö on the 3rd October. Dr. Kjellman sums up the scientific results of the expedition as follows:—

"We botanists have endeavoured not only to ascertain what species of plants Novaya Zemlya possesses, but also to get an insight into the varying distribution of the different species, the nature of the vegetation at different localities, in different latitudes, at varying heights above the sea, at varying distances from the seashore, &c. We have made a great number of such observations, and thereby will, I believe, be in a position to give such an account of the vegetation of Novaya Zemlya as will satisfy the requirements of science. Of flowering plants we have rich collections from Matotschkin Scharr, from many places on the west coast of Southern Novaya Zemlya, from Waigats Island and the mainland lying opposite to it, from the Samoyede peninsula and the region lying round Dickson's Harbour, and these collections contain a considerable number of species new to those localities. The phanerogamic vegetation of Novaya Zemlya has a strong resemblance to that of Spitzbergen, but at the same time, as might be expected from

its position, has a more southern stamp. This appears partly by Novaya Zemlya being much richer in species than Spitzbergen, of which species several occur which belong to families not represented on Spitzbergen, and partly by the vegetation of Novaya Zemlya being richer in individuals. At many places, especially in the more southerly parts of the land and the interior of the fiords, the ground is covered with thickly-matted plants, to which there is nowhere on Spitzbergen anything corresponding. Their closeness and variety of colour often awoke our surprise and astonishment. The phanerogamic vegetation of Novaya Zemlya connects itself by means of common species not only with that of Spitzbergen, but also with the floras of Arctic America and northern Norway, and that of the shores of the Gulf of Bothnia and the Asiatic Continent.

"The more southern character exhibited by the phanerogamic vegetation of Novaya Zemlya, as compared with that of Spitzbergen, is as good as absent in its marine algæ. The same dissimilarity is also apparent with regard to the fauna. The land fauna is more southern, the marine fauna is high Arctic. The most of the marine algæ known to exist at Spitzbergen are found at Novaya Zemlya, and of the species collected here there is only one that is wanting on the coasts of Spitzbergen.

"Of fresh-water algæ, mosses, and lichens, we have made considerable collections. Of mushrooms, on the contrary, we obtained very few. Either it was a bad mushroom year on Novaya Zemlya, or else, what is less probable, this class of plants is very sparingly distributed on these islands.

"As on the coasts of Greenland and Spitzbergen, so in the parts of the Polar Sea we now visited, the surface of the sea at certain places which appear to be sharply defined is quite full of diatomaceæ. A belt of special richness we found on the north coast of Norway, extending in an easterly direction from North Cape to the mouth of Tana Fiord; another, less rich and of less extent, we found in the neighbourhood of the Samoyede peninsula.

"Through the researches of Th. von Heuglin, we have already a good knowledge of the vertebrates of Novaya Zemlya. The attention of our zoologists has, however, been directed to this group of animals, and by their observations our knowledge of them has been very considerably extended. This specially holds good of the birds.

"Along the whole west coast south of Matotschkin Scharr, as well in the open sea as in the fiords and sound where we sailed through and lay at anchor, dredging has been assiduously carried on. The rich collections thus made will certainly, when they are examined, afford a very complete idea of animal life in this region. Few species of animals were previously known as existing here, and as to the distribution of the different species along that extensive coast all information has hitherto been wanting.

"Among the zoological work a conspicuous, place is occupied by a rich insect collection by which the knowledge that we previously had of Novaya Zemlya's insect world will be very considerably extended. Formerly from this region only four or five species of insects were known. The expedition's collection consists of about 500 specimens, and includes numerous representatives of nearly all the orders of insects.

"Most important, however, in a zoological aspect, appear to me the numerous dredgings which were carried on in the Kara Sea, and which prove that in this sea there is, as has been already mentioned, abundant animal life of very various types. The collections made here are large, and must be specially valuable for zoological science as coming from a considerable region of the Polar Sea, of which the zoology is little known, but especially because this extent of sea exhibits in different tracts so considerable dissimilarities with respect to depth, content of salt in the water, &c."

BOTANICAL NOTES

THE CALCUTTA BOTANICAL GARDENS.—Dr. King's report on the Royal Botanical Gardens, Calcutta, for the year ending March 31, 1875, to which we have recently referred (vol. xii. p. 541), contains some interesting notes on the cultivation of useful plants, especially the Para rubber plant (*Hevea braziliensis*) and the Ipecacuanha (*Cephælis ipecacuanha*). With regard to the former, Dr. King is of opinion that the plants will not thrive in that part of India. Mr. Collins, in his report on the Caoutchouc plants, describes the *Heveas* as growing in their native country in situations where the heat is not generally above 87° Fahr. in the afternoon, and below 74° at night, and shows, on the authority of Wallace, that the temperature in the caoutchouc districts during three years only once reached to 95°, the greatest heat being about 2 P.M., when it ranges from 89° to 94°, and never lower than 73°. The meteorological returns for Calcutta show a wide difference between the Brazilian and the Indian climates. Another Caoutchouc plant, however, the *Vahea madagascariensis*, Boj., a climbing apocyneous shrub, native of Madagascar, promises to thrive much better than the *Hevea*. The fact of the plant being of climbing habit militates considerably against its value as a cultivated plant, owing to the difficulty in providing supports as well as in obtaining the caoutchouc. Nevertheless, it is a kind highly valued in the English market, realising a price next to Para rubber. With regard to Ipecacuanha, which has been shown to require much care and attention as to soil and situation, we learn that a number of sets of plants were put out during the early part of the year at different spots at low elevations in the Cinchona reserve at Sikkim; warm, well sheltered situations, with good virgin soil, were chosen. "Some of the plants thus put out were protected by the natural shade of the forest, others by a sloping thatch of grass. Until the arrival of the cold weather all went well, but the unusually low temperature that prevailed during that season was fatal to the majority of the plants." Dr. King further says that he is "driven reluctantly to the conclusion that it is doubtful whether ipecacuanha can be successfully cultivated as an out-door crop in Sikkim." Further trials, however, are to be made before its experimental cultivation is recommended to be abandoned.

Eucalyptus globulus has had its share of attention in India, and without considering the question of the truth or otherwise of its reputed value, it is proved that although it grows quickly and with vigour on the Neilgherries and Khasia hills at 5,000 to 8,000 feet above the sea, it cannot be induced to live even for a year or two in the hot plains of India. Dr. King's description of the fine old Banyan tree, "one of the greatest curiosities and ornaments of the place," will, we are sure, be read with interest. He says: "Although considerably damaged by the cyclone of 1864, which carried away two of its largest arms, this fine tree continues to grow vigorously. It now covers an area of ground 800 feet in circumference; its trunk girths 51 feet, and from its branches no fewer than 170 aërial roots are sent down to the ground, some of them being more than ten feet in circumference. This fine old tree supports quite a colony of orchids, ferns, and creeping plants of about twenty distinct species, and gives shelter to innumerable birds. Its exact age is not known, but, considering how rapidly banyans grow, it probably does not much exceed that of the garden, and is therefore less than a century."

GUM ARABIC.—In a recent number of the *Revue des Sciences Naturelles*, Prof. Charles Martins, of Montpelier, draws attention to a peculiar mode of exudation of gum arabic from the *Acacia verek* of Senegal. On the authority of Schweinfurth, quoted in the "Pharmacographia," p. 206, it is stated that this tree, exclusively, yields the fine white gum of the countries bordering the Upper Nile, and especially of Kordofan. It is described as growing to a height of about twenty feet, and though the gum is one of the principal productions of the colony, being collected in large quantities by the Moors, who exchange it for European commodities, no notice occurs of any peculiarity in its formation or collection; indeed, it is stated that "the gum generally exudes from the trees spontaneously, in sufficient abundance to render wounding the bark superfluous. The Somali tribes of East Africa, however, are in the habit of promoting the outflow by making long incisions in the stem and branches of the tree. In Kordofan the lumps of gum are broken off with an axe, and collected in baskets." Prof. Martins shows that the exudation of the gum is often promoted by the growth of a species of Loranthus, his observations being founded on actual specimens of branches of the Acacia upon which the parasite had formed. In several instances the gum had exuded in a vermicular form always at the point of union of the parasite with the stock. This union of the two plants forms, as is usual with other Loranthaceous species, an irregular, gnarled-like protuberance, from which are given off both the branches of the Acacia and also of the Loranth, each of which is very distinct from the other, those of the Acacia being spiny and more slender than those of the parasite. Rather than this mode of exudation being rare, it would seem to be of frequent occurrence. M. Martins considers the parasite to be a new species of Loranthus, for which he proposes the name of *Loranthus senegalensis*, placing it near *L. pentagonia*, DC.

SOCIETIES AND ACADEMIES

London

Royal Society, Nov. 25.—"On the Replacement of Electro-positive by Electro-negative Metals in a Voltaic Cell," by J. H. Gladstone, Ph.D., F.R.S., Fullerian Professor of Chemistry in the Royal Institution, and Mr. Alfred Tribe, Lecturer on Chemistry in Dulwich College.

It is well known that one metal exerts a greater chemical force than another, and is capable of displacing it from its combinations. Among those metals with which we are familiar, potassium is looked upon as the most powerful; and it is a certain fact that calcium, barium, strontium, aluminium, and magnesium have been isolated by its agency. It could scarcely be expected, therefore, that any other metal could directly replace potassium. If such should happen, we should have an instance of reversal, and should expect to find, on examination of the conditions, an agent capable of doing just the reverse work of what is usually assigned to affinity.

It is also well known that in a simple voltaic cell, such as zinc connected with platinum in dilute hydrochloric acid, the more powerful or electro-positive metal, zinc, displaces the hydrogen that is in combination with chlorine, and the hydrogen makes its appearance against the less powerful or electro-negative metal, platinum. The chemical theory of galvanism supposes that the force originates in the chemical action which takes place between the zinc and the acid; the contact theory supposes that it originates in some unexplained manner in the opposite electrical condition of the two metals induced by their contact. If the chemical theory be the true one, it is evident that a zinc-platinum cell can only become active when the binary liquid contains hydrogen or some metal which is less powerful than zinc. If, for instance, we were to employ a potassium-salt instead of a hydrogen compound, it is inconceivable, on the pure chemical theory, that there should be any action at all.

Such an action, however, does take place if we substitute the chloride of potassium for the hydrochloric acid; the zinc combines with the chlorine, and the potassium is set free in some form against the platinum, manifesting itself by the presence of free alkali and hydrogen gas. The same holds good with chloride of sodium, or ammonium, or barium, strontium, calcium, or magnesium.

This action is slow; but if magnesium be used instead of zinc, it takes place sufficiently rapidly to be easily observed, and we have therefore studied the action of platinum and magnesium in connection.

After an account of the experiments, the paper concludes as follows:—

If one metal in conjunction with another more electro-negative than itself will decompose the salt of a more positive metal, it may be expected, *à fortiori*, that it can decompose one of its own salts. Instances of this are not wanting.

Magnesium connected with platinum will decompose a magnesium salt, the almost insoluble hydrate of magnesium being found adhering to the negative metal. The deposition of zinc on the plates of an old-fashioned battery, when the battery is pretty well exhausted, is a well-known phenomenon. In our experiments with copper and silver in conjunction in a solution of nitrate of copper, we never succeeded in reducing the galvanic action to *nil* by our utmost efforts to exclude all oxygen, and the whole of the present inquiry originated in an experiment described by us before the Physical Society, that mercury and gold in conjunction would decompose mercuric chloride, with deposition not only of lower chloride, but also of metallic mercury upon the gold.

These experiments are inexplicable on the theory that the chemical action supplies the whole of the decomposing force, but show that there is an antagonistic force produced somewhere in the circuit which is greater in amount than the superior affinity of potassium over magnesium for the negative radicals.

Little doubt can be entertained but that this force is called into existence by contact; but our experiments do not teach us whether the energy requisite to keep up the action results from the disappearance of heat at the junction of the metals or contact of the metals and liquids (an idea that has long been in our minds), or at the expense of some other form of energy. Of course a momentary disappearance of heat would give only a momentary supply of voltaic energy; but since the loss of heat would be constantly made up by absorption from surrounding objects, the action would be continuous.

Linnean Society, Dec. 2.—Dr. G. J. Allman, F.R.S., president, in the chair.—Mr. J. G. Baker made some remarks on *Pyrus Briggsii*. The following papers were then read:—On Polynesian Ferns of the *Challenger* Expedition, by Mr. J. G. Baker. The new species amounted to ten or twelve, closely allied to species already known, and establishing no new genus.—Genera and Species of Liliaceæ, by Mr. J. G. Baker. The present instalment, completing the series, comprises the Tribes Anthericeæ and Eriosperineæ; the latter characterised by remarkably woolly seeds.—Botanical Notes from Darjeeling to Tongle, by Dr. C. B. Clarke.—On *Edgaria*, a new genus of Cucurbitaceæ, by Dr. C. B. Clarke.

Chemical Society, Dec. 2.—Prof. Abel, F.R.S., president, in the chair.—Dr. J. H. Gladstone read a paper, by himself and Mr. A. Tribe, on the decomposition of alcohol and its homologues by the joint action of aluminium and its halogen compounds. The action on alcohol gives rise to hydrogen and aluminic ethylate, a greenish white fusible solid.—The second communication, a note on incense resin, by Dr. J. Stenhouse and Mr. C. E. Groves, was read by the latter. The authors have succeeded in obtaining a crystalline substance and a liquid hydrocarbon from it.—Mr. J. Spiller gave a notice of the occurrence of native calcium chloride at Guy's Cliffe, Warwickshire; after which Mr. G. S. Johnson described certain sources of error in the ultimate analysis of organic substances containing nitrogen, upon which an interesting discussion took place.—The other papers were: On certain bismuth compounds, by Mr. M. M. P. Muir; and On bismuthiferous tesseral pyrites, by Dr. W. Ramsay.

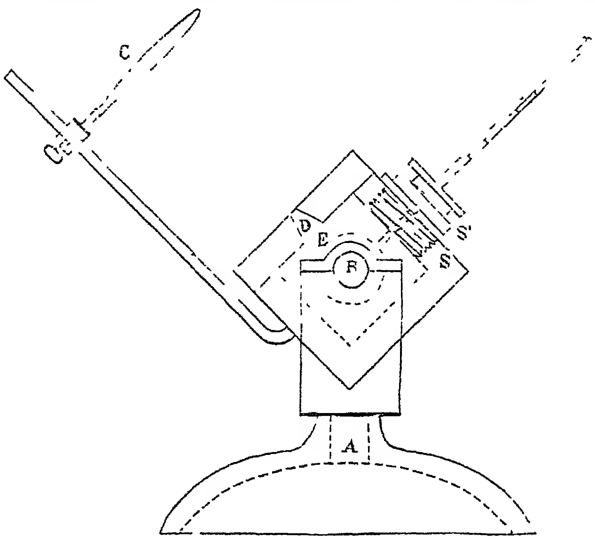
Royal Microscopical Society, Dec. 1.—Mr. H. C. Sorby, F.R.S., president, in the chair.—A number of presents were announced, including an injected specimen of the ova of *Amphiuma* presented by Mr. Beck.—A very useful addition to microscopes with concentric rotating stage was exhibited by Mr. Crouch, by which the instrument could be accurately adjusted to the centre of the stage when different objectives were employed.—Dr. Lawson exhibited and described a new apparatus termed the *Hematimetre*, designed by M. Hagen and constructed by Nachet, for the purpose of estimating the number of corpuscles in a given quantity of blood.—Mr. A. W. Bennett called attention to some minute organisms which he had discovered upon the leaves of Drosera and other carnivorous plants, and which he regarded as being intimately connected with the process of nutrition.—A very interesting paper was read by Prof. W. Rupert Jones, on Foraminifera with special reference to their variability of form. The subject was profusely illustrated by large diagrams, models, &c.

Manchester

Literary and Philosophical Society, Nov. 2.—Mr. R. Angus Smith, F.R.S., vice-president, in the chair.—Mr. Peter Spence, F.C.S., &c., exhibited a piece of 2 to 3-inch lead pipe in which the metal had been entirely transformed into galena, the crystallisation being visible through the whole of the specimen. The pipe had been used for the conveyance of gas ammoniacal water, and was sunk under ground. A considerable leak of gas-water having occurred, a constant atmosphere of sulphide of ammonium would surround the pipe, and this seems to have been the cause of the conversion of the lead into sulphide, as only that part of the pipe which was in the vicinity of the leak was found to be transformed.—On the principle of the electro-magnet constructed by Mr. John Faulkner, by Prof. Osborne Reynolds. The magnet which forms the subject of this paper consists of a soft iron bar with a flat plate attached to one end, and surrounded by a coil of wire in the same way as the ordinary electro-magnet. Outside this coil is placed a tube of soft iron of the same length as that portion of the interior bar which projects beyond the plate; this tube has flat ends, one of which is in contact with the plate, while the other comes up flush with the end of the bar, so that a plate or keep placed over the end is in contact with both the bar and the cylinder. The magnet is excited in the ordinary way, by connecting the ends of the wire which forms the coil with the poles of a battery. When thus excited this magnet exhibits certain peculiarities as compared with a common magnet. The object of the paper was to suggest explanations of these phenomena.

Nov. 16.—Rev. William Gaskell, vice-president, in the chair.—On an instrument for measuring the direct heat of the Sun, by Prof. Balfour Stewart, F.R.S. The instrument generally em-

ployed for giving the radiant energy of the sun's rays acts upon the following principle:—In the first place the instrument is sheltered from the sun, but exposed to the clear sky, say for five minutes. Let the heat so lost be termed r. Secondly, the instrument is turned to the sun for five minutes. Let the heat so gained be termed R. Thirdly, the instrument being now hotter than it was in the first operation, is turned once more so as to be exposed to the clear sky for five minutes while it is shielded from the sun. Let the heat so lost be termed r'. It thus appears that r denotes the heat lost by convection and radiation united, when the instrument, before being heated by the sun, is exposed for five minutes to the clear sky, while r' denotes the heat lost by these same two operations by a similar exposure after the instrument has been heated by the sun; and it is assumed that the heat lost from these two causes during the time when the instrument is being heated by the sun will be a mean between r and r', and hence that the whole effect of the sun's rays will be in reality $R + \frac{r + r'}{2}$. Now although this assumption may in the average of a great number of experiments represent the truth, yet in many individual cases it may be far from being true. It would therefore seem to be desirable to get rid of this uncertainty by constructing an instrument in which we are sure that the causes of variability are not allowed to operate. These causes of variability I have attempted to get rid of in the following manner. With the help of Mr. Jordan, mechanician at Owens College, the following instrument has been constructed. It consists of a large mercurial thermometer with its bulb in the middle of a cubical cast-iron chamber, this chamber being of such massive material that its temperature will remain sensibly constant for some time. The chamber with its thermometer has



a motion in azimuth round a vertical axis A, and also a motion in altitude round a horizontal axis B. A 3-inch lens C of 12 inches focal length is attached by means of a rod to the cubical chamber, so as to move with it. The nature of this attachment will be seen in the figure. Thus the whole instrument may be easily moved into such a position that the lens, as well as the upper side of the chamber which is parallel to the plane of the lens, may face the sun, and an image of the sun be thrown through the hole D in the side of the chamber upon the thermometer bulb E. The stem of the thermometer protrudes from the chamber as in the figure. A screw S, somewhat larger in diameter than the bulb of the thermometer, is made use of to attach the thermometer to its enclosure, and a smaller screw S′, pressing home upon india-rubber washers, enables the thermometer to be properly adjusted and kept tight when in adjustment. In the present instrument the internal diameter of the chamber is two inches, while the bulb of the thermometer is about $1\frac{1}{4}$ inches in diameter. The scale of the thermometer is very open, more than an inch going to one degree. I have generally allowed the image of the sun given by the lens to heat the thermometer bulb for one minute, during which time an increase of temperature, not exceeding in any case two degrees, has been produced. As far as principle is concerned there appears to be no objection to the present instrument; nevertheless it is open to a very serious practical objection. The scale being so very open, the stem comprehends only a few degrees; frequently, therefore, the temperature is such that the extremity of the mercurial column is either below or above the stem. Now the thermometer has a small upper chamber, and by means of a method of manipulation well known to those who work with thermometers, it is possible to add to or take away from the main body of mercury in the bulb, so as to keep the end of the mercurial column always in the stem. But experience has convinced me that for a thermometer with such a large bulb, frequent manipulation of this kind is not unattended with danger to the bulb. On this account the instrument in its present form is, I conceive, unsuited for steady work in an observatory from year to year. It is however possible, without any appreciable sacrifice of the scientific principle of the instrument, to alter it in such a manner as to remedy this defect. Without altering the size of the bulb, I should propose for a permanent instrument a stem say eighteen inches long with a bore of such diameter that the stem should embrace a range of temperature between 20° Fahr. and 92° Fahr. Thus somewhat less than five degrees will go to the inch. The stem might be protected from the risk of accident by an appropriate shield. Let such a thermometer be heated for two minutes and the size of the lens be somewhat increased. In this case a rise of something like 5° Fahr. will be obtained, and this heating effect might very easily be estimated to one hundredth of the whole, while the same thermometer would serve for all the temperatures likely to occur in these islands during the course of the year. I ought to add that a pasteboard cover, gilded on the outside, is made to surround the chamber, and also that between the lens and the chamber there is a pasteboard shield with a hole in it to permit the full rays from the lens to pass—the object of this shield being to prevent rays from the sun or sky from reaching the instrument. In such an instrument r, or the change taking place in the thermometer before exposure to the sun, will in all probability completely disappear, while r' will be extremely small. At any rate we may be quite certain that $R + \frac{r + r'}{2}$ will accurately represent the heating effect of the sun. We may probably suppose that in the same instrument the lens (which must always be kept clean) will always stop the same or nearly the same proportion of the solar rays. But the lens of one instrument may not stop the same proportion as that of another instrument. This, however, is no objection if it be borne in mind that the instrument is a differential one. In practice there would be some standard instrument which would be retained at a central observatory, and all other instruments would, before being issued, be compared with it. It would be thus possible to compare together the indications of various instruments working in different places, provided that these before being issued had their co-efficients determined at the central observatory.—On a colorimetric method for determining small quantities of copper, by Thomas Carnelley, F.C.S., Demonstrator in the Chemical Laboratory of Owens College. Communicated by Prof. H. E. Roscoe, F.R.S.

Berlin

German Chemical Society, Nov. 22.—A. W. Hofmann, president, in the chair.—V. Gomp-Besanez has discovered diastatic ferments, transforming fibrine and albumin into peptones in malt and in linseed and hemp-seed, proving thereby a hypothesis of Hooker and Darwin respecting the power of plants for dissolving starch, &c. (expressed in Darwin's "Insectivorous Plants," p. 362).—F. Salomon, in a paper on the formation of anhydrides in chemical reactions, tries to explain why sulphocarbonate of ethyl treated with methylate of potassium yields sulphocarbonate of methyl, while *vice versâ* sulphocarbonate of methyl and ethylate of potassium yield sulphocarbonate of ethyl. He supposes that in these reactions CSO is set free and reacts on methylate or on ethylate of potassium.—H. Skraup described a product of the action of chlorine on ferricyanide of potassium, perhaps $FeCy_6K_2$.—L. Barth has obtained a ferrocyanide of tetramethylammonium (yellow crystals) by saturating ferrocyanic acid with tetramethylammonium-hydrate.—L. Barth and C. Senhofer, in preparing disulphobenzolic acid, have found this acid to be, when prepared at a moderate temperature, metadisulphobenzolic acid, at a higher temperature paradisulphobenzolic acid; the former yielding isophtalic, the latter terephthalic acid; both, however, by fusion with potash yielding resorcine.—C. Senhofer has prepared naphthalintetrasulphurous acid, $C_{10}H_4(SO_3H)_4$, by treating naphthalin with oil of vitriol and

phosphoric anhydride.—O. Hausamann, by distillation of β-naphtoate of calcium, has obtained a ketone identical with the one that β-naphthoyl-chloride and naphthalin yield by heating them with zinc.—C. Jaeger, by fusing nitrosophenol with potash, has obtained azophenol, $C_6H_4(OH)NNC_6H_4(OH)$, crystals of the constant melting-point 214°.—Robert Schiff has succeeded in producing nitroso-thymol, $C_{10}H_{12}(NO)OH$, by treating thymol with nitrite of potassium and sulphuric acid. Nitrosothymol yields nitrophenol when oxidised with ferricyanide of potassium. Nitrothymol has been transformed into amidothymol and diazothymol by the ordinary methods.—O. Rembold, by treating ellagic acid ($C_{14}H_8O_9$) with zinc powder at high temperatures, has obtained a new isomeride of anthracene, to which he gives the name ellagene (melting-point, 88°, boiling-point, 252°; its chinone insoluble in sulphite of ammonium, yielding itself no precipitate with picric acid). Ellagic acid boiled with potash yields a new acid ($C_{14}H_8O_6$), which, by sodium amalgam (?) and water, is transformed into the acid $C_{14}H_{10}O_7$.—F. Schardinger described nitro-derivatives of anthraflavone.—A. Vogel showed absorption-bands of manganic, uranic, and chromic salts; also absorption-bands of hydrate of cobalt, which, suspended in water, shows absorption-bands on D and between D and C. They appear also in the presence of nickel with great clearness. Sulphocyanate of iron shows an absorption-band between G and E.—A. Pinner, who from 1870 up to the present time has studied the derivatives of what he considered croton-chloral, has now come to the conclusion that the greater part of his researches have been erroneous, in as far as all the compounds described by him contain two atoms of hydrogen more than he has alleged. Thus what has been called crotonic chloral is really butyric chloral. Its derivative with hydrocyanic acid is not trichloroangelic, but trichorovalerianic acid. Its product of oxydation and subsequent reduction are not chlorocrotonic, but chlorobutyric acids. Potash does not produce a chloride $C_3H_2Cl_2$, but chloride of allylene ($C_3H_4Cl_2$), which by sodium is not transformed into "a new hydrocarbon, C_3H_2," of which he has lately taken the trouble of giving a structural formula, but into allylene, C_3H_4!—W. Weith has proved the sulpho-ureas produced by the action of aniline on ethylic isosulphocyanide, and of ethylamine on phenylic isosulphocyanide, to be identical. Oxide of lead transforms them into an imide, $C(NC_2H_5)(NC_6H_5)$; and the action of aniline and of HCl NC also produce identical derivatives.

Geneva

Society of Physics and Natural History, Nov. 4.—Prof. Calladon published in 1872 (tome xxi. of the Memoirs of the Society) a paper on the effects of lightning on trees, &c. A case of a pyramidal poplar struck by lightning on August 4 last, near Rolle, in the Canton de Vaud, enabled him to verify some of his previous conclusions, and to add some new observations. The flash which struck this tree, situated 11 metres from the shore of the Lake of Geneva, left perfectly intact the upper portion. At seven-eighths of its height commences the trace left by the lightning, in the form of a wound (*plaié*) three to four centimetres in width, and from seven to eight centimetres in depth. This wound descends as far as the ground, turning round the trunk in the form of a screw, and describing four-fifths of the complete circumference of the tree. Fragments of wood of various sizes were projected to distances as far as fifty metres. Some are pierced by jagged holes, indicating a violent eruption of the electric fluid from the interior to the exterior, the track of the fluid having probably been in the layer which separates the alburnum from the old wood or duramen. The places where the emission of the fluid occurred are sometimes indicated by spots of a red colour, similar to the effect which might be produced on wood by the application of a hot iron. They correspond to a slight depression of the surface of the wood. The wound of the tree is turned from the shore of the lake, lightning striking more readily plants which grow near watercourses, visible or underground.

Paris

Academy of Sciences, Nov. 29, M. Frémy in the chair.—The following papers were read:—Theorems in which there is a condition of equality of two segments taken on normals and tangents of curves of any order and class, by M. Chasles.—Reply to notes of M. Duchartre and M. Violette, *àpropos* of stripping off the leaves of beet, by M. Cl. Bernard.—Memoir on organic elements considered as electro-motors, by M. Becquerel.—Examination of a piece of wood petrified by subcarbonate of lime found at Bourbonne-les-Bains, in a Roman cesspool, by M. Chevreul. This is regarded as confirming the author's theory of petrefaction given in 1866.—Mineralisation of organic *débris*, vegetable and animal, in the thermal water of Bourbonne-les-Bains, by M. Daubrée.—Thermal researches on phosphoric acid, by MM. Berthelot and Louguinine.—Atmospheric perturbations of the hot season of 1875; group of rains from 21st to 24th of June; Flood of the Garonne, disasters at Toulouse, by M. Belgrand. The floods of the Garonne since 1770 have always been in spring or early summer, and, almost without exception, the maximum of rain and flood has been on the 23rd of June.—Reply to some objections raised by our recent communications on the useful effect of steam injectors, by M. Ledieu.—M. Daubrée presented a flattened angular meteorite sent by Prof. Hinrichs, from Iowa.—On the coefficient of capillary flow, by M. Guerout. The flow is in a horizontal tube; and in the case of alcohols the coefficients do not form a regular series; they diminish for alcohols richer in carbon; but bodies of similar composition and density often differ in fluidity.—On the composition of arable land in Auvergne; importance of phosphoric acid for its fertility, by M. Truchot.—On a system of irrigation of meadows by means of rain-water, in mountainous and impermeable regions, by M. Le Play.—On the Meteorological Observatory of the Pic du Midi de Bigorre (Hautes-Pyrenees), by General de Nansouty.—On some indications of the existence of Edentata at the commencement of the miocene epoch, by M. Gaudry.—On the contraction produced by rupture of the battery current, in the case of unipolar excitation of nerves, by M. Chauveau. The negative pole has but little aptitude to produce contraction at opening. Positive or negative, the opening contractions are distinguished for their brevity and equality.—On the poisonous principle in damaged maize, and its application in pathology and therapeutics, by M. Lombroso. The action is like that of strychnine.—On the earth-worms of the Philippine Islands, and of Cochin China, by M. Perrier.—Application of a theorem, complementary of the principle of correspondence, to determining, without calculation, the order of multiplicity of a point O, which is a multiple point of a given geometrical place, by M. Saltel.—On the discussion of equations of the first degree, by M. Rouché.—On the points of a curve or a surface, which satisfy a condition expressed by a differential equation or partial derivatives, by M. Halphen.—Crystallised sulphydrocarburet, from the interior of a mass of meteoric iron, by Mr. Lawrence Smith.—On the nature of flame, according to Galen and Aristotle, by M. Calliburcés. The experiment of the two candles, as proving that flame is a phenomenon produced by ignition of gas, is carried back to Aristotle.—On certain anatomical details of *Sarcoptes scabiei* and its numerous varieties, by M. Megnin.—On the musculoid cilia of the common mussel, by M. Sabatier. These organs have affinity with muscular tissue when they are agglutinated, and with vibratile cilia when dissociated and isolated.

THURSDAY, DECEMBER 16, 1875

HAECKEL'S HISTORY OF CREATION

The History of Creation. From the German of Ernst Haeckel, Professor in the University of Jena; the translation revised by Prof. E. Ray Lankester, M.A., F.R.S., Fellow of Exeter College, Oxford. In two vols. crown 8vo, pp. 374, 401; 15 lithographic plates, woodcuts, and genealogical tables. (London: King and Co., 1876.)

HAVING in a review of Prof. Haeckel's "Anthropogenie" (see NATURE, vol. xi. pp. 4, 22) criticised both the manner and the substance of his popular lectures on Evolution, it is unnecessary to repeat what was then said. The "Schöpfungsgeschichte" is the earlier work of the two; it deals more with the general question of the evolution of the Organic Kingdom and less with its special application to Man; its tone is somewhat more moderate, and its statements and plates are less highly coloured. But the object and the style of both books are essentially the same, and they will be praised or condemned together.

Even in the short time since the delivery of the present lectures several points have been established which necessitate a modification of the views here expressed. The origin of the urino-genital organs has been proved in the classes as yet completely examined to be from the middle layer of the embryo; the embryology of Amphioxys and of Mollusca has been elucidated—by none more than by the editor of this translation; the placental classification of Mammalia, never accepted by all zoologists, has been almost reduced to the same rank as Waterhouse and Owen's cerebral system; the true nature of Lichens has been cleared up, and relations between Algæ and Fungi have been established which disturb the roots of the genealogical tree on Plate V. Moreover, Dr. Dohrn's bold speculations lately published in his pamphlet "Der Ursprung der Wirbelthiere und das Princip des Functionwechsels," have brought the question of degradation of many lower forms as well as of the genetic relations of Vertebrata into a new phase. It is remarkable how little the previously well-known instances of "degraded forms" are considered in these lectures. Surely some of the numerous twigs of the fifth, sixth, and fourteenth plates might have been turned downwards.

But whatever may be thought of the advantage of exhibiting together established truths and more or less erroneous speculations, in a dogmatic and controversial form, before an uncritical audience, there is no question of the value of these lectures to naturalists. They awaken thought, provoke criticism, and stimulate inquiry.

Turning from the subject-matter to the translation, we must call it an exceedingly good one. No one who has not tried knows the difficulty of presenting a continuous work in a foreign language to an English reader so as to drop the idiom and yet retain its character. If a page of the body of the work be compared with Prof. Haeckel's own preface—written in very good English, but as a foreigner writes—the reader will see at once how much he is indebted to the lady who, we are told, made the first draft, or to Mr. Lankester, who revised it.

The following passage is a fair specimen of the book:—

"Of the twelve species of men distinguished in the following table [namely Papuan, Hottentot, Caffre, Negro, Australian, Malay, Mongolian, Arctic, American, Dravidan, Nubian, Mediterraneanese, beside hybrids], the four lower species are characterised by the woolly nature of the hair of their heads; every hair is flattened like a tape, and thus its section is oval. These four species of woolly-haired men (*Ulotrichi*) we may reduce into two groups, 'tuft-haired' and 'fleecy-haired.' The hair on the head of tuft-haired men (*Lophocomi*), Papuans and Hottentots, grows in unequally divided tufts. The woolly hair of fleecy-haired men (*Eriocomi*) on the other hand, in Caffres and Negroes, grows equally all over the skin of the head. All *Ulotrichi*, or woolly-haired men, have slanting teeth, and long heads, and the colour of their skin, hair, and eyes, is always very dark. All are inhabitants of the Southern Hemisphere: it is only in Africa that they come north of the equator. They are, on the whole, at a much lower stage of development, and more like apes than most of the *Lissotrichi*, or straight-haired men. The *Ulotrichi* are incapable of a true inner culture and of a higher mental development, even under the favourable conditions of adaptation now offered to them in the United States of North America. No woolly-haired nation has ever had an important history.

"In the eight higher races of men which we comprise as straight-haired (*Lissotrichi*), the hair of the head is never actually woolly, although it is very much frizzled in some individuals. Every separate hair is cylindrical (not like a tape), and hence its section is circular (not oval).

"The eight races of *Lissotrichi* may likewise be divided into two groups—stiff-haired and curly-haired. Stiff-haired men (*Euthycomi*), the hair of whose heads is quite smooth and straight, and not frizzled, include Australians, Malays, Mongolians, Arctic tribes, and Americans. Curly-haired men, on the other hand, the hair of whose heads is more or less curly, and in whom the beard is more developed than in all other species, include the Dravidas, Nubians, and Mediterranean races."

The Caucasian, or to adopt Fr. Müller's less recognised name, the Mediterranean race, is divided into four sub-races by the aid of language: these are (1) the Caucasians proper of Georgia and the surrounding mountainous district; (2) the Basques; (3) the Semitic nations, including not only the Arabs and Jews (*Eusemites*), but also the Hamitic or "Dyssemitic" Egyptians and Berbers, with some other African tribes; (4) the great Indo-Germanic or Aryan race, including Indo-Persians, Greeks, Italians and Kelts, Sclavonians and Teutons. The following passage concludes the chapter:—

"The third and most important main branch of primæval Malays, the curly-haired races or *Euplocomi*, have probably left in the Dravidas of Hindostan and Ceylon that species of man which differs least from the common primary form of the *Euplocomi*. The principal portion of the latter, namely, the Mediterranean species, migrated from their primæval home (Hindostan?) westwards, and peopled the shores of the Mediterranean, South-Western Asia, North Africa, and Europe. The Nubians in the north-east of Africa must perhaps be regarded as an offshoot of the primæval Semitic tribes who migrated far across Central Africa almost to the western shores.

"The various branches of the Indo-Germanic race have deviated furthest from the common primary form of ape-like men. During classic antiquity and the middle ages, the Romanic branch (the Græco-Italo-Keltic group), one of the two main branches of the Indo-Germanic species, outstripped all other branches in the career of civilisation; but at present the same position is occupied by the Germanic. Its chief representatives are the

English and Germans, who are in the present age laying the foundation for a new period of higher mental development in the recognition and completion of the theory of descent. The recognition of the theory of development and the monistic philosophy based upon it, forms the best criterion for the degree of man's mental development."

A noteworthy feature in the present translation is the attempt Mr. Lankester has made to use English equivalents for the technical terms of anatomy and zoology. The facility with which Prof. Haeckel invents terms, and the habitual use in German of vernacular phrases in scientific writing, made this a good opportunity for trying an experiment which the translator has before now recommended. The result shows great ingenuity and good judgment, and is probably as successful as the conditions of the attempt allow.

It will be generally admitted that the English language is incomparably richer and more flexible than the French, while it lacks the precision and neatness which with ordinary French writers is apt to become too mechanical and uniform, but in the hands of a master produces the most perfect instrument for scientific exposition. On the other hand, German is far more cumbersome and undisciplined than English, but has a slovenly ease, a picturesque force and a power of adaptation and word-making, which reminds one of our own language in the first half of the seventeenth century.

A French scientific writer cannot make a new term or form a compound in his own language, but must construct a Greek compound (often ill-formed), and even this must be modified so as to assimilate it to French pronunciation. And comparing the style of Bichat and of Cuvier with that of contemporary writers, we see that the stiffness and severity of the language has increased during the present century. Germans, on the other hand, can invent compounds without limit in number or in length, and can introduce foreign terms as they are wanted, even declining them in accordance with the German prepositions against which they are thrown.

The English language has much less power of forming compounds, though poets like Tennyson and Morris show us how flexible it becomes in powerful hands; but it has a remarkable capacity for assimilating foreign words. The unequalled richness of the language chiefly depends on its having so many synonyms, and this again on its composite character. The choice of words like friendship, amity; righteous, just; begin, commence; wax, increase; weariness, fatigue; spue, vomit; raise, erect; fruitful, fertile, gives peculiar accuracy, character, and delicacy to modern English.

If purely English words were to be generally adopted in science, we should, in the first place, be obliged to shock modern decorum in a way that would be practically impossible. Germans still write of *Kothentleerung, Wollustorgane, Afterbildung;* but such plainness of speech would be intolerable in English. Even such words as sweat, spue, spit are much better kept for rhetoric and poetry than used as physiological terms.

Moreover, our purely English names are too popular to be tied down to technical definition. The word "worm," for instance, applied by Milton to the serpent, and universally to the larva of diptera, can never be limited to correspond with the class Vermes. The objection that English terminology is not "scientific" can only mean that it is not scientifically accurate. To make it so would injure it for every other purpose.

Surely it is better to speak of the *ophidian* character of a vertebra than to call it "serpentine" or "snake-like." The first word refers to the anatomical distinctions of the class Ophidia, the second to the peculiar, lateral, wriggling locomotion of these animals, and the last to their supposed mental characteristics. In the same way *avian* is a better scientific term than "bird-like,"* *mammalian* than "beastly," and *piscine* than "fishy;" because those are at once recognised as referring to the technical characters of the classes Aves, Mammalia, and Pisces respectively, while these suggest far more vividly the special peculiarities which common observation associates with them.

It must however be admitted that a vernacular synonym is often of value. It brings an unobvious fact vividly and clearly before one. Thus the phrases, "a fox is a kind of dog," "a tiger is only a large cat," "the swordfish is a sort of mackerel," are certainly more easily remembered than corresponding statements in "scientific" language.

The simplicity and directness of idiomatic English is often an advantage as a matter of style.

For teaching botany to children, and generally for explaining scientific facts to persons unfamiliar with technical names, it is often desirable to use vernacular terms, either to avoid disgusting them with hard words to begin with, or to fix the attention on facts rather than names and prevent the learner supposing that he has made a step in knowledge when he has learned to call hardness impenetrability, or a buttercup Ranunculus.

Lastly, for the probably increasing number of persons who study science without having learnt Greek, it is of great importance that even when using technical names they shall know the English synonym as a kind of ready translation. When everyone wrote in Latin many terms which are now become technical were simply descriptive. Thus "the passage from the third to the fourth ventricle of the brain" was certainly never meant to be a proper name, nor was "the waterpipe of Sylvius:" but now when "iter," "aquæduct," "tympanum," "cilium," have become restricted to single objects, it is well that their meaning should be readily apprehended by the use of appropriate English synonyms. At all events the attempt was worth making, and we will conclude this notice by giving a list of some of the synonyms used by Mr. Lankester.

Cotyledon	= Seed-lobe or germ-leaf.
Nucleus	= Kernel.
Nucleolus	= Kernel-speck.
Cytod (surely this should be cythode).	
Catallacta	= Flimmer balls.
Labyrinthuleæ	= Tramweavers.
Diatomaceæ	= Flintcells.
Rhizopoda	= Raystreamers or Rootfeet.
Algæ	= Tangles or waterweeds.
Labiatæ	= Lipblossoms.
Gamopetalæ	= Bell-flowers.
Ctenophora	= Combjellies.
Lamellibranchiata	= Mussels.
Gasteropoda	= Snails
Crustacea	= Crabfish.

* The prettily invented word "unbirdly" occurs in Cowley's fine Ode on Liberty—

"Even to the universal tyrant love
You homage pay but once a year,
None so degenerous and unbirdly prove
As his perpetual yoke to bear."

Sagitta	= Arrowworm.
Tunicata	= Sea-sacs, including sea-squirts (*Phallusia*), and sea-barrels (*Salpa*).
Chitonidæ	= Beetle-snails.
Tetrabranchiata	= Chamber-poulps.
Pycnogonida	= Nobody-crabs.
Arthropoda	= Insects.
Insecta	= Flies.
Phocidæ	= Sea-dogs.
Sirenia	= Sea-cows. (This order is allowed to remain in unnatural alliance with Cetacea.)

We have noticed a few verbal errors, such as "cetae" for "cete," "coecum" for "caecum," two misprints on p. 308, and an unlucky form of the name of an African tribe on p. 330.

The plates are excellently reproduced, and the print, paper and index show the care with which these two volumes have been prepared. P. H. P. S.

BURTON'S GORILLA LAND AND THE CONGO

Two Trips to Gorilla Land and the Cataracts of the Congo. By Richard F. Burton. Two vols. (London: Sampson Low and Co., 1876.)

THE journeys here recorded were made so long ago as 1862 and 1863. Since that time Capt. Burton has not been idle; between exploring and publishing the results of his explorations he has sufficient excuse for having kept from the public for so long the narrative of his trips to the Gaboon and the Congo. Moreover, as he says himself, Africa moves so slowly, that ten years makes scarcely any appreciable change on a locality. The publication of the work at the present time is opportune, as public attention is being directed to the region with which it is concerned; the German African Society have taken up the Congo district as a *point de départ* for the interior, and although the expedition sent out has not been so successful as might be wished, still Dr. Pogge and Dr. Lasaulx, according to the latest news, are endeavouring to push inwards from Loanda. There have been several explorers on the same ground since Capt. Burton visited it twelve years ago, and there have been many previous explorers—the stretch of coast included in the two narratives contains some of the earliest Portuguese settlements; but as was shown in his recently-published book on Iceland, this widely experienced traveller and keen observer can shed new and unexpected light even on the most frequently trodden paths. The present work will be found a substantial contribution to our knowledge of the Gaboon and Congo districts, especially in the matters of geography, topography, and people.

Capt. Burton's visit to the Gaboon extended over only a few weeks in March and April 1862, but during that time, his first volume shows, he managed to see and to learn much. He is nothing if not unflinchingly true to his opinions, and these, as usual, he expresses freely and without respect of persons throughout the two volumes. He gives rather an unpleasant picture of the character and condition of the French trading establishments on the Gaboon, and indeed has not much praise to bestow on any of the establishments, French, Portuguese, or English, which he has occasion to mention in his work. Capt. Burton's chief object in visiting the Gaboon was to obtain some specimens of Gorilla, and, if possible, get a young one alive. He did not, however, get a shot at one during all the time of his visit; but a fine specimen was sent him by a native before he left, which, in a sadly deteriorated condition, now rests in the British Museum.

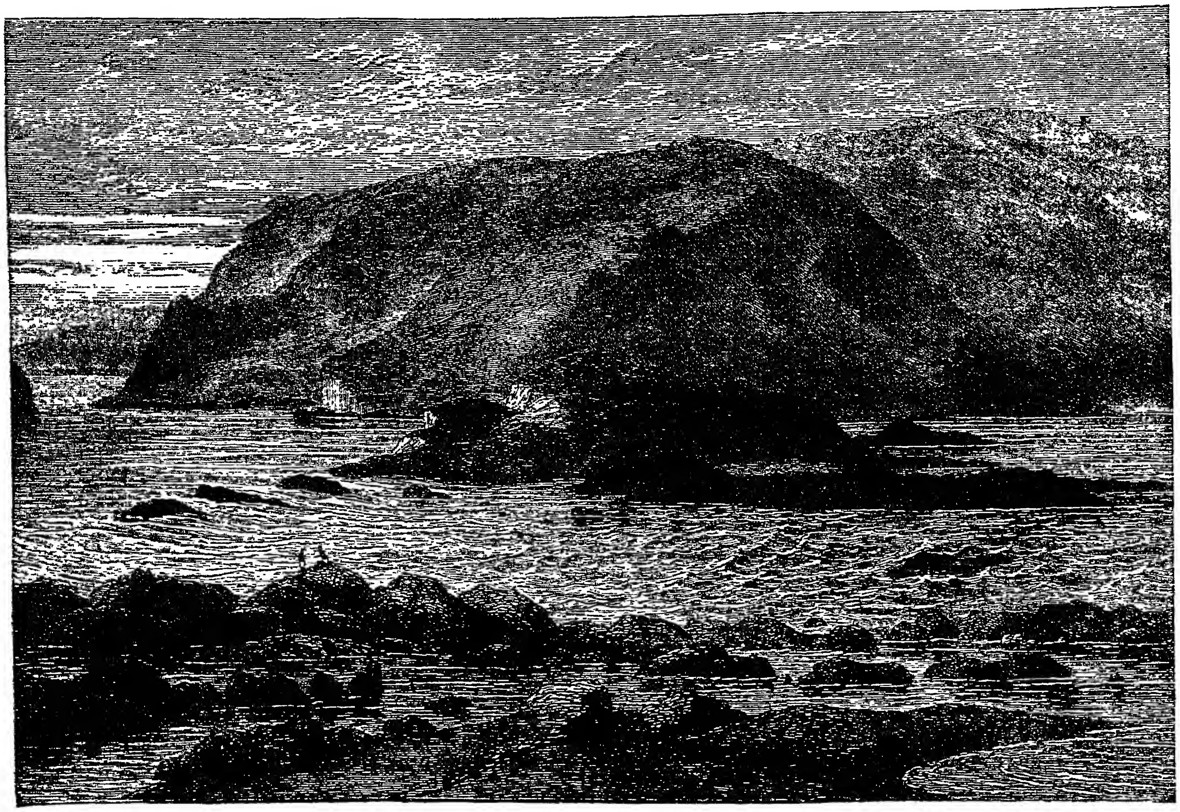
The traveller made a trip in pursuit of "our big brother," as he calls the animal, to the south side of the river, and gives some very graphic pictures of the degraded natives who inhabit the many villages of the district. His remarks on the customs of the people, the Mpongwe, as they are called, especially their marriage and religious customs, are extremely interesting. This chapter is interspersed with many shrewd philosophical remarks, in Capt. Burton's well-known style, on human customs generally, and shows extensive knowledge derived both from reading and experience. What he says upon the curious resemblance between certain customs among the Mpongwe and other West-Coast tribes, and the religious rites of the Jews, seems to us of real value. He also refers to what has been done to obtain a knowledge of the language of these people. His lively description of the troubles he had with the slippery and lazy natives in seeking the Gorilla will be found very amusing. With reference to the habits of the Gorilla, Burton substantially confirms the statements of Du Chaillu, though in some few points the matter-of-fact Englishman shows that the Frenchman had given way to exaggeration; *e.g.*, in the matter of the elaborately-constructed canopied nest or hut, Capt. Burton thinks Du Chaillu must have been deceived by some vagary of nature. The natives ridiculed the idea, and all that Capt. Burton saw were heaps of dried sticks built in forks of trees, and which a schoolboy might have taken for birds' nests. One entire chapter is devoted to "Mr., Mrs., and Master Gorilla," in which are discussed the results of his own and of other observations. It includes a historical account of references to the Gorilla, from Hanno the Carthaginian, downwards; the geographical limits of the animal are pointed out, as well as the modifications which ought to be made in Du Chaillu's account.

Capt. Burton made a trip down the coast for a few miles and another up the river to the Fan (Fa*n* he spells it, to indicate that the *n* is strongly nasalized cannibals; but the existence of cannibalism, in the ordinary sense of the term, seems doubtful. They do roast and eat portions of their enemies slain in battle, but this evidently is regarded as a quasi-religious rite. As might be expected, Capt. Burton indulges in a brief dissertation on anthropophagy in general, bringing to bear upon it much knowledge of the customs of peoples in various parts of the world. With regard to the Fans, Du Chaillu's account led him to expect to see "a large-limbed, black-skinned, ferocious-looking race, with huge mustachios and plaited beards. A finely-made, light-coloured people, of regular features and decidedly mild aspect, met my sight." On the whole, the Fans seem to be a very fair specimen of savage man. Capt. Burton gives details concerning the various tribes at the head and to the east of the Gaboon, about whom little or nothing is as yet known, and points out the suitability of the river as a *point de départ* for exploration in Inner Africa. One chapter is devoted to the geography of the Gaboon region. On the voyage back Capt. Burton visited Corisco Island in the bay of that name, about which and the missionaries

upon it he gives some interesting details. A good map of the coast districts for two degrees on each side of the equator accompanies the first volume.

The second volume refers to a visit made in July–September, 1863, to the Congo and the Portuguese settlements on the adjoining coast. Concerning these settlements many valuable and curious facts are given throughout the volume, both historical and as the result of the traveller's own observation at the colony of Loanda. Capt. Burton notes a considerable improvement in the morals and manners of the settlers as compared with previous accounts. The picture of the English establishments at Loango is not a very bright one. He paid a visit to Calumbo on the Cuanza or Quanza river, and mentally noted an exploration eastwards which he purposed to make in the future, but which he is glad to see has been taken up by Capt. von Homeyer. Ambriz to the north of Loanda was visited, and a short trip inland was made, during which, of course, many notes are made on the character and customs of the people. Ambriz has recently come to the front in connection with the German African expedition.

The chief interest of the second volume is connected with the Congo river, up which Burton journeyed as far as the Yellala, or rapids, which he calculates to be between 116 and 117 miles from the mouth, the total fall in that distance being 390 feet, of which 195 feet occurs between the Yellala and Boma, 64 miles. From the Great Rapids to the Vivi or lowest rapids, a distance of five miles, the fall is 100 feet. Some important facts are given as to the character of the Congo mouth and the changes which are constantly taking place, which must even yet be of value to chart constructors. Considerable details are also given concerning the delta or series of islands at the mouth of the Congo, and a chapter is devoted to the explorations of previous travellers. An amusing account is given of his interview with the native king at Banza Chisalla, a few miles above Boma, and in this connection an attempt is made to account for the fondness for what seems to us a most ridiculous dress on the part of African and other savage potentates. The author gives a minute and graphic description of the river and its many reaches between Boma and the rapids; the scenery on the banks is often quite Rhine-like in its character. The river itself Capt. Burton regards as one of the noblest in the world. With a valley area of 800,000 square miles, it has a yearly mean volume of 2,500,000 cubic feet per second, nearly four times that of the Mississippi, which has a very much larger drainage area. In this connection some interesting data are introduced concerning the four great African arteries, the Nile, the Niger, the Zambeze, and the Congo or Nzadi, as Capt. Burton makes the true native name to be. In the chapter, "Notes on the Congo River," which contains the summary of the explorations of previous travellers, Capt. Burton discusses the probable



The Yellala (rapids) of the Congo River.

connection of the Congo with the water system of Central Africa. This chapter altogether is one of the most valuable in the book.

On his way to the rapids he was detained for some time at the village Banza Nokki, near one of the upper reaches of the river, and of course took the opportunity of studying the people, who seem to have been but little affected by the labours of the Portuguese missionaries who lived among them for so many generations. The district Burton describes as a perfect paradise, the country lovely, and the climate all that can be desired. Very full details are given as to the ways of life of the people, their various customs, their superstitions, their language, &c. After the usual vexatious delays, Capt. Burton was able at last to set out on Sept. 16 for the cataracts of the Congo. These and their surroundings, the character of the country on the river banks and of the people dwelling near, are described in his usual graphic style, and with consider-

Fetish boy (Congo district), showing dress during the novitiate at puberty.

able minuteness. He had hoped to be able to push on as far as Nsundi, upwards of 100 miles beyond the Yellala, but the difficulties thrown in his way by the chiefs on whose expensive favour he was dependent, compelled him to return. In a chapter on "The Slaver and the Missionary on the Congo River," he records opinions which are well deserving the attention of all who not only wish well to the native African, but who desire that the best means be taken for developing the immense resources of that continent, and of tropical countries generally. He concludes "with the hope that the great Nzadi, one of the noblest and still the least known of the four principal African arteries, will no longer be permitted to flow through the White Blot, a region unexplored and blank to geography as at the time of its creation, and that my labours may contribute something, however small, to clear the way for the more fortunate explorer." There can be no doubt that his labours, short as his time was, have added materially to our knowledge of the region visited, and his work must henceforth be regarded as one of the chief authorities, not only on the river and its geography, but on its people, and to a considerable extent its natural history and meteorology. Like all Capt. Burton's narratives, it is complete and comprehensive, and includes far more than the mere title would lead us to expect; it cannot fail to greatly interest and instruct every intelligent reader.

An excellent chart of the river from the sea to the rapids accompanies the second volume, and the illustrations to both volumes add to its value and interest. Appended are some meteorological data, a list of plants collected in the Congo, at Dahome, and the island of Annabom, and a list of heights of stations on the Congo computed from observations made by Capt. Burton.

THE GERMAN NORTH SEA COMMISSION

Jahresbericht der Commission zur wissenschaftlichen Untersuchung der deutschen Meere in Kiel für die Jahre 1872, 1873. Im Auftrage des Königlich Preussischen Ministeriums für die landwirthschaftlichen Angelegenheiten, herausgegeben von Dr. H. A. Meyer, Dr. K. Möbius, Dr. G. Karsten, Dr. V. Hensen, Dr. C. Kupffer. 1 Abtheilung. (Berlin, 1875.)

THE Prussian Minister of Agriculture has just published Part I. of the Report of the Commission appointed to inquire into the scientific conditions of the German Ocean at Kiel (for the years 1872, 1873). This Report forms a very important document, filling a small folio volume of 170 pages, with 12 plates and a chart. The editors are Drs. H. A. Meyer, K. Möbius, G. Karsten, V. Hensen, and C. Kupffer. The Report on the currents, temperature, and specific gravity of the sea-water, based on 255 observations made from July 21 to Sept. 9, 1872, is by Dr. H. A. Meyer, and to it there is appended a memoir "On the Air in Sea-water," by Prof. Dr. Oscar Jacobsen. The marine flora of the district is reported on by Drs. Magnus and Schmidt. The only Phanerogams met with were *Zostera marina* and *Z. nana*, and *Potamogeton pectinatus*. Of Algæ, excluding the Diatoms, 116 species are recorded. Of these, *Callithamnion membranaceum* and *Chytridium tumefaciens* are described by Dr. Magnus as new species; the former was found growing over the stems of *Sertularia abietina*, between Sprogoe and Corsoer, in from twenty to thirty fathoms, the latter protruding from the cells of *Ceramium flabelligerum*; these new species are well illustrated in two plates. The presence of claspers is noticed in *Plocamium coccineum* intertwining between Annelid tubes. *Hildebrandtia rosea*, Kütz., is held to be quite a distinct form from *H. rubra*, Meneg., though by Harvey it and *H. sanguinea*, Kütz., were all regarded as one and the same thing. *Hapalidium confervicola*, Kütz., is recorded, but nothing added to clear up our ignorance of this curious little alga. *Bonnemaisonia asparagoides*, Ag., was found bearing both Conceptacles and Antheridia on the same stem. *Myrionema orbiculare*, J. Ag., is the name given with much doubt to a form found very common on the sea-grass. The plant is not figured, but appears to differ from any known species of Myrionema: if proved to be generically distinct, the author proposes the name Ascocylus for a genus to receive it. *Chytridium tumefaciens* is described as a new species, growing on the root-hairs and stem-cells of *Ceramium flabelligerum*, taken near Edinburgh. In the description of this species and in the

details given about *Ch. pinnulæ*, Cohn, the interesting question turns up as to what these Chytridia really are. Magnus treats them as a family of Algæ; Henfrey always, we believe, regarded them rather as the products of diseased protoplasm, if not modifications of the antheridial structures of some of the Confervoids. Their apparently common occurrence on Florideæ as well as on Confervoids, ought to enable this question to be definitely answered. Magnus is satisfied that the so-called Antheridea of *Callithamnion dispar* figured by Harvey in Tab. 227 of the "Phycologia Australica," are only Chytridia; certainly the figures represent a very antheridium-like structure, and the original dried specimen from which the figure was drawn is marked "fruit of an abnormal character," and on examination proves rather to favour Magnus's view.

Algologists, especially those engaged with the description of marine Algæ, have been rather neglectful of describing the minute details to be met with in the structure of the cells of Algæ. The arrangement of the cells, *inter se*, is necessarily studied, as on it the classification of the group depends; but the appearance and arrangement of the cell-contents will, we think, prove to be of as much importance in the investigation of the marine Algæ as it has proved to be in that of the unicellular freshwater forms.

Adolf Schmidt, of Aschersleben, describes the Diatomaceæ met with; there are three plates representing 134 forms or portions thereof. These are apparently photographs from drawings of the author.

The zoological results are given in eleven memoirs, with eight plates.

F. E. Schulze describes the Rhizopods and Cœlenterata; O. Schmidt the Sponges; K. Möbius and Bütschli the Echinoderms; K. Möbius the Vermes and Copepods; Kirchenpauer is to describe the Bryozoa, C. Kupffer the Tunicata, Metzger and H. A. Meyer the Mollusca, Metzger the Crustacea, and Möbius and Heincke the Fishes.

A long list of Foraminifera is given. H. B. Brady's papers on the synonymy of this group do not appear to have been consulted; an apparently new species of Gromia, about 8mm. in length, is described and figured. Some minute and doubtful-looking forms are described and figured as *Psammosphæra fusca*, n. g. et sp., *Storthosphæra albida*, n. g. et sp., and *Asterodiscus arenaceus* n. g. et sp.

Several new genera and species of Sponges are described and figured by O. Schmidt.

Among the Cœlenterates a new species of Aglaophenia (*A. moebii*) is figured and described, and *Kophobelemnon Leuckartii* is figured from a perfectly fresh specimen.

No very rare species among the Echinoderms is catalogued, and some common forms are absent.

Of the Vermes, seventy-six species of Annelida, fourteen of Turbellarea, five of Gephyrea, two of Chætognatha, and one Leech are enumerated. Although some of the species were collected off the very shores of Scotland, yet MacIntosh's works on the British Nemertians seem to have been overlooked in the determination of the species. A remarkable new form near Phascolosoma is described as *Crystallophrison nitens*. Almost the whole body is thickly encircled with colourless shining scales. The scales are somewhat wedge-shaped, with the narrow edge imbedded in the skin. This new species was dredged off the Silver Pit on the edge of the Dogger Bank. Further investigation may cause this species to be relegated to the Echinoderms. Three new species of worms are described.

The Second Part, containing the remaining orders, has just been published, and shall be reviewed in a second notice. To the British naturalists these Reports will be most valuable, but their form of publication may cause them to be easily overlooked; we have therefore noticed them somewhat in detail.

E. P. W.

OUR BOOK SHELF

The Origin of the Sun's Heat and the Chemical Constitution of the Matter of his System. (Troy, N.Y., 1875.)

THE author's name does not appear on the title-page of this pamphlet, so that it was not till we had inflicted ourselves with its contents that we discovered at the end the signature William Coutie. The author, judging from the present production, is referable to that class of visionary speculators which includes among its numbers circle, squarers, seekers for perpetual motion, and those who perform what we may call arithmetical juggles with the atomic weights of the chemical elements. First comes a preface containing an extract from Priestley's narrative of the discovery of oxygen to which we shall again refer; after which follows a page headed "From the Acid Relations of the Elements" 1871, from which we select the two first paragraphs:—"I have now examined all the well-known elements with so much care that I cannot believe any general mistake possible, and find they are all compounds of hydrogen and three others whose weights are exact multiples of the weight of hydrogen. It is probable, therefore, they are all hydrogen; but before saying more I would request the aid of your skill in proving the above by experiment or the favour of your remarks so that I may correct errors or make the subject more clear or complete." We now lay before our readers the state in which Mr. Coutie leaves the question of the origin of the sun's heat. After demonstrating to his own satisfaction that none of the existing hypotheses are sufficient to account for this supply of heat, the author makes a series of statements leading up to the following conclusion, which must be allowed to speak for itself:—"As the energy of the earth in its orbit is 26,900 miles, and the reversing force of gravity in a year is four times greater, or 107,600 miles, and the energy required to melt ice $142\frac{1}{2}^{\circ} \times 772$ feet $= 20$ miles, the reversing of its motion by gravity, if converted into heat, would melt the weight of itself of ice 5,380 times a year, and would melt a mass of ice equal to the mass of the sun in 60 years, or in the same time the whole known heat of the sun would. But if the sun's heat is the direct result of this action, the total heat of the sun ought not to be the equivalent of the reversed energy of the earth, but ought to be the equivalent of the whole system; but it is the equivalent of the earth's energy in orbit. We have therefore found what we sought for, and, as usual in such cases, it is not as we expected, and if we had hit it exactly, we would have found ourselves as far as ever from the end of that chain which stretches across infinity. We therefore withdraw our surmises and leave it as it is to the labours of others." The next section treats of "the nature and relations of the chemical elements," the research (?) which has led to the results announced having been undertaken because the atmosphere of the earth mainly consisting of nitrogen the author determined to find out what nitrogen was "with a view of finding the process by which the system is formed." It is probably out of respect for

his reader's feelings that the author does not at once disclose the astounding discovery which is to revolutionise chemical science, but leads the imagination gently up to it—first informing us that he has spent his life in trying to practise the precepts of Newton and Watt—then indulging in a series of disparaging remarks on modern chemical theory, which remarks we may state *en passant*, perfectly bristle with mis-statements. The discovery which we are now approaching is, we are told, the result of an attempt to apply mechanical principles to chemistry—then the author lets us into a *trait* of his personal character, after which comes the *dénouement*. Here it is: "What I claim is the discovery of an element whose weight is 5; it combines directly with nitrogen, and forms fluorine, chlorine, bromine, and iodine; with carbon, and forms oxygen and sillicon (*sic.*); and with hydrogen and forms sulphur and lithium." This extraordinary and pantogenic element "is best described as being the opposite of hydrogen," which "opposition constitutes its energy, and this energy constitutes, or rather will constitute the science of chemistry. Its combinations, direct and indirect, with hydrogen, carbon, and nitrogen, form all the other elements except phosphorus." In the new chemistry potassium is "ammonia acid," sodium, "ammonium acid," lithium, and sulphur, "hydrogen acids," &c. We find no evidence in the pamphlet of the method employed in discovering the new element—before listening to Mr. Coutie's vague speculations, chemists will be justified in calling upon him to produce his *Pantogen*, and describe its properties—at present it exists only on paper. We may appropriately conclude this notice with a quotation from Priestley, printed by the author in the preface to the present rhapsody. "For my own part I will frankly acknowledge that at the commencement of the experiments recited in this section, I was so far from having formed any hypothesis that led to the discoveries I made in pursuing them, that they would have appeared very improbable to me had I been told of them." Mr. Coutie lays this missile so very temptingly within our reach, that we may be excused for throwing it at his very fragile fabric.

The author's language does not properly fall into our province, but enough has been quoted to give our readers a fair specimen of its quality;—of Mr. Coutie's science no further criticism is necessary. R. M.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Theophrastus *versus* Millington

IN a letter in NATURE, vol. xiii. pp. 85, 86, Mr. Bennett appears to contend—

1. That if the credit of suggesting the true function of the stamens of flowering plants is to be attributed to either, it belongs to Grew rather than to Millington.

2. But that even the views of the former were not materially in advance of those of Theophrastus.

First, as to a bibliographical matter, Mr. Bennett speaks of a second edition of Grew's book. There is no such thing. The "Anatomy of Plants," 1682, contains four books; the first of these was published in 1671, the second in 1673, the third in 1675. The fourth book, not published till 1682, contains the celebrated passage on the sexuality of plants. This was read before the Royal Society, Oct. 26 [Nov. 9], 1676.

Turning to p. 172, we find Chap. V. "Of the Use of the Attire" (stamens).

In § 1 he alludes to the "Secundary use." This (book i. p. 39) he explains to be the provision of food for animals.

"We must not think that God Almighty hath left any of the whole Family of his Creatures unprovided for; but as the Great Master, some where or other carveth out to all; and that for a great number of these little Folk, He hath stored up their peculiar provisions in the Attires of Flowers; each Flower thus becoming their Lodging and their Dining-Room both in one."

Having given this proper recognition to the pious teleology of the time, he proceeds to remark in § 2 that "the Primary and chief Use of the Attire is such as hath respect to the Plant it self." He infers this very conclusively from the constant occurrence of stamens, even when the more conspicuous parts of the flower are wanting.

Then in the § 3 he tells us how Sir Thomas Millington gave him the clue—

"In discourse hereof [not as Mr. Bennett puts it, but on the nature of the Primary use of the Attire] with our Learned Savilian Professor, Sir Thomas Millington, he told me he conceived, That the Attire doth serve as the male, for the Generation of the seed."

In § 4 he proceeds: "I immediately reply'd, 'That I was of the same opinion;' and gave him some reasons for it, and answered some objections, which might oppose them."

Surely it is hardly necessary to comment on this charming little history. Grew gets the hint of the true solution from his friend, immediately perceives its importance, and eagerly proceeds to apply it to facts and to explain away apparent difficulties in accepting it. Surely scientific historians can hardly set aside Grew's own modest pleasure in attributing the discovery to Millington.

Next, however, we are told it is no discovery at all. It will be sufficient, in answer to this, to quote from p. 172 a few lines, omitting unnecessary analogies.

"The Globulets [pollen grains] and other small particles . . . in the Thecæ [anther-cells] are as the vegetable sperme which . . . falls down upon the seed-case [ovary] or womb, and so touches it with a prolifick virtue."

To say that Theophrastus in the fourth century B.C. possessed all the detailed information necessary to come so near the truth as Grew did in this statement, shows a wanton disregard for facts which it is sad to contemplate even though it be a momentary *lapsus* in the case of Mr. Bennett.

As to attributing all the credit in the matter to Camerarius, I cannot do better than appeal to an authority of which no one can question the impartiality.

Sprengel, in his "Historia rei Herbariæ," vol. ii. pp. 14, 15, has the following remarks:—

"Una fere cum Grewio Jacobus Bobartus, horti Oxoniensis præfectus, experimenta cum Lychnide dioica instituit (1681), quæ ovula in capsula obvia haudquaquam fœcunda esse, dum filamenta apicibus suis seu antheris careant, docuerunt. Id e Sherardi ore accepit Patricius Blair (" Botan. Essays," p. 243). Mox etiam Jo. *Raius* eamdem sententiam, de fœcundandi functione antherarum (1686) . . . uberrime et optime defendit. Unde elucet, *quantopere aberrent à veritate*, qui Rud. Jac. Camerarium inventorem credunt, licet plura hic argumenta pro sexuum differentia adduxerit. Cum historia spernat nationum arrogantiam, fatendum etiam est, Anglorum gloriam esse, quod primi tum phytotomiæ tum doctrinæ, quam sexualem dicunt, fundamenta jecerint."

There really is no case for discussion. Everyone is familiar with the fact that a large amount of time, paper, and ink may be wasted in contentions of this kind, and it is to be regretted that Mr. A. W. Bennett should employ his energies in furnishing additional experimental proof on this head. That the writer in NATURE and the reviewer of Sachs were each and severally justified in their allusion to Millington is also clear enough.

A. B. C.

Estimation of Fractions

THE question of "Personal Equation in the Tabulation of Thermograms," &c., which was recently considered in this journal, is but a portion of the general subject of the estimation of fractions, and the various influencing causes connected with it. Having made some experiments on this matter some time ago, and more fully of late, I subjoin some of the results, as it is a subject on which there seems but little accurately known in general, and which is important in thousands of readings made every day.

The experimental readings were made with appliances varying in each case, but in all cases the whole space or division was perfectly free from any visible marks besides the movable index, as they might bias or help the division; also the reader avoided noticing during each set of readings whether they were mostly + or — the truth, as this would bias the judgment. Moderate sunlight shining on white paper led to more accurate results than

diffuse daylight. Each result stated below is the mean of from ten to fifty readings under fairly favourable circumstances. d is used for the whole division or space on which the position of the index was estimated; and i is the inch, which is the unit used throughout.

(1) The first question is the average amount of error made by different persons with regard to the fraction of *division*; in fact, the personal variation of average error. This on a 10-inch space was—

By A	mean error	$d \div 112$
„ B	„	$d \div 60$
„ C	„	$d \div 50$
„ D	„	$d \div 36$
„ E	„	$d \div 21$

(2) The average amount of error with regard to the fractions of an *inch* (the *divisions* being too small to see the above fractions of them) were—

By A	on space of	$i \div 41$	mean error	$i \div 1890$
„ A	„	$i \div 139$	„	$i \div 3200$
„ C	„	$i \div 41$	„	$i \div 1640$

Under the best circumstances and reading with the right eye, A's mean error is only $i \div 5000$ on the space of $i \div 139$; and as the distance was about six inches, this is $\frac{1}{30000}$ of the distance; agreeing with the size of the smallest line visible, which is about $\frac{1}{25000}$ to $\frac{1}{80000}$ of the distance according to circumstances, but without any *shadow* to the wire examined. As to the observers, A has had practice lately in measuring; B had much practice some years ago; C and E are ladies of artistic tastes but unmetrical; D is moderately accustomed to measuring, but has a difference between the focus of his eyes. It would be highly interesting to have a good collection of statistics on this question, from among surveyors, mechanics, and the unmetrical classes. I proceed to readings for other points, made by A.

(3) The mean errors on spaces of various lengths stand thus:—

$10\,i$ space,	mean error	$d \div 112$	
$1\,i$ „	„	$d \div 89$	
($i \div 41$	„	$d \div 70$	read by right eye only)
$i \div 41$	„	$\therefore d \div 106$	if read by both eyes.

Thus the size of the division does not seem to much affect the estimation, the extreme difference being 4 : 5. If the angular width of a space exceed 5° it is not so easily grasped by the eye, though the error is not perceptibly increased till it exceeds 20°. The $i \div 41$ space was read with a magnifier, (× 3), so it was equivalent to $i \div 14$.

(4) The relative error of the first guess (or the numerical idea produced instantaneously at the first glance) and the most carefully considered readings stand thus:—

	First sight.	Carefully considered.	Ratio.	Distance of observer.
$10\,i$ space,	$d \div 55$	$d \div 114$	2·1 : 1	$110\,i$ or $11d$
$1\,i$ „	$d \div 54$	$d \div 78$	1·4 : 1	$18\,i$ „ $18d$
$i \div 139$ „	$d \div 13·6$	$d \div 13$	1 : 1	$6\,i$ „ $840d$

apparently indicating that the first guess is worst where the space is rather too wide angularly to be grasped by the eye at once; and therefore that the want of grasp is the defect corrected by consideration.

(5) The effect of looking at the space askew was tried by viewing it at 30° to either side; shifting sides ten times so as to avoid any gradual change in the quality of the reading, and so as to call up the contrast more strongly. The results of careful readings were:—

	In sum of errors. per cent. +	−
$10\,i$ space to right hand	31	69
$10\,i$ „ left „	45	55

and it was noticeable that the fraction nearest to the reader was invariably guessed smaller at first sight, than it appeared on careful examination, showing that the tendency to diminish the nearest side which is noticeable in the above percentage of the space to right hand, was still stronger at first, and was corrected by consideration.

So far the results have been independent of differences between the eyes, but it would seem that these are considerable from the following:—

(6) Comparison of the percentage of + and − errors of the two eyes separately; the sum of the amounts of errors being taken, and not the number of errors.

	Right eye. +	−		Left eye. +	−	
$1\,i$ space ...	55	45	...	58	42	white light
$1\,i$ „ ...	75	25	...	34	66	coloured light
$i \div 139$ „ ...	92	8	...	28	72	on silver
Mean ...	73	27		39	61	

The elements of this mean, and all others after, are weighted by the number of observations. As in all these readings the zero was to left hand, it would seem that each eye imagines the fraction on its own side smaller than it really is, this being in exact accordance with the effect produced by both eyes viewing the object from one side. See (5).

(7) When both eyes are used together the readings appear to be well balanced on an average:—

	per cent. +	−
$10\,i$ space	42	58
$1\,i$ „	59	41
Mean	53	47

The variations, however, of different series of readings are as wide as + 80, − 20; and + 20, − 80; this may be partly due to temporary rest of one eye, involuntarily; and to a slightly skew view of the space.

(8) The comparative amount of error of the two eyes stands thus:—

	Right	:	Left : :	
$1\,i$ space	100	:	109	white light
$1\,i$ „	100	:	120	coloured lights
$i \div 139$ „	100	:	150	on silver
Mean	100	:	121	

So 5 : 6 is the relative error of the right and left eyes.

(9) The relative errors of each eye separately and of both together are:—

	Right eye.	Left eye.	Mean of both.	Both used together.
$1\,i$ space ...	1·52 ...	1·64 ...	1·59 ...	1·00

So that the advantage of two eyes over one is more than $\sqrt[2]{2} : 1$, which it would be, if regarded as the mean of two readings; the excess of 1·59 over $\sqrt[2]{2}$ may be due to the restraint of keeping one eye shut. The accuracy seems to be about $\sqrt[1\frac{1}{2}]{\ }$ the number of eyes.

(10) A most important practical question is that of the influence of colour on the error of estimation. On trying this with coloured glasses the results were most unexpected.

	Relative amount of error. No glass.	Blue.	Green.	Red.
$1\,i$ space...	1·0	·81	1·06	1·70
$1\,i$ „	1·0	1·17	·88	1·23
Mean	1·0	·99	·97	1·46

The two series (each of ten readings with each colour) are given to show how far uniform the results are; they were read on different days, completely reversing the order of the four columns; and they were equally divided between the eyes, five by right and five by left.

I had expected that red would hold about the above relation to white; but that green, and especially blue, would have been worse; the colours were spectrally tolerably pure, except the blue, which contained some yellow. The badness of blue on the second trial in diffuse daylight is accounted for by a want of sufficient light; blue containing such a small proportion of light-rays.

So far I have remarked on those points which are perhaps, or probably, *not* due to idiosyncrasies; the question of partiality for certain digits is clearly a personal error, as has been demonstrated in NATURE; so it is not worth noting further, as its interest in *individual* cases is confined to the observer, who should try (being "forewarned") to be "forearmed," and so allow for it in reading; of course a series of statistics on it would have much interest.

(11) One point, however, which is probably alike in all is the relative amount of error in different parts of a scale; the mean I find to be thus:—

0 to 1	1 to 2	2 to 3	3 to 4	4 to 5	5 to 6	6 to 7	7 to 8	8 to 9	9 to 10
·65	1·53	1·36	1·52	1·47	1·54	2·2	1·30	1·09	1·14
−	+	−	+	+	+	+	−		

The + and − below show the mean error in that digit to exceed or fall short of the mean of all (1·44). The readings are on a 1-inch space. Thus it is apparent that the errors exceed the mean in the four middle digits, and fall short of it in the others with but one exception.

Now, the practical results which may be deduced from these data are as follows :—

From (1), that there is considerable variation in accuracy of estimation; yet, in persons fit to estimate, it may be put at $d \div 50$ up to $d \div 100$; and therefore as the maximum error in some hundreds of readings is only about three times the average error, it is useless (and, worse than that, confusing) to have divisions smaller than $20 \times$ the quantity required to be read. The application of this result to surveyors' rods, &c., would be very conducive to ease in distant reading.

From (2), that for ordinary eyes about $i \div 2000$ is the mean error of reading (with one eye only), and therefore that $i \frac{80}{2000}$ is the smallest size useful for reading with the naked eye; consequently any closer divisions than these ($\frac{1}{25}$ of an inch) are detrimental because of the greater confusion they introduce.

From (4), that in small divisions no consideration is necessary, as the first instinctive impression is nearly, or quite, as accurate as careful estimation.

From (5), that it is important not to look at a space askew; and that if unavoidable, careful consideration is desirable.

From (6), that in reading a series of observations of one amount, the right and left eyes should be used alternately to equalise the + and − errors.

From (8), that the right eye should be used in preference to the left.

From (9), that both eyes should be used wherever possible.

From (10), that red is the worst colour for measures, and that green or blue are as good as white; so that blue and white would probably be the best practically, and more distinct from vegetation, &c., than the green at a distance.

From (11), that more care is required in readings in the central portions of a space than at the ends. This is as true on spaces of $i \div 41$ as on $10\,i$ spaces.

Of course some of these results may be *personal* errors, and not generally true, but at least this notice will perhaps call the attention of those accustomed to estimation to the subject, and so elicit some definite statistics. There are many other interesting questions which I have not touched on here as being of less consequence, and not affecting practical questions so much as the foregoing results; these results it is to be hoped may lead to a better acquaintance with a subject of such practical importance. W. M. FLINDERS PETRIE

Bromley, Kent

The late Dr. von Willemoes-Suhm

IN the list of papers given in Prof. Wyville Thomson's obituary of the late Dr. von Willemoes-Suhm (NATURE, vol. xiii., p. 88), is omitted—"Notes on some young stages of Umbellularia, and on its Geographical Distribution;" ("Ann. and Mag. Nat. Hist.," 4th ser., vol. xv., p. 312, and pl. xviii. A.) This animal is a Pennatulid, and was obtained during the *Challenger's* cruise at depths from 1,375 to 2,600 fathoms. It is usually associated with decidely deep-sea forms.

To this may be added two papers which were read at the meeting of the Royal Society on Dec. 9th, "On the Development of *Lepas Fascicularis*, and the '*Archizoea*' of Cirripedia;" and "Preliminary Remarks on the Development of some Pelagic Decapoda." J. C. G.

Seasonal Order of Colour in Flowers

I HAVE often noticed during spring and summer that flowers appear to follow the spectrum from the blue of the wild hyacinth to the deep scarlet of our summer flowers. Will any of your correspondents tell me if during spring the actinic rays of the sun are in greater force, and whether these chemical rays are those which revivify seeds and plants after their winter's hibernation? During autumn I have noticed the same gradations in the colours of flowers. C. E. HERON ROGERS

Retford, Notts, Dec. 7

OUR ASTRONOMICAL COLUMN

ATLAS PLEIADUM, Σ 453.—Has anyone provided with a large telescope examined this object of late for duplicity? It appears very improbable that Struve's epoch of 1827 can have been put upon record through an illusion. We find in "Mensuræ Micrometricæ," p. 2 :—

1827·16 Position 107°·8 Distance 0″·79 Mag. 5 and 8.

It is then termed "duplex difficillima." On subsequent examination, 1830·25, the position was found to be 29°·2, and the distance only 0″·35. In 1831 and 1832 it was not seen double with the Dorpat refractor under a power of 600. Struve remarks, "si justa est anni 1827 notatio, quod vix dubitare potest, cum nullum observans dubium expresserim, motus in hoc systemate egregrie celer inesse debet." From 1840 to 1847, Mädler observing with the same instrument, says he always found the star "quite round," and to our knowledge a few years since the star was pronounced single after close scrutiny with more than one of the larger telescopes.

THE "GEGENSCHEIN" OF THE ZODIACAL LIGHT.—The last number of the "Monthly Notices of the Royal Astronomical Society" contains some interesting remarks by Mr. Backhouse, of Sunderland, bearing upon this phenomenon of the zodiacal light, as observed by him between the years 1871 and 1875, which are the more notable, as the observer does not appear to have been aware of its previous observation, and consequently the particulars he has placed upon record afford a very satisfactory confirmation of the existence of this feature of the light. The "gegenschein" consists in an elliptical patch of light almost directly opposite the sun's place, with the greater axis nearly in the plane of the ecliptic. Attention was first directed to it in the year 1854 by Herr Brorsen (the discoverer of the comet of short-period—February 1846)—while observing at Senftenberg in Bohemia. It may be inferred that it is generally difficult to distinguish or trace, with certainty, as even Prof. Heis, of Münster, with his excellent vision and long practice, did not succeed in verifying Brorsen's observations for several years (Zodiacallicht-Beobachtungen, Heis, 1875). Observations of the phenomenon will be found in various numbers of the "Astronomische Nachrichten." Brorsen thought this opposition-glow of the zodiacal light was more distinctly seen near the vernal than the autumnal equinox; the observations of Heis are in January, April, and in December. There are also observations by Schmidt at Athens, Schiaparelli at Milan, &c.

THE COMET OF 1729.—This very remarkable body presented a case which is quite unique in the history of these interesting denizens of the solar system. It was visible without telescopic aid, or with little optical assistance, at distances from the earth and sun not greatly inferior to those to which any other comet has been followed even with such an instrument as the Poulkova refractor, and it may be inferred was of very different constitution.

The comet was first detected by Sarabat, an ecclesiastic of the Jesuit order, at Nismes, on the 31st of July; the moonlight, which was then on the increase, prevented his seeing it on the following evenings until Aug. 8, when the moon being totally eclipsed, he recovered the comet and gave intimation of his discovery to Cassini at Paris, by whom it was observed on forty-four nights between Aug. 31 and Jan. 18 following. Cassini saw the comet without fixing its position until the end of the same month. While it was visible with difficulty to the naked eye, in a 16-feet telescope it appeared "en forme d'une petite étoile nébuleuse avec une chevelure autour d'elle, dont l'étendue paraisait au moins aussi grande que le diametre de Jupiter, vu avec une pareille lunette." This is about the extent of our information relating to the aspect of the comet.

The best orbits are those of Burckhardt (hyperbola and parabola), published in the "Connaissance des Temps" for 1821. If we employ the parabolic elements we find the following distances of the comet from the sun and earth expressed in units of the earth's mean distance from the sun :—

12h G.M.T.	Distance from Sun.	Distance from Earth.
1729, July 31	4·065	3·121
,, Aug. 8	4·072	3·134
1730, Jan. 18	4·452	5·152
,, ,, 31	4·499	5·225

For comparison with these distances take the case of the great comet of 1861, which was observed by Mr. Otto Struve at Poulkova till 1862, May 1, when its distance from the sun was 4·46, and from the earth 4·70; or that of Mauvais's comet of 1847, followed by Bond with the great refractor at Cambridge, U.S., till 1848, April 21, and then distant from the sun 3·85, and from the earth 4·40; or again, the case of the celebrated comet of 1811, last seen by Wisniewsky at Novo-Tcherkask, 1812, August 17, when the radius-vector was 4·54, and the distance from the earth 3·50.

RÜTIMEYER ON TRACES OF MAN RECENTLY DISCOVERED IN THE INTERGLACIAL COAL-BEDS OF SWITZERLAND

THE last number of the *Archiv für Anthropologie* contains a short but important article by the eminent zoologist of Basle, Prof. Rütimeyer, on some traces of man recently discovered in the interglacial coal-bed at Wetzikon. Escher von der Linth first called attention to the fact that at several places in East Switzerland, especially on the eastern shore of Lake Zurich from Wetzikon to Utznach, and again in the neighbourhood of the Lake of Constance, there are beds of coal, which are not only covered by, but which also repose on, well-marked glacial deposits, thus clearly proving the existence of more than one period of extreme cold, as first remarked by Morlot, and since confirmed by many observers, and especially by Geikie.

These interglacial coal-beds contain numerous remains of plants and animals, among the most interesting being those of *Elephas antiquus* and *Rhinoceros merkii*. The remains of plants are indeed so numerous that Dr. Scheuermann, of Basle, has been in the habit of breaking up himself all the coal used as fuel in his house, in search of vegetable remains. In doing so he was struck on one occasion by observing a number of pointed rods lying side by side, and he placed the block of coal containing them in the hands of Prof. Rütimeyer.

Prof. Rütimeyer has now given a description and figures of these rods, from which it is clear that they have been intentionally pointed, and that they formed a portion of rough basket or wattle work. They are four in number, and are closely embedded in the coal, which they precisely resemble in colour, while the texture is that of the ordinary wood found in these coal-beds. Moreover, as is usual in such cases, the stem has been compressed, so that the section is not circular but oval. According to Prof. Schwendener, the wood is that of *Abies excelsa*. The points bear evident traces of cutting, while at one part of the rods are marks as if of a string wound round and round them. Here, then, we appear to have clear evidence of the existence of man during one of the warm intervals of the glacial epoch. J. L.

THE THEORY OF "STREAM LINES" IN RELATION TO THE RESISTANCE OF SHIPS *

III.

IN this treatment of the propositions concerning the flow of fluid through pipes, I have at length laid the necessary foundation for the treatment of the case of the flow of an infinite ocean past a submerged body. I have shown these propositions to be based on principles which are undeniable, and the conclusions from which, when in any way startling or paradoxical, you have seen confirmed by actual experiment.

I have dealt with the case of a single stream of uniform sectional area (and therefore of uniform velocity of flow) enclosed in a pipe of any path whatever; I have dealt with the case of a single stream of very gradually varying sectional area and velocity of flow; and I have dealt with the case of a combination (or faggot, as it were) of such streams, each to some extent curved and to some extent varying in sectional area, together composing the whole content of a pipe or passage having enlargements or contractions in its course; and in all these cases I have shown that, provided the streams or pipe-contents finally return to their original path and their original velocity of flow, they administer no total endways force to the pipe or channel which causes their deviations.

I am now going to deal with a similar combination of such streams, which, when taken together, similarly constitute an infinitely extended ocean, flowing steadily past a stationary submerged body; and here also I shall show that the combination of curved streams surrounding the body, which together constitute the ocean flowing past it, return finally to their original direction and velocity, and cannot administer to the body any endways force.

The argument in this case is, in reality, precisely the same as that in the case of the contractions and enlargements in pipes which I have already dealt with; for, in fact, the flow of the ocean past the stationary submerged body is only a more general case of the flow of fluid through a contracted pipe; but, though the cases are really the same, there is considerable difference in their appearance; and therefore I will proceed to point out how the arguments I have already used apply equally to this case.

Every particle of the fluid composing the ocean that passes the body must undoubtedly follow some path or other, though we may not be able to find out what path; and every particle so passing is preceded and followed by a continuous stream of particles all following the same path, whatever that may be. We may, then, in imagination, divide the ocean into streams of any size and of any cross-section we please, provided they fit into one another, so as to occupy the whole space, and provided the boundaries which separate the streams exactly follow the natural courses of the particles.

I before suggested a similar conception of the constitution of the ocean flowing past the stationary body, and there pointed out that the streams forming this system must not only be curved in order to get out of the way of the body, but might each require to have to some extent a different sectional area, and therefore a different velocity of flow at different points of their course. If we trace the streams to a sufficient distance ahead of the body, we shall there find the ocean flowing steadily on, completely undisturbed by, and as we may say ignorant of, the existence of the body which it will ultimately have to pass. There, all the streams must have the same direction, the same velocity of flow, and the same pressure. Again, if we pursue their course backwards to a sufficient distance behind the body, we shall find them all again flowing in their original direction; they will also have all resumed their original velocity; for otherwise, since the velocity of the ocean as a whole cannot have changed, we should have a number of parallel streams having different velocities and therefore different pressures side by side with one another, which is an impossible state of things.*

Although, in order to get past the body, these streams follow some courses or other, various both in direction and velocity, into which courses they settle themselves in virtue of the various reactions which they exert upon one another and upon the surface of the body, yet ultimately, and through the operation of the same causes, they settle themselves into their original direction and original velocity. Now the sole cause of the original departure of each and all of these streams from, and of their ultimate return to, their original direction and velocity, is the submerged stationary body; consequently the body must receive the sum total of the forces necessary to thus affect them. Conversely this sum total of force is the only force which the passage of the fluid is capable of administering to the body. But we know that to cause a single stream, and therefore also to cause any combination or system of streams, to follow any courses

* Address to the Mechanical Section of the British Association, Bristol, August 25, 1875; by William Froude, C.E., M.A., F.R.S. President of the Section. Revised and extended by the author. Continued from p. 93.

* In an imperfect fluid it *is* possible to have parallel streams having different velocities and the same pressures side by side with one another, because, in an imperfect fluid, change of velocity may have been communicated by friction instead of by difference of pressure.

changing at various points both in direction and velocity, requires the application of forces the sum total of which in a longitudinal direction is *zero*, as long as the end of each stream has the same direction and velocity as the beginning. Therefore the sum total of forces (in other words the only force) brought to bear upon the body by the motion of the fluid in the direction of its flow, is *zero*.*

I have now shown how it is that an infinite ocean of perfect fluid flowing past a stationary body cannot administer to it any endways force, whatever be the nature of the consequent deviations of the streams of fluid. The question, what will be in any given case the precise configuration of those deviations, is irrelevant to the proof I have given of this proposition. Nevertheless it is interesting to know something, at least, of the general character which these deviations, or "stream-lines," assume in simple cases; therefore I have exhibited some in Figs. 26, 27, which are drawn according to the method explained by the late Prof. Rankine.

The longitudinal lines represent paths along which particles flow; they may therefore be regarded as boundaries of the streams into which we imagined the ocean to be divided.

We see that, as the streams approach the body, their first act is to broaden, and consequently to lose velocity, and therefore, as we know, to increase in quasi-hydrostatic pressure. Presently

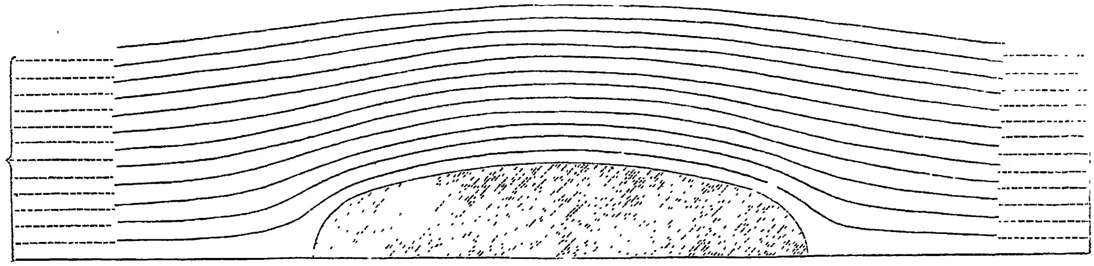


FIG. 26.

they again begin to narrow, and therefore quicken, and diminish in pressure, until they pass the middle of the body, by which time they have become narrower than in their original undisturbed condition, and consequently have a greater velocity and less pressure than the undisturbed fluid. After passing the middle they broaden again until they become broader than in their original condition, and therefore have less velocity and greater pressure than the undisturbed fluid. Finally, as they recede from the body they narrow again until they ultimately resume their original dimension, velocity, and pressure.

Thus, taking the pressure of the surrounding undisturbed fluid as a standard, we have an excess of pressure at both the head and stern ends of the body, and a defect of pressure along the middle.

We proved just now that, taken as a whole, the fluid pressures could exert no endways push upon the stationary body. We now see something of the way in which the separate pressures act, and that they do not, as seems at first sight natural to expect, tend all in the direction in which the fluid is flowing; on the contrary, pressure is opposed to pressure, and suction to

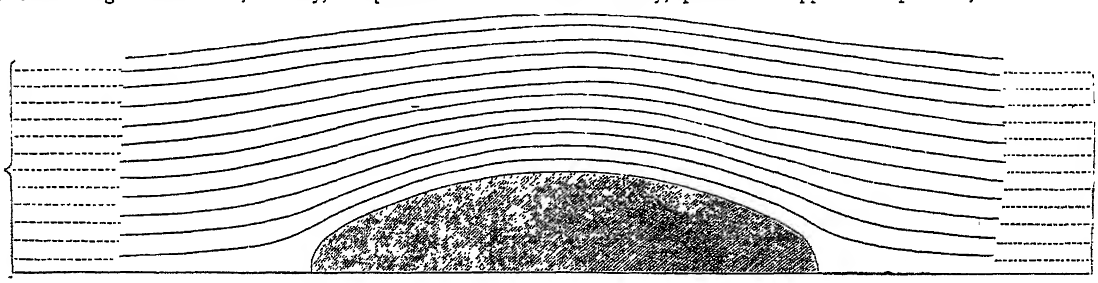

FIG. 27.

suction, and the forces neutralise one another and come to nothing, and thus it is that an ocean of perfect fluid flowing at steady speed past a stationary submerged body does not tend to push it in the direction of the flow. This being so, a submerged body travelling at steady speed through a stationary ocean of perfect fluid will experience no resistance.

We will now consider what will be the result of substituting an ocean of water for the ocean of perfect fluid.

The difference between the behaviour of water, and that of the theoretically perfect fluid is twofold, as follows:—

First. The particles of water, unlike those of a perfect fluid, exert a drag or frictional resistance upon the surface of the body as they glide along it. This action is commonly termed surface-friction, or skin-friction; and it is so well-known a cause of resistance that I need not say anything further on this point, except this, that it constitutes almost the whole of the resistance experienced by bodies of tolerably easy shape travelling under water at any reasonable speed.

Secondly. The mutual frictional resistance experienced by the particles of water in moving past one another, combined with

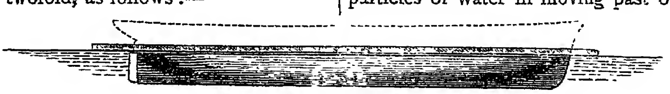

FIG. 28.

the almost imperceptible degree of viscosity which water possesses, somewhat hinders the necessary stream-line motions, alters their nice adjustment of pressures and velocities, and thus defeats the balance of stream-line forces and induces resistance. This action, however, is imperceptible in forms of fairly easy shape. On the other hand, angular or very blunt features entail considerable resistance from this cause, because the stream-line distortions are in such cases abrupt, and degenerate into eddies, thus causing great differences of velocity between adjacent particles of water, and great consequent friction between them.

"Dead water," in the wake of a ship with a full run, is an instance of this detrimental action.

So far we have dealt with submerged bodies only; we will now take the case of a ship travelling at the surface of the water. But first, let us suppose the surface of the water to be covered with a sheet of rigid ice, and the ship cut off level with her water-line, so as to travel beneath the ice, floating, however, exactly in the same position as before (see Fig. 28). As the ship travels along, the stream-line motions will be the same as for a submerged body, of which the ship may be regarded as the lower half; and the ship will move without resistance, except that due

* See Supplementary Note C.

to the two causes I have just spoken of, namely surface-friction and mutual friction of the particles. The stream-line motions being the same in character as those we have been considering, we shall still have at each end an excess of pressure which will tend to force up the sheet of ice, and along the side we shall have defect of pressure tending to suck down the sheet of ice. If, now, we remove the ice, the water will obviously rise in level at each end, so that excess of hydrostatic head may afford the necessary reaction against the excess of pressure; and the water will sink by the sides, so that defect of hydrostatic head may afford reaction against the defect of pressure.

The hills and valleys thus formed in the water are, in a sense, waves; and, though originated in the stream-line forces of the body, yet when originated they come under the dominion of the ordinary laws of wave-motion, and, to a large extent, behave as independent waves.

The consequences which result from this necessity are most intricate; but the final upshot of all the different actions which take place is plainly this—that the ship in its passage along the surface of the water has to be continually supplying the waste of an attendant system of waves, which, from the nature of their constitution as independent waves, are continually diffusing and transmitting themselves into the surrounding water, or, where they form what is called broken water, crumbling away into froth. Now, waves represent energy, or work done; and therefore all the energy represented by the waves wasted from the system attending the ship, is so much work done by the propellers or tow-ropes which are urging the ship. So much wave-energy wasted per mile of travel is so much work done per mile; and so much work done per mile is so much resistance.

The actions involved in this cause of resistance, which is sometimes termed "Wave-Genesis," are so complicated that no extensive theoretical treatment of the subject can be usefully attempted. All that can be known about the subject must, for the present, I believe, be sought by direct experiment.

Having thus briefly described the several elements of a ship's resistance, I will proceed to draw your attention more particularly to certain resulting considerations of practical importance. Do not, however, suppose that I shall venture on dictating to shipbuilders what sort of ships they ought to build: I have so little experience of the practical requirements of shipowners, that it would be presumptuous in me to do so; and I could not venture to condemn any feature in a ship as a mistake, when, for all I know, it may be justified by some practical object of which I am ignorant. For these reasons, if I imply that some particular element of form is better than some other, it will be with the simple object of illustrating the application of principles, by following which it would be possible to design a ship of given displacement, to go at given speed, with minimum resistance, in smooth water—in fact, to make the best performance in a "measured mile" trial.

I have pointed out that the causes of resistance to the motion of a ship through the water are: first, surface-friction; secondly, mutual friction of the particles of water (and this is only practically felt when there are features sufficiently abrupt to cause eddies); and thirdly, wave-genesis. I have also shown that these are the *only* causes of resistance. I have shown that a submerged body, such as a fish, or torpedo, travelling in a perfect fluid, would experience no resistance at all; that in water it experiences practically no resistance but that due to surface-friction and the action of eddies; and that a ship at the surface experiences no resistance in addition to that due to these two causes, except that due to the waves she makes. I have done my best to make this clear: but there is an idea that there exists a kind of resistance, a something expressed by the term "direct head-resistance," which is independent of the above-mentioned causes. This idea is so largely prevalent, of such long standing, and at first sight so plausible, that I am anxious not to leave any misunderstanding on the point.

Lest, then, I should not have made my meaning sufficiently clear, I say distinctly, that the notion of head-resistance, in any ordinary sense of the word, or the notion of any opposing force due to the inertia of the water on the area of the ship's way, a force acting upon and measured by the area of midship section, is, from beginning to end, an entire delusion. No such force acts at all, or can act; as throughout the greater part of this address I have been endeavouring to explain. No doubt, if two ships are of precisely similar design, the area of midship section may be used as a measure of the resistance, because it is a measure of the size of the ship; and if the ships were similar in every respect, so also would the length of the bowsprit, or the height of the mast, be a measure of resistance, and for just the same reason. But it is an utter mistake to suppose that any part of a ship's resistance is a direct effect of the inertia of the water which has to be displaced from the area of the ship's way. Indirectly the inertia causes resistance to a ship at the surface, because the pressures due to it make waves. But to a submerged body, or to the submerged portion of a ship travelling beneath rigid ice, no resistance whatever will, be caused by the inertia of the water which is pushed aside. And this means that, if we compare two such submerged bodies, or two such submerged portions of ships travelling beneath the ice, as long as they are both of sufficiently easy shape not to cause eddies, the one which will make the least resistance is the one which has the least skin surface, though it have twice or thrice the area of midship section of the other.

The resistance of a ship, then, practically consists of three items—namely, surface-friction, eddy-resistance, and wave-resistance.

Of these the first-named is, at least in the case of large ships, much the largest item. In the *Greyhound*, a bluff ship of 1,100 tons, only 170 feet long, and having a thick stem and sternposts, thus making considerable eddy-resistance, and at ten knots visibly making large waves, the surface-friction was 58 per cent. of the whole resistance at that speed; and there can be no doubt that with the long iron ships now built, it must be a far greater proportion than that. Moreover the *Greyhound* was a coppered ship; and most of the work of our iron ships has to be done when they are rather foul, which necessarily increases the relative importance of the surface-friction item.

The second item of resistance, namely the formation of eddies, is, I believe, imperceptible in ships as finely formed as most modern iron steamships. Thick square-shaped stems and stern-posts, more especially the latter, are the most fruitful source of this kind of resistance.

The third item is wave-resistance. To this alone of the three is the stream-line theory directly relevant, and here, as we have seen, it rather suggests tendencies, than supplies quantitative results, because, though it indicates the nature of the forces in which the waves originate, the laws of such wave-combinations are so very intricate, that they do not enable us to predict what waves will actually be formed under any given conditions.

There are, however, some rules, I will not call them principles, which have to some extent been confirmed by experiment. At a speed dependent on her length and form, a ship makes a very large wave-resistance. At a speed not much lower than this, the wave-resistance is considerably less, and at low speeds it is insignificant. Lengthening the entrance and run of a ship tends to decrease the wave-resistance; and it is better to have no parallel middle body, but to devote the entire length of the ship to the entrance and run, though in this case it be necessary to increase the midship section in order to get the same displacement in a given length.

With a ship thus formed, with fair water-lines from end to end, the speed at which wave-resistance is accumulating most rapidly, is the speed of an ocean-wave the length of which, from crest to crest, is about that of the ship from end to end.

I have said we may practically dismiss the item of eddy-resistance. The problem, then, to be solved in designing a ship of any given size, to go at a given speed with the least resistance, is to so form and proportion the ship that at the given speed the two main causes of resistance, namely surface-friction and wave-resistance, when added together, may be a minimum.

In order to reduce wave-resistance we should make the ship very long. On the other hand, to reduce the surface-friction we should make her comparatively short, so as to diminish the area of wetted skin. Thus, as commonly happens in such problems, we are endeavouring to reconcile conflicting methods of improvement; and to work out the problem in any given case, we require to know actual quantities. We have sufficient general data from which the skin resistance can be determined by simple calculation; but the data for determining wave-resistance must be obtained by direct experiments upon different forms to ascertain its value for each form. Such experiments should be directed to determine the wave-resistance of all varieties of water-line, cross section, and proportion of length, breadth, and depth, so as to give the comparative results of different forms as well as the absolute result for each.

An exhaustive series of such experiments could not be tried with full-sized ships; but I trust that the experiments I am now

carrying out with models, for the Admiralty, are gradually accumulating the data required on this branch of the subject.

I wish in conclusion to insist again, with the greatest urgency, on the hopeless futility of any attempt to theorise on goodness of form in ships, except under the strong and entirely new light which the doctrine of stream-lines throws on it.

It is, I repeat, a simple fact that the whole framework of thought by which the search for improved forms is commonly directed, consists of ideas which, if the doctrine of stream-lines is true, are absolutely delusive and misleading. And real improvements are not seldom attributed to the guidance of those very ideas which I am characterising as delusive, while in reality they are the fruit of painstaking, but incorrectly rationalised, experience.

I am but insisting on views which the highest mathematicians of the day have established irrefutably; and my work has been to appreciate and adapt these views when presented to me.*

No one is more alive than myself to the plausibility of the unsound views against which I am contending; but it is for the very reason that they are so plausible that it is necessary to protest against them so earnestly; and I hope that in protesting thus, I shall not be regarded as dogmatic.

In truth, it is a protest of scepticism, not of dogmatism; for I do not profess to direct anyone how to find his way straight to the form of least resistance. For the present we can but feel our way cautiously towards it by careful trials, using only the improved ideas which the stream-line theory supplies, as safeguards against attributing this or that result to irrelevant or, rather, non-existing causes.

(*To be continued.*)

* I cannot pretend to frame a list of the many eminent mathematicians who originated or perfected the stream-line theory; but I must name, from amongst them, Prof. Rankine, Sir William Thomson, and Prof. Stokes, in order to express my personal indebtedness to them for information and explanations, to which chiefly (however imperfectly utilised) I owe such elementary knowledge of the subject as alone I possess.

THE CHANNEL TUNNEL—SUBMARINE EXPLORATIONS †

AN important Report in connection with the proposed Channel Tunnel has just been issued by the French Submarine Railway Association, giving the results of a detailed examination of the French coast, and of soundings taken in the bed of the Channel during the past autumn. The subject has on previous occasions been referred to in the pages of this Journal; ‡ but before giving an account of the recent explorations it may be well briefly to refer to what has already been done.

A tunnel under the Channel has long been talked of, and many schemes have been brought forward; but the only one which has been received with general favour is that of Sir J. Hawkshaw, who proposes to carry the tunnel from the South Foreland to near Sangatte. In 1864 Mr. E. C. H. Day was employed by Sir J. Hawkshaw to make a geological survey of the neighbouring coasts with the view of obtaining some guide as to the probable outcrops beneath the Channel; the map thus produced was published with the early statements of the Company. In 1866 borings were made on both coasts to prove the succession of the strata at points near which the tunnel was to leave the shores; that on the shore at St. Margaret's Bay traversed 240 feet of upper chalk and 296 feet of lower chalk, and was stopped in the gault at a depth of 567 feet from the surface. The boring on the French coast was put down a little north of Sangatte; it passed through 70 feet of drift-sand, &c., 190 feet of chalk with flints, 284 feet of chalk without flints, and was stopped at a depth of 551 feet from the surface owing to an accident to the hole. This boring, therefore, did not reach the Upper Greensand, and the depth to this bed was estimated from information obtained in the deep boring at Calais. This accident was unfortunate, because, owing to a misreading of the accounts of the Calais boring, I believe that the thickness of the lower chalk was considerably over-estimated at Sangatte.

At a later date soundings were taken along the line of the proposed tunnel, and at varying distances to the south-west of that line; the instrument used penetrated the bottom for a few inches, and brought up specimens of the ocean floor. The larger number of these were from the superficial covering (sand, &c.), but many brought up pure chalk, and several specimens of gault were obtained near the English coast. This examination was not detailed enough to test very severely the geological map; but so far as the information went it tended to confirm the previous surveys; the only difference then observed was that the gault appeared to run rather further north towards Dover than would have been expected. But it may be doubtful whether such small borings always give trustworthy evidence on this point. The lowest beds of chalk are very clayey, and when thoroughly saturated with water are often quite dark and bluish in colour. In fact, these lowest beds, when freshly exposed in railway cuttings, have been at first mistaken for gault by good observers.

No further explorations have been made till the present year. The concession to the Company was voted by the National Assembly on the 2nd of August, and was signed by Marshal MacMahon on the 5th of the same month. Anticipating the result of the vote the Company commenced work in July. By means of a steamer, soundings were taken on the bed of the Channel. A tube was fixed at the bottom of the sounding-lead, by means of which specimens were brought up. Various appliances were used, but tubes of from 20 to 22 millimètres in diameter, and 15 to 20 centimètres long were found to give the best results. The number of soundings taken per day varied according to circumstances; it averaged 70 or 80, but sometimes reached 100.

The Commission entrusted with the explorations was presided over by M. Lavalley, and consisted of MM. Delesse, Potier, and Lapparent as geologist, and M. Larousse as hydrographer. The position of the boat was at each observation carefully determined by bearings on landmarks. Every specimen collected was marked and sent to Paris for future determination and reference. In all 1,522 soundings were made; 753 specimens of the bottom were obtained, of which 335 have been determined with certainty.

The results show that the outcrop of the gault makes a bend to the north just off the French coast. The Commission carefully tested this district by divers (the water being shallow), and they believe that this bend is due to an anticlinal fold of the strata, and not to a fault; the dip of the beds probably not exceeding 10°. From the French waters across the Channel as far as the observations went (to within about five miles of the English coast), the beds run with great regularity. Supposing the observations to be trustworthy, there cannot be a transverse fault of any magnitude along this line. But the outcrop of the gault lies further to the south than was expected; in fact, it is striking direct for Folkestone church. As before remarked, the earlier observations showed the gault near the English shore to run a little further to the north than was expected; so that here there must either be a roll of the beds or a fault with a downthrow to the south-east.* The engineers point out the importance of following up this inquiry, and doubtless it will be done as early as possible next year.

No one has expected to tunnel through twenty miles of chalk without meeting with a fault, and therefore the possibility of encountering one near the English shore need cause no uneasiness. It may give no extra trouble, or yield no more water than the rest of the work. Faults are often cut in coal workings under the sea, but they do

† Chemin de Fer Sous-Marin entre la France et l'Angleterre. Rapports sur les Sondages exécutés dans le Pas de Calais en 1875. Fol., Paris, 1875.

‡ Vol. i. pp. 160, 303, 631. Prof. Hébert made a communication to the meeting of the British Association at Bristol, on the folds likely to occur beneath the Channel. (See NATURE, vol. xii. p. 407.)

* Mr. G. H. Kinahan, writing to me last year, expressed his belief in the existence of a considerable fault in the Channel, with a downthrow to the south-east.

not cause any uneasiness or extra expense on this account. For the rest the explorations are highly satisfactory, and the extension southwards of the gault is no disadvantage.

Besides the outcrop of the "craie glauconieuse," which almost corresponds to the outcrop of the gault, the engineers profess to have determined the line between the "craie de Rouen," or lower chalk, and a nodular bed which lies above it. One cannot help feeling doubts as to the possibility of this being done, with any degree of certainty, by the means at their disposal. It is, however, important to fix if possible the breadth of outcrop of one of the beds; because, the thickness being known, we can thus estimate the dip. The soundings, as interpreted by the Commission, show that the dip is greatest near the French coast, and that it gets gradually less towards the English coast. Borings at and near Calais show that the dip there lessens towards the north, and by analogy it may be inferred that towards the proposed tunnel the beds under the sea will also lessen in dip.

It is proposed to continue the soundings further north, with the view of fixing exactly the outcrops of the higher beds of chalk. As the report states, if these attempts are successful we shall know exactly, and not by hypothesis, the geological structure of the strait. We shall know too the geological structure of the bed of the sea better than we now know that of much of the dry land; for no geologist has attempted to trace out all the chalk divisions on either coast; they have been measured in the cliffs, but not mapped in detail inland.

The Commission recommends that a new and larger borehole be put down at Sangatte with the view of testing the water-bearing qualities of the chalk at different levels, and of proving the exact thickness of the chalk. It is proposed to carry the hole through the gault and into the Palæozoic rocks, with the view of testing whether these rocks are absorbent, and capable of carrying off water from the tunnel. The *possibility* that they may serve this purpose has been suggested by the present writer.* The Commission proposes to test the point, but observes that it is unlikely to be the case. The Palæozoic rocks yield water near Lille, though they have not done so at Calais and Harwich; this may be because the old rocks are only slightly permeable, and if so they will be only slightly absorbent. It was on this gronnd that Prof. Prestwich proposed to tunnel through the Palæozoic rocks.

The Commission has examined in great detail the chalk of the French cliffs, and the results of their observations are drawn in a section in this Report. W. Phillips in 1819 published a description of the cliffs on each side of the Channel. So far as his observations go they are exact, and need no correction; later observers having only worked out the beds in greater detail. The Report refers in terms of well-merited praise to this early work of Phillips, but it is slightly in error in stating that English geologists have done nothing since his time. The Geological Survey has been over the ground; the maps are published, and descriptions have been given by Mr. Whitaker. Mr. Dowker has also studied the higher chalk of Kent.

The Report contains a large chart showing the positions of all the soundings, and is further illustrated by sections and diagrams in the text. It is one of the most valuable publications which has yet appeared on this important subject, and is well worthy of the reputation of its distinguished authors. W. TOPLEY

* Quart. Journ. Science, April 1872.

NOTES

IT is with great regret that we hear of the death of Mr. R. C. Carrington, F.R.S., whose name is so intimately associated with solar observation, which indeed he was the first to start in this country. His failing health of late years, was no doubt due to his unceasing assiduity. For seven and a quarter years scarcely a single day passed that Mr. Carrington did not make an observation on sun-spots. The book which contains these observations, published by Williams and Norgate, partly at the expense of the Royal Society, is one of the astronomical works of which England has good cause to be proud. Up to his death Mr. Carrington was engaged in designing and planning instruments of more than curious construction, which he intended eventually to fit up in his observatory. Before he took up sun-spot observations he constructed charts and a catalogue of the circumpolar stars, into which he introduced the most minute accuracy. The "Redhill Catalogue" will long be consulted by the practical astronomer.

AT the meeting of the Royal Society on Thursday last, the following Fellows were appointed Vice-Presidents of the Society for the ensuing year:—Mr. William Spottiswoode, M.A.; Prof. J. Couch Adams, LL.D.; Captain F. J. O. Evans, R.N.; Dr. A. C. Günther, M.A., and Dr. William Pole, C.E.

COUNT SALVADORI, of the Royal Museum of Turin, has recently described in the "Annals of the Civic Museum of Natural History of Genoa," a large new rapacious bird, discovered by the naturalist D'Albertis in New Guinea, which he proposes to call *Harpyopsis novæ Guineæ*. The existence of this bird probably gave rise to the exaggerated report of the enormous "eagles" which were seen during the voyage up an unexplored river in New Guinea, recently published in the *Daily News* (NATURE, vol. xiii., p. 76.)

AT Monday's meeting of the Royal Geographical Society the paper read was by Mr. Octavius Stone, on the discovery of the Mai-Kassa or Baxter River, New Guinea. Mr. Stone sailed up the river in the missionary vessel *Ellangowan*, and the account given is essentially the same as that which has already appeared in our journal, though Mr. Stone seems to make no mention of the monstrous bird referred to by Mr. Smithurst (vol. xiii., p. 76.) At the furthest point reached (about 100 miles from the mouth) the Mai-Kassa was ten yards wide, although the depth was still two fathoms. Even so far in the interior it is influenced by four half-tides daily, as when the first waters meet the sea a rebound is caused, so that the second half-tide is of slightly longer duration than the first. The rise of tide at the furthest point is from 3 feet to 4 feet, but its waters are entirely fresh. It is on account of the sluggish motion and continued depth of this river that Mr. Stone believes it may run for another 100 miles into the interior. A boa-constrictor was shot, 15 ft. 3 in. long, having a protuberance in his body 14½ inches in diameter, which, when cut open, proved to be the body of a whole kangaroo only partially digested.

LAST Saturday's meeting at Bristol, under the presidency of the Mayor, in connection with the proposed University College of that city, was quite a successful one. A constitution, sufficiently comprehensive, was adopted, on the basis of which the general committee were empowered to incorporate the college, and to prepare the necessary legal documents. Thus the college may now be regarded as fairly set afloat, and judging from the enthusiasm of the meeting we should think it likely that it will soon be at work. Out of 40,000*l*. which were wanted, 22,000*l*. have been collected mainly in Bristol and neighbourhood; besides which, it is stated, some colleges at Oxford are willing to give 1,000*l*. a year towards University teaching at Bristol. Among those who spoke were Prof. Jowett and the Rev. Mr. Robinson, of New College, Oxford.

WE are authoritatively informed that the delay which has this year taken place in the zoological publications of the Linnean Society will not occur again, and has depended on causes over which the zoological secretary has no control, and for which he is not responsible.

PROF. MAX MÜLLER has been elected a Knight of the Order of Maximilian for Science and Art. The election to this Order, as to the Order *pour le mérite*, rests with the Knights themselves, and is confirmed by the King of Bavaria.

OUR letter last week (p. 106) on the late Dr. Stoliczka's collection of mammals was from Major H. H. Godwin-Austen, Deputy Superintendent of the Topographical Survey of India.

WE take the following from the *Pall Mall Gazette*:—In his last book ("Ziele und Wege der heutigen Entwickelungsgeschichte") Prof. Haeckel, the great apostle of Evolutionism in Germany, announces the discovery of the following law:—"In all the magnificent scientific institutes founded in America by Agassiz, the following empirical law, long recognised in Europe, has been confirmed,—viz. that the scientific work of these institutes and the intrinsic value of their publications stand in an inverse ratio to the magnitude of the buildings and the splendid appearance of their volumes." "I need only refer," he adds, "to the small and miserable institutes, and the meagre resources with which Baer in Königsberg, Schleiden in Jena, Johannes Müller in Berlin, Liebig in Giessen, Virchow in Würzburg, Gegenbaur in Jena have not only each advanced their special science most extensively, but have actually created new spheres for them. Compare with these the colossal expenditure and the luxurious apparatus in the grand institutes of Cambridge, Leipzig, and other so-called great universities. What have they produced in proportion to their means?"

IT is stated in communications received by the Scottish Meteorological Society from their observers in Iceland, that the volcanic eruptions continued till the 18th October, but since then no fresh eruptions have been noted. Up to the 4th inst. the weather in Iceland continued to be remarkably mild, little snow had fallen, and frost had been only of occasional occurrence.

The *Times* Naples correspondent, writing under date Dec. 7, gives details concerning the state of Vesuvius, which confirm Prof. Palmieri's prognostication referred to by us in a recent number (p. 94). The mountain is evidently in a state of great internal agitation, and all the circumstances seem to forbode an early eruption. There have been several earthquake shocks recently in Naples and the surrounding region, one of the most alarming being at 3.24 A.M. on the 6th. Prof. Palmieri does not, however, consider Vesuvius to be the centre of the disturbances; he is inclined to place it at Puglia.

A BOMBAY telegram states that a severe shock of earthquake was felt on Sunday last at Lahore and in the Peshawur district. Several lives were lost.

NEWS has been received lately from Gen. Nausouty and one of his friends who are spending the winter on the Pic du Midi, one of the most elevated mountains in the Pyrenean range, for the purpose of registering meteorological phenomena. The temperature of 22° cent. below zero C. was recorded during the recent cold weather. The observers, however, felt no inconvenience, as the interior temperature of the observatory was always kept above + 10° C. Last year this was impossible, and the observers were obliged to give up their task and to return to warmer regions, being almost starved and frozen to death when retreating.

ON December 5, at two o'clock in the afternoon, a slight earthquake was felt at Blideh, province of Algiers; the duration was only two seconds. A great storm was raging.

THE *Gazetta Medica di Roma*, which has reached its fifth number, is a journal we would commend to the attention of those interested in scientific medicine. It is well conducted and printed, and the original articles seem to us to be of a high class, creditable altogether to Italian medical research.

THE Auckland (New Zealand) *Southern Cross* hears from Taupo that Mount Tongariro is in a high state of activity, throwing stones for a distance of eight miles from the crater. All the springs and geysers in the neighbourhood are in full play, and some wonderful sights may be seen in this extraordinary region.

AT Rotherham the Committee formed in the town to conduct the Science Classes contains the following: a Clergyman of the Established Church holding the rank of Doctor of Divinity, a Unitarian Minister, a Wesleyan Minister, a Primitive Methodist Minister, and an Independent Minister. We do not need to point the moral.

A NEW periodical has been started in Paris, under the title of *Tour de France*. It records excursions within the borders of the French Republic, and contains maps and illustrations. It will do for France what the *Tour du Monde* does for foreign parts, its aim being to remind Frenchmen of the natural resources and beauties of their own land.

IN the beginning of 1876 there will be opened at Paris, in the Champs Elysées Palace, an exhibition, including all the objects relating to the exploitation of railways and electric telegraphs. This exhibition will interfere in no way with the contemplated Electrical Exhibition which is to take place in 1877.

MR. CASELLA, the well-known scientific instrument-maker, has sent us a specimen of a compass which will be a great boon to the many who are ignorant of the difference between the magnetic and the geographical poles, and of the fact that an ordinary compass points to the former and not to the latter, the difference in this country at present being about 19°. The great advantage of Mr. Casella's "unmistakable true north compass," is that it points to the true or geographical north, being corrected for use in the United Kingdom, and capable of adaptation to any locality in any part of the world. It is a card compass of beautiful workmanship, swings with perfect ease, and by means of a black cone on a white ground, the merest tyro can read it. It is made in various sizes, and sold at various prices, and deserves to come into extensive use.

THE projected programme of vegetable products issued by the Commission of the International Horticultural Exhibition, proposed to be held at Amsterdam in 1877, is one of the best, if not the best, we ever remember seeing. It contains a list of fourteen distinct articles, upon each of which information of the fullest description is asked, from a complete set of specimens of any particular plant of economic value through its various species or varieties down to the implements used in the collection or preparation of the product and the books or writings bearing on the subject. In the matter of vegetable fats and oils, as well as in paper materials, large fields of work present themselves, and much matter of great interest may be exhibited. If the exhibition is carried out in accordance with the designs of the projectors it cannot fail to be most successful and interesting.

TWO lectures, suited for a juvenile audience, will be given in connection with the Society of Arts, on Tuesday, January 4, and Tuesday, January 11, by Dr. W. B. Carpenter, F.R.S., on "The Wonders of the Microscope." the lectures will commence at 7 P.M., and will be illustrated by the oxyhydric and electric lights.

A SAD balloon accident occurred at Vincennes, near Paris, on the 8th inst. The balloon *Univers* having started at 11 o'clock in the morning descended with terrific force thirty-five minutes later from an altitude of 1,000 feet. The balloon was in charge of Eugene Godard, one of the most experienced French aëronauts. Eight persons were on board, amongst whom were Col. Laussedat and some officers who had made the ascent for topographical

purposes. Four persons were injured and the others experienced severe bruises. The real cause of the catastrophe is to be investigated officially by M. Giffard, the celebrated French engineer. At present it is supposed that the band of india-rubber which acts as a spring gave way under influence of the frosty weather.

THE Italian Geographical Society (the *Daily News* Roman correspondent telegraphs) held its first monthly meeting of the winter session on Sunday. Capt. Barrattieri read the report of the Society's expedition to the Tunisian Sahara last June. It gave interesting details of the journey to Gabes, to the Island of Gerba, and to other islands, described the country minutely, and proved the impossibility of the French project for connecting the Sahara with the Mediterranean by canal. The next paper, that of Deputy Caperio, on the latest explorations of Lake Victoria, dwelt on the importance of investigating the sources of the Nile between the mountains parallel to the coast and Lake Victoria. This was the task of the Italian expedition.

IN illustration of some remarks in the address of the president, Mr. H. R. Robson, of the Scottish Institution of Engineers and Shipbuilders, the number of the *Transactions* of that Society just published contains a large and carefully executed plate exhibiting a section of the Sub-Wealden bore-hole to the depth of 940 feet.

No. 166 of the *Notizblatt des Vereins für Erdkunde zu Darmstadt und des Mittelrheinischen geologischen Vereins* contains a detailed *résumé* of the meteorological observations made at Darmstadt during 1874, accompanied with a neat and cleanly constructed diagram showing the daily and monthly results; and also the maximum and minimum temperatures, rainfall, and fog at six stations, during September 1875, in the Grand Duchy of Hesse. Among the many points detailed in the summary for Darmstadt may be noted the dates of the last and the first snow in the course of the year, the last and first frost, the last and first frost-day, mean temperature being 32° or lower; the number of frost-days each month, and of summer-days, temperature being 77°·0, or higher, and the particular days on which thunder and other weather-phenomena occurred. From November to June the ozone was greatly in excess during the night, but during the other months the excess occurred during the day. Among other matters, there is an interesting table of the mortality during September last from various diseases, at thirteen towns in the Grand Duchy. The deaths from diarrhœa alone, which amounted to sixty-two, were a sixth of the whole. This high diarrhœa death-rate, which is three times greater than that of London during the same season, and the unequal manner in which these deaths, as well as deaths from phthisis, convulsions, and brain diseases, are distributed among the thirteen towns, suggest the desirableness of an inquiry into their sanitary conditions.

AT recent meetings of the Executive Committee of the British Pharmaceutical Conference, grants amounting in all to 75*l.*, were made to a number of chemists for the purpose of obtaining material to enable them to carry on scientific researches into the nature and properties of certain substances used in pharmacy.

THE additions to the Zoological Society's Gardens during the past week include a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Demerara, presented by Mrs. Sproston; a Tree Sparrow (*Passer montanus*), two Mountain Linnets (*Linaria flavirostris*), European, purchased; a West African Python (*Python sebæ*) from West Africa, presented by Mr. W. H. Berkeley.

AT the annual meeting on the 4th inst. of the Huddersfield Naturalists' Society, the Secretary read a satisfactory report. The number of members is 134, the finances are in a flourishing condition, and during the past year twenty-two papers have been read.

ON SOME PROPERTIES OF GALLIUM

IN a communication just made to the French Academy, M. Lecoq de Boisbaudran states that he has succeeded, after considerable labour, in obtaining salts of gallium sufficiently pure to give, in addition to the gallium spectrum, only faint traces of the zinc lines Zn α 144·62 and Zn γ 150·05.

After adding a few facts regarding mixtures of gallium and zinc, he proceeds to examine certain reactions of the pure salts.

1. The electric spectrum of chloride of gallium, a little concentrated, is very brilliant. The line 417 is much brighter than the line 404. The author did not observe any other line attributable to gallium; there certainly are none of notable intensity, under the conditions. The colour of the spark in chloride of gallium is a beautiful clear violet.

2. In the gas flame he got only the line Ga α 417, and very faint and fugitive, even with a salt which gave a brilliant electric spectrum.

3. The chloride and the sulphate of Ga are precipitated by NH_3, but the precipitate is redissolved, in great part, in an excess of NH_3. Taking up with HCl the portion not dissolved by NH_3, and recommencing the operation, all the Ga is promptly obtained in ammoniacal solution.

4. An ammoniacal solution of sulphate or chloride of Ga is precipitated in the cold or hot state by an excess of acetic acid. The liquor must be extremely diluted.

5. The chloride and the sulphate of Ga are not precipitated in the cold state by the acid acetate of ammonia, but the reaction takes place on heating.

6. The sulphate of Ga is soluble in a 60 per cent. alcohol solution.

8. A salt was obtained which the author believes to be ammoniaco-gallic alum; though, in default of sufficient quantity, he was unable to analyse it or measure the angles.

9. The alum of Ga is soluble in cold water, but, on heating, the salt is decomposed, and the liquor becomes greatly troubled.

10. This alum is not decomposed in the hot state by water with addition of acetic acid.

11. It crystallises very easily in cubes and octahedra, presenting exactly the aspect of ordinary alum; its solution, evaporated under the microscope, also presents the characteristic changes of known alums.

12. The crystals do not act on polarised light (between two Nicols giving extinction).

13. A small crystal was kept some time under a layer of water, then transferred to a slightly supersaturated solution of alumino-ammoniacal alum; it immediately increased in it, and caused the crystallisation of the liquor.

14. With ammonia in excess, the alum of Ga behaves like the other salts of this metal; a portion of the oxide is precipitated, the other portion remains in solution.

15. The very acid solution of Ga_2Cl_6 is precipitated by the yellow prussiate.

16. The ammoniacal solution of sulphate of Ga is decomposed by the voltaic current. Metallic gallium is deposited on the platinum plate serving as negative electrode. The positive electrode is covered, at the same time, with a whitish pellicle, which is easily detached from the platinum, and is insoluble in a large excess of NH_3. In a first operation 1·6 mgr. of Ga were deposited in 4h. 30m. on a platinum plate of about 185 square millimetres surface. The surface of the positive electrode was about 877 sq. mm. The battery consisted of five bichromate couples (zincs: 17 cm. × 10 cm.) coupled in tension. The author presented to the Academy a specimen weighing 3·4 mgr.; it was deposited in 5h. 40m. on a surface of about 123 to 124 sq. mm. The positive electrode 877 sq. mm.; the current furnished by ten bichromate elements (as above) coupled in tension.

17. Electrolytic gallium forms a very adherent layer; it is hard; it is polished with difficulty by friction with an agate burnisher. A better polish is obtained by strong compression under the burnisher; the metal thus acquires great brightness, and appears whiter than platinum. When the electric current and the relative dimensions of the electrodes are properly regulated, the gallium presents a beautiful dull surface of silvery white, finely granulated, and interspersed with small brilliant points, which the microscope shows to be crystals.

18. Gallium, deposited on a platinum plate, is not much oxidised during washing in cold or boiling water, nor on being dried in free air raised to about 200°. It decomposes water acidulated with HCl in the cold state, and more rapidly in the hot state, with a brisk liberation of hydrogen.

The salts of Ga which M. Lecoq de Boisbaudran has used in his researches, have been from the blend of Pierrefitte; he has, however, found the new metal in other ores of zinc, and notably in a transparent blend from Santander. He believes Ga will be met with in all blends. The Ga he extracted from the blends comes really from these minerals, and not from metallic zinc.

The author's last researches have confirmed the rarity of gallium in blend. The extreme sensibility of the spectral reaction led him even to over-estimate the quantities obtained. "I do not think I exaggerate," he remarks, "in saying that in my first observation I possessed at the most $\frac{1}{100}$ of a milligramme of the new substance dissolved in a very small drop of liquid. The spectral analysis of so small a quantity of matter would have been impracticable before the considerable reduction I made in the dimensions of the apparatus for obtaining electric spectra, and without using very small sparks.

"If, as I suppose, there is no error as to the nature of my alum of Ga, the existence of this salt fixes the atomicity of the new element, and attributes to its oxide the same chemical function as that of alumina. The oxide of gallium, then, will be written Ga_2O_3."

The author, in conclusion, refrains, for the present, from discussing the theoretical considerations raised in a recent note by M. Mendeleeff. Questions of the kind have long interested him; but he thinks it very probable that without the particular method followed in the present research, neither M. Mendeleeff's theories nor his own would soon have led to the discovery of gallium.

SCIENTIFIC SERIALS

American Journal of Science and Art, November.—The original articles in this number are:—On the variation in the strength of a muscle, by F. E. Nipher.—Studies on magnetic distribution, by H. A. Rowland. This, Part I., is on linear distribution, and the scope is indicated by the titles of the sections: 1. Preliminary Remarks; 2. Mathematical Theory; 3. Experimental Methods for Linear Distribution; 4. Iron Rods magnetised by induction; 5. Straight Electro-magnets and permanent Steel Magnets; 6. Miscellaneous Applications.—Œstivation and its terminology, by Asa Gray.—A note in relation to the mass of meteoric iron that fell in Dickson County, Tenn., 1835, by J. L. Smith.—Specific gravity balance, by Roswell Parish. The object of this is to determine the specific gravities of minerals, and other solids heavier than water, without the use of exact weights and without mathematical computation.—A paper on Southern New England, by Prof. Dana.—Iowa county meteor and its meteorites, by N. R. Leonard.—On the post-Pliocene fossils of Sankoty Head, Nantuck Island, by A. E. Verrill. This article, referring to the paper by Desor and Cabot (Geol. Soc. Lond., 1849), purports to correct some matters of detail in that paper, and raises the number of known species from seventeen to sixty, of which a list is given.—In the short articles under "Scientific Intelligence" are:—Arithmetical relations between the atomic weights; Evidence of glacial action on the summit of Mount Washington; Discovery of the horns of an extinct species of ox in Ohio.—The two following reports are noticed: On the geology and resources of the region in the vicinity of the 49th parallel from the Lake of the Woods to the Rocky Mountains; A reconnaissance of the Black Hills of Dakota made in the summer of 1874.—In an appendix Prof. O. C. Marsh contributes a paper on the Odontornithes, or birds with teeth. After recapitulating facts he has already contributed, he gives this classification: — Sub-class, ODONTORNITHES: A. Teeth in sockets; vertebræ biconcave; sternum with keel; wings well developed; order, *Ichthyornithes*. B. Teeth in grooves; vertebræ as in recent birds; sternum without keel; wings rudimentary; order, *Odontolcæ*. There are two plates in illustration of this paper.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Oct. 15.—In the concluding part of his article on the higher atmospheric strata, Dr. Hellmann gives the following results:—(2) Moisture: time of maximum, upper station, 4.30 P.M.; lower station, 5.43 P.M.; time of minimum: upper station, 7·3 A.M.; lower station, 7.30 A.M. The daily variation at the upper station is only half that at the lower station. From a table of relative humidity we learn that the air is much moister at the upper station and removed by an almost constant quantity from saturation. In the morning and evening the lower air is the moister, at midday the upper. (3) Wind. Easterly winds were less prevalent at the summit than at the foot of Mount Washington, in the proportion of 1 : 2. It is now well ascertained that the wind at ordinary heights increases in strength daily from early morning till about 2 P.M., and then decreases until about 9 P.M. Herr Hellmann was surprised to discover a variation exactly contrary to this to hold on the summit. In fact, the least velocity occurs about 1 P.M., the greatest after 12 at night; while at the foot the usual variations were followed. Dove explains the generally observed increasing velocity in the morning in our climate by the combined action of a large mass of heated air ascending in the east, and the prevalence of westerly winds. In the evening the heated area would lie westward, the two influences would oppose each other and the wind would decrease in velocity. Similarly the diminution of velocity from early morning to mid-day at great heights may be caused by the overflow westward of the air heated in an area east of the station opposing the prevailing west wind, and the acceleration in the afternoon by the overflow eastward from the heated area now in the west adding itself to the west wind. In agreement with this view is the fact, shown by observations on the Rigi, that velocity in summer is least about mid-day, much greater in the early morning and late evening, and in winter on the contrary, in harmony with the variations at low levels. The greatest observed velocity was ninety-six miles an hour. While this storm blew aloft a calm reigned below. But is it not likely that a current was drawn upwards by it? We have no instruments to register vertical currents. With respect to the relation of temperature to height, clearly it cannot be simply formulated, and will differ according to the altitude at which the daily ascending current flows off laterally. (4) Clouds. There was more cloud and fog at the summit about midday than at other times, and, roughly speaking, the amount of cloud varied inversely as that below during the daytime.

Memorie della Società degli Spettroscopisti Italiani, March, contains a table by Father Secchi, showing the number of protuberances and spots viewed, and the number of days on which observations were made during each revolution of the sun from April 1871 to March 1875, in all forty-two revolutions. The number of protuberances or spots seen during each revolution, divided by the number of days, gives an average for each day; this in 1871 was about 26 for protuberances and 100 for spots, and decreases gradually down to 5·45 for protuberances and 18·8 for spots, in March last. Drawings of the chromosphere for January, February, and March, by Secchi and Tacchini, also accompany this number.

May.—A paper by Prof. Bredichin, on spectroscopic observations of the sun, referring to the relation between spots and prominences, or the latter being the cause of the former. A long series of observations by Prof. Tacchini, from February to June 1873, showing the positions on the sun in which prominences containing magnesium or giving the 1474 line wer seen. The maximum number of positions in which magnesium was observed for any one day was sixty, and the same number for the 1874 line.—Prof. Fisati contributes a paper on the theories of electro-static induction.

June.—Prof. Tacchini writes on a method of determining the angles of position of spots and faculæ. In this case the image of the sun is thrown by the eye-piece of the telescope on to a screen on which is a divided circle, with which the image of the sun coincides.—Father Secchi contributes a paper on the solar prominences observed from April 1871 to June 1875. Accompanying this paper are tables showing the number of prominences in each ten degrees of solar latitude, together with their heights and sizes.

July.—A note on the presentation of a medal to Prof. H. Draper by the United States Government for his assistance in preparing for the Transit of Venus.—Observations of the positions in which prominences containing magnesium occurred during July 1873, by Prof. Tacchini.—Drawings of chromosphere during March and April 1874, by Secchi and Tacchini.

August.—A continuation of table by Tacchini, showing positions on sun where prominences containing magnesium occurred during August and September 1873.—Prof. Tacchini writes on observation of the Perseids of last August, in which he gives the mean radiant point as 2h. 5cm. and + 53° 8'·6.

Verhandlungen der k. k. geologischen Reichsanstalt. Vienna, Sept. 30.—In this number Dr. Schimper describes the geological conditions of the district of Arrho, in Abyssinia, and a curious apparently volcanic phenomenon met with there. The district is a cleft-crossed plain near (and below the level of) the

Red Sea, from which it is separated by a low range of hills. The gentle rains at one part of the year supply sufficient moisture to heat the iron pyrites scattered over the surface of Arrho to a mild glow; the substance is decomposed, lixiviated, and brought into combination with several combustible matters, and eruptions like those of volcanoes take place; slime cones are formed from four to twelve feet in height, from which, as from pipes, issue steam and flame. These generally ephemeral formations consist of mud which is mixed with sulphur and salt, and in the dried cones may be found almost pure sublimated sulphur. The general appearance of the place is like that of pulp boiling in a huge, angular, zig-zag cauldron. The phenomenon continues till increased rains lay the ground under water, after disappearance of which at the end of the rain periods, a hard salt crust, several inches thick, covers the ground.—The trachytes of the island of Cos are described by Dr. Dölter; Dr. Stache gives an account of the eruptive rocks in the Ortler region and the mountain group of the Zwölfer-Spitz in Upper Vintschgau; and Dr. Hornes, of observations in the district where the Rienz takes its rise.

SOCIETIES AND ACADEMIES

London

Royal Society, Nov. 25.—On the production of Glycosuria by the effect of oxygenated blood on the liver, by F. W. Pavy, M.D., F.R.S.

The conclusions arrived at are that the amyloid substance found in the liver is a body which tends to accumulate in certain animal structures under the existence of a limited supply of oxygen, and that it is through the liver exceptionally receiving the supply of venous blood it does, that the special condition belonging to it is attributable. It is also shown that the undue transmission of oxygenated blood to that organ at once induces an altered state, which is rendered evident by the production of glycosuria.

On the Structure and Relations of the Alcyonarian *Heliopora cærulea*, with some account of the anatomy of a species of *Sarcophyton*; notes on the structure of species of the genera *Millepora*, *Pocillopora*, and *Stylaster*, and remarks on the affinities of certain Palæozoic Corals, by H. M. Mozeley, Naturalist on the *Challenger* Expedition.

The title of this paper indicates the nature of its contents. The author has not been able to decide whether *Millepora* is one of the actinozoa or belongs to the hydrozoa as stated by Prof. Agassiz. *Heliopora* is undoubtedly alcyonarian.

Mathematical Society, Dec. 9.—Prof. H. J. S. Smith, F.R.S., president, in the chair.—Major J. R. Campbell and Prof. G. M. Minchin were elected members.—Prof. Clifford read a paper on the transformation of elliptic functions, in which he attempted to apply Jacobi's geometrical representation of the addition-theorem in elliptic functions to the theory of their transformation.—Prof. Cayley spoke on a system of algebraical equations connected with Malfatti's problem. The communication was an extension of a paper by the same gentleman in the *Cambridge and Dublin Mathematical Journal*, tom. iv., 1849, pp. 270–275.—The chairman next communicated three short notes: 1. On a problem of Eisenstein's. If p is an uneven prime, the function $4\,\dfrac{x^p - 1}{x - 1} = Z$ can always be expressed in the form $Y^2 - (-1)^{\frac{1}{2}(p-1)} p X^2$, where X and Y are rational and integral functions of x, having integral coefficients. This is a theorem of Gauss. Eisenstein's problem (*Crelle's Journal*, vol. xxvii. p. 83) is "to determine the cases in which the equation $Z = Y^2 - (-1)^{\frac{1}{2}(p-1)} p X^2$ admits of a multiplicity of solutions, and to ascertain the law connecting the various solutions, when there is more than one." The solution of this problem is as follows:—If $[T, U]$ is *any* solution whatever in integral numbers of the equation $T^2 - (-1)^{\frac{1}{2}(p-1)} p\, U^2 = 4$, and $[X, Y]$ is any one given solution of Gauss's equation, then all the solutions of Gauss's equation are comprised in the formula—

$$\left[\tfrac{1}{2}\left(TX + (-1)^{\frac{p-1}{2}} p\, UV\right), \tfrac{1}{2}(UX + TY)\right].$$

Thus if $p = 4n + 3$ the equation admits of but one solution (the four solutions $[\pm X, \pm Y]$ being regarded as but one) except in the case $p = 3$, when it admits of three; if $p = 4n + 1$, the equation admits of an infinite number of solutions. That the functions $[\frac{1}{2}(TX + p\,UY), \frac{1}{2}(UX + TY)]$ are all of them solutions of Gauss's equation is evident; the proof that this formula comprises all the solutions of the equations is less elementary, because it depends on the irreducibility of the function Z. There exists a general theory of the representation of rational and integral functions of x by quadratic forms; such representation being, of course, only possible when the given function of x is capable of resolution into two factors by the adjunction of a quadratic surd.—2. On the joint invariants of two conics, or two quadrics. Let P and Q be two conics, and let 1 2 3 be any triangle self-conjugate with regard to P. Let also P_1, P_2, P_3, be the rectangles of the points 1, 2, 3, with regard to the conic P, these rectangles being taken upon transversals measured in any fixed direction; and let Q_1, Q_2, Q_3, have similar meanings with regard to the conic Q, the direction of the transversals being also fixed. Then the expression $\dfrac{Q_1}{P_1} + \dfrac{Q_2}{P_2} + \dfrac{Q_3}{P_3}$ has the same value for all self-conjugate triangles of P; and is, in fact, that invariant of P, Q, which is linear with regard to Q, and quadratic with regard to P, and the evanescence of which expresses that Q harmonically circumscribes P. The corresponding theorem in the geometry of the straight line is: "If Q_1, Q_2, P_1, P_2, are two pairs of fixed points on a line, and if A_1, A_2, is any pair of harmonic conjugates of $P_1\,P_2$, the value of the expression

$$\frac{A_1\,Q_1 \cdot A_1\,Q_2}{A_1\,P_1 \cdot A_1\,P_2} + \frac{A_2\,Q_1 \cdot A_2\,Q_2}{A_2\,P_1 \cdot A_2\,P_2}$$

is independent of the particular pair $A_1\,A_2$ considered." From this theorem, the result given above for two conics follows immediately; from it the corresponding property for two quadrics may be inferred, viz.:

$$\frac{Q_1}{P_1} + \frac{Q_2}{P_2} + \frac{Q_3}{P_3} + \frac{Q_4}{P_4} = \text{constant};$$

and so on for quadratic functions containing any number of indeterminates. 3. On the equation $P \times D =$ constant, of the geodesic lines of an ellipsoid. From this equation (in which P is the perpendicular from the centre upon the tangent plane at any point of the geodesic, and D is the semi-diameter parallel to the tangent line of the geodesic) it is convenient to be able to infer directly the principal properties of the geodesic line, without having first to transform the equation into M. Liouville's form, $\mu^2 \cos^2 i + \nu^2 \sin^2 i = a^2$. In Dr. Salmon's "Geometry of Three Dimensions," the theorem of the constancy of the sum or difference of the geodesic radii vectores, drawn from any point of a line of curvature to two umbilics, is thus demonstrated. And it is worth while to add (though it is very improbable that the point has not been noticed before) that a proof of the theorem that two geodesic tangents of a line of curvature which intersect at right angles, intersect on a sphero-conic, may similarly be obtained without transforming the equation. Let Q be the point where the two geodesic tangents intersect at right angles, O the centre of the ellipsoid; let $c = O\,Q$, and let a, b be the semi-axes of the central section parallel to the tangent plane at Q. The two geodesics make angles of 45° with the lines of curvature at Q: hence, for either of these geodesic lines, $D^2 = \dfrac{2a^2 b^2}{a^2 + b^2}$. Let Q' be a second point where two geodesic tangents to the same line of curvature intersect at right angles; then $\dfrac{2\,P^2 a^2 b^2}{a^2 + b^2} = \dfrac{2\,P'^2 a'^2 b'^2}{a'^2 + b'^2}$, because $P \times D$ has the same value for all geodesic lines touching the same line of curvature. But $P^2 a^2 b^2 = P'^2 a'^2 b'^2$, because parallelepipeds circumscribing an ellipsoid with their faces parallel to conjugate diametral planes are equal. Hence $a^2 + b^2 = a'^2 + b'^2$. But also $a^2 + b^2 + c^2 = a'^2 + b'^2 + c'^2 \therefore c = c'$, and Q and Q' lie in the same sphero-conic. Mr. Tucker (in the absence of the author) brought before the Society a paper by Mr. H. W. Lloyd Tanner on the solution of certain partial differential equations of the second order, having more than two independent variables. The equations considered are included in the form—

$$\sum_{i=1}^{i=n} \sum_{j=1}^{j=n} V_{ij} \frac{d^2 z}{dx_i dx_j} + V_0 = 0 \quad . \quad . \quad . \quad (1)$$

where $V_{ij}\,V_0$ are functions of

$$x_1 \ . \ . \ . \ x_n,\ z,\ p_1 \left(\equiv \frac{dz}{dx_1}\right) \ . \ . \ . \ p_n \left(\equiv \frac{dz}{dx_n}\right),$$

and it is proposed to investigate the conditions that (1) should be soluble in terms of arbitrary functions, the arguments of

which are definite functions of z, $x_1 \ldots x_n$; and when these conditions are satisfied to determine the solution. Three cases arise for discussion: (1) $n - 1$ of the arguments independent, (2) n of them independent, (3) $n + 1$ of them independent. The paper concludes with a note on the application of a similar method to equations of an order higher than the second.

Zoological Society, Dec. 7.—Mr. George Busk, F.R.S., V.P., in the Chair.—Mr. Sclater read an extract from a letter addressed to him by Mr. H. A. Wickham, on the occurrence of the large blue Hyacinth Macaw, (*Ara hyacinthina*) near Santarem, on the river Amazons.—Mr. Sclater exhibited and made remarks on a Skin of *Hypocolius ampelinus.*, Bp, obtained by Mr. W. T. Blanford, in Upper Scinde, to the west of Shikaprur.—Prof. Owen, C.B., read the twenty-second part of his series of Memoirs on Dinornis. This part contained a restoration of the skeleton of *Dinornis maximus.*—Mr. J. W. Clark read a paper on the Eared Seals of the islands of St. Paul and Amsterdam, to which he added a description of the Fur Seal of New Zealand from specimens kindly furnished by Dr. Hector. Mr. Clark further read copious extracts from the narratives of the older Explorers in these seas, and attempted to reconcile the notices given by them with the subsequent description of Naturalists.—A communication was read from the Rev. R. Boog Watson, on the generic peculiarities of the distinctively Madeiran Achatinas of Lowe.—A communication was read from Dr. Hermann Burmeister, Director of the National Museum, Buenos Ayres, containing the description of a new species of *Dolichotis*—which Dr. Burmeister proposed to call *Dolichotis salinicola.*—Mr. W. T. Blanford communicated particulars respecting some large Stags' Horns, obtained by the Expedition to Western Turkestan to which the late Dr. Stoliczka was attached as Naturalist, said to have been brought originally from the Thian Shan Mountains. These horns were of very large size, each measuring 51 inches in length round the curve. Mr. Blanford, considering that these horns clearly showed the existence of a species hitherto undescribed, gave a full description of them, and proposed to give the name of *Cervus eustephanus* to the animal to which they belong.—Dr. O. Finsch communicated some notes on *Phœnicomanes iora*, Sharp, and *Abrornis atricapilla*, Blyth, and pointed out that the first named bird is identical with *Iora lafresnayei* of Malacca, while *Abrornis atricapilla*, said to be from China, is in fact a *Myiodioctes pusillus*, Wils., a well known North American bird.—A second communication from Dr. Finsch contained the description of a bird from the Arfak Mountains, New Guinea, which appears to form a new genus and species. This Dr. Finsch proposed to call *Pristornamphus versteri.*—A third communication from Dr. Finsch gave the characters of six new Polynesian birds in the Museum Godeffroy at Hamburg.—A communication from Mr. J. Caldwell, contained some notes on the Zoology of the Island of Rodriguez.—Dr. E. Von Martens communicated a list of the Land and Fresh Water Shells collected by Mr. Osbert Salvin in Guatemala in 1873-74.

Geological Society, Dec. 1.—Mr. John Evans, V.P.R.S., president, in the chair.—M. Rodolfo de Arteaga, William Henry Barnard, the Rev. J. Clifford, M.A., Lieut.-Gen. Robert Fitzgerald Copland-Crawford, R.A., Walter Derham, B.A., James Duigan, George R. Godson, the Rev. Algernon Sydney Grenfell, Sir David Salomons, Bart., Aubrey Strahan, B.A., William Thomas, Edward Wethered, F.C.S., the Rev. Burgess Wilkinson, and Edward Alfred Wunsch were elected Fellows of the Society. The following communication was read:—On the granitic, granitoid, and associated metamorphic rocks of the lake-district.—Parts III., IV., and V., by Mr. J. Clifton Ward, of the Geological Survey of England and Wales. Part III. On the skiddaw granite and its associated metamorphic rocks. The subject was treated under the three heads of (1) Examination in the field, (2) Microscopical examination, (3) Chemical examination, and the following were the general results arrived at. The metamorphism of the skiddaw slate extends for many miles around the several granitic masses, and commences by the formation of small spots which become developed into chiastolite crystals. The chiastolite *slate* passes into spotted *schist*, by the great increase of the small oblong spots arranged along planes of foliation, and mica appears. The spotted schist graduates into mica-schist, which, however, often retains to the last faint spots, and occasionally chiastolite crystals. The junction between the mica-schist and the granite is generally rather abrupt. On the whole, chemical and field evidence especially are *against* regarding the granite, now exposed, as the result of the extreme metamorphism of the skiddaw slates *immediately* around it; but whether it may not have resulted from the metamorphism of underlying parts of the same series is an open question. The great contortion of the mica schist around the granitic centres may be in part due to the, at any rate, *partially* intrusive character of the granite. In an appendix abstracts of papers by various authors who have written in connection with the subject were given.—Part IV. On the quartz felsite, syenitic, and associated metamorphic rocks of the lake district. This part was treated under the same three heads of field, microscopical, and chemical evidence as the last. The quartz felsite of St. John's Vale, and the syenitic granite of Buttermere and Ennerdale, lie for the most part at the junction of the volcanic and skiddaw series, and seem by their line of strike, and by the occasional presence of bands of slate or volcanic rock enclosed within or running through them, to represent the transition beds between the two series, metamorphosed in great measure *in situ*. Both microscopic and chemical evidence demonstrate the possibility of this process. Evidence gathered in the field, and microscopic and chemical examination, all seem to suggest that the rocks of Carrock Fell, &c., represent the base of the volcanic series, consisting largely of contemporaneous traps, thrown into a synclinal, the axis of which ranges generally east and west, and metamorphosed into rocks of greatly varying character, such as sphærolitic felsite, hypersthenite, and diorite. Although all the various masses treated of were probably formed in the main by the metamorphism of beds *in situ*, it is probable that some parts of the resulting magma became occasionally intrusive among and absorptive of higher beds. In an appendix notices of papers on these rocks by other authors were given.—Part V. General summary. In this part the leading results of the four preceding divisions of this memoir were briefly brought forward, followed by the discussion of various considerations relating to metamorphism, under the following heads:—1. Granite at various depths; 2. How far granite may be an ultimate universal product of metamorphism; 3. Distribution of metamorphism (selective metamorphism); 4. Classes of metamorphism. The paper was illustrated by a large geological map of the northern part of the Lake district, by a geological model of the Keswick district, by rock specimens, and large coloured photographs taken from water-colour microscopic drawings made by the author.

Physical Society, Dec. 11.—Prof. Gladstone, F.R.S., president, in the chair.—The following candidates were elected members of the Society:—C. Higgins and S. O. Thompson, B.A., B.Sc.—In the absence of Prof. G. C. Foster, Mr. Lodge exhibited and described a simple form of chronoscope for measuring short intervals of time, which Prof. Foster has recently devised. In experiments commenced about eight years ago the apparatus consisted essentially of three parts: 1. An arrangement for releasing the bullet or other body whose fall was to be timed, when the apparatus is employed for such determinations; 2. An arrangement for directing a gauged stream of water into a vessel during the time occupied by the fall of the body; and 3. A platform to receive the falling body. The stream of water was directed into the vessel by means of a bent funnel brought under a constantly flowing stream by an electro-magnet. But this apparatus had two serious defects, one of which was caused by the difficulty of accurately gauging the stream, and the other by the inertia and consequent sluggishness of movement of the funnel. The arrangements, however, for dropping and receiving the bullet being satisfactory, were finally adopted. The former is simply a clip one side of which is a spring, and this forms the armature of a small electro-magnet. On completing the circuit the spring is drawn aside and the bullet released, momentarily breaking a current which passes through it, as subsequently described. The bullet, at the end of its fall, strikes a small mahogany table, so arranged that the blow slightly depresses it, and permanently breaks the same current, which in the interval has been closed by a subsidiary wire. The author abandoned the method of indicating the commencement and end of the fall by an independent electro-magnet and, substituting the trace made on blackened paper by a vibrating tuning-fork for the stream of water, he registered them by perforations made by induction-coil sparks in the blackened paper, a method suggested by the description of Beetz chronoscope. The apparatus is difficult to describe without the aid of diagrams, but the following will perhaps sufficiently indicate the general arrangement. The two terminals of the secondary coil are connected, the one with the tuning-fork, and the other with the metallic drum on which the blackened

paper is carried. The other connections are as follows:—The current passes from one pole of battery to spring of releasing apparatus (which is also connected with one terminal of a separate condenser), thence through the bullet to the fixed portion of the clip, and by a wire to the lower table, which is also in electrical connection with the face of the electro-magnet which releases the bullet, in order that the current may be completed immediately the falling body is released. From this table the current passes through an adjusting screw to one terminal of the primary wire of the induction coil which is connected with the other condenser terminal. The other pole of the battery is connected with the primary. The spark in each case is caused by the breaking of the current which takes place when the bullet is released and when it strikes the table, the perforations in the black paper of course being made in the trace produced by the tuning-fork. It is hardly necessary to mention that the releasing electro-magnet is worked by one or two independent cells. The author considers that with a fork making sixty-four complete vibrations in a second the error, in determining an interval of not more than two or three seconds, should not exceed $\frac{1}{100}$th of a second, and that with a more rapidly vibrating fork probably much greater accuracy might be attained. Mr. Lodge made four experiments before the Society with falls of 2 ft. and 1 ft., from which the value of gravity was found to be 32·21. Prof. Guthrie inquired whether the instrument was sensitive to the influence of temperature on the time of vibration of the tuning-fork. Mr. Ladd suggested that the pressure of the marker on the end of the tuning-fork might hinder its vibration, and referred to difficulties which Capt. Noble had met with in the working of his chronograph. Mr. Lodge stated that experiments had only been made in a laboratory having a fairly equable temperature, and that therefore the effect of considerable changes of temperature had not been ascertained. He considered that the slight resistance referred to by Mr. Ladd would rather tend to diminish the amplitude of vibrations than to change their number per second.—Prof. McLeod then described and exhibited an arrangement for ensuring that the charge given to a Leyden jar shall not exceed any fixed limit. Through a cork in the upper end of a bell-glass passes a brass rod, insulated through its entire length by means of a glass tube, through which it passes freely. To the upper end is attached a brass knob, and the lower end is pointed and provided with a screw-thread, so that it can be set at any distance within, or through, a hollow brass ball, perforated below and rigidly fixed to the glass tube. Within the bell-glass is a loose cage of perforated sheet zinc and a vessel containing strong sulphuric acid. The whole stands on a metallic plate to secure a good earth connection. The action is as follows:—If the rod be screwed down so that the point projects through the hollow ball, the upper knob and lower metallic plate being connected with the two poles of a Holtz machine, only short sparks can be obtained, because a large amount of electricity escapes at the point; but if the rod be raised so that the rod barely enters the hollow ball, at the top, no escape takes place from it, and the machine will give its full length of spark. By varying the position between these two extreme limits, any required length of spark or amount of charge for an interposed Leyden jar can be obtained.

Entomological Society, Dec. 1.—Sir Sidney Smith Saunders, C.M.G., president, in the chair.—Mr. W. A. Forbes exhibited a variety of the Burnet Moth (*Zygæna filipendulæ*), with yellow spots, of which he had bred a number from larvæ taken near Winchester.—Mr. Champion exhibited some rare British Coleoptera.—Mr. William Cole exhibited carefully-executed drawings of the pupæ of a species of the Dipterous genus *Ephydra*, which he had taken clinging to the stems of grass, in brackish water, near Southend, Essex.—The President referred to the numerous parasites found on bees of the genus *Osmia*, and remarked that M. Jules Lichtenstein had recently obtained *Zonitis præusta* from the cells of *Osmia tridentata*; and likewise *Euchalus vetusta*, Duf., from its desiccated adult larvæ, in the same way that *Halticella osmicida* effects its metamorphosis, thus making the thirteenth parasite recorded as infesting this particular species of bee.—A paper was communicated by Dr. Burmeister, of Buenos Ayres, giving a description of a new genus belonging to the family *Scaritidæ* (nearly allied to *Clivina*), taken on the shore of the river Uruguay, near the town of Concordia.

PARIS

Academy of Sciences, Dec. 6.—M. Frémy in the chair.—On the constitution of phosphates, by MM. Berthelot and Louguinine.—Atmospheric perturbations of the hot season of 1875, by M. Belgrand.—On the colouring matter of fruits of Mahonia, and the characters of the wine these fruits give by fermentation, by M. Is. Pierre.—On the astronomical phenomena observed in 1597 by the Dutch in Novaya Zemlya, by M. Baills.—Note on the double touch process of magnetisation, by M. Gaugain.—On the temperature of elevated layers of the atmosphere, by M. Mendeleeff. The temperatures observed there are constantly higher than those calculated; this is accounted for by aqueous vapour.—On the transparence of flames and of the atmosphere, and on the visibility of scintillating lights, by M. Allard. From experiment he adopts 0·81 as mean value of the coefficient of transparence of flame, referred to the centimetre of thickness traversed. The absolute intensity of flame increases more rapidly than the weight of oil consumed, but the amount of light absorbed in passage of rays through the flame increases still more rapidly.—On the distribution of magnetism in circular or elliptical steel plates, by M. Duter.—On some properties of gallium, by M. Lecoq de Boisbaudran. This is noticed fully elsewhere.—Note on a derivative by hydratation of cellulose, by M. Aimé Gerard.—Researches on the constitution of albuminoid matters, by M. Schutzenberger.—On the development of the fruit of *Chaetomium*, and the supposed sexuality of Ascomycetes, by M. van Tieghem.—On new fossil pieces discovered in the phosphorites of Quercy, by M. Gaudry.—On the virulent state of blood of healthy horses, killed by falling or asphyxia, by M Signol. The blood taken from the body after sixteen hours proves rapidly fatal to goats or sheep inoculated with it (twenty-four drops). Motionless bacteridia are present, but there is no sign of putridity.—Discovery of the 157th small planet at Marseilles on Dec. 1. Ephemerides and observations of planets lately discovered, by M. Stephan.—Observations of planets (152) and (154) made at the Paris Observatory, by M. Prosper Henry.—On the isochronism of the spirals of chronometers, by M. Caspari.—Note on the distribution of magnetism in the interior of magnets, by MM. Trève and Durassier.—On the fermentation of fruits, by MM. Lechartier and Bellamy.—On panification in the United States, and the properties of hops as ferment, by M. Sacc.—On the presence, in present seas, of a type of Sarcodaria of the secondary strata, by M. Fischer.—On larval forms of Bryozoa, by M. Barrois.—On the organisation of Acarians of the family of Gamasides; characters showing that they form a natural transition between hexapodan insects and Arachnida, by M. Megnin.—Nidification of the rainbow fish of India, by M. Carbonnier.—On the ferns and Lycopodiaceæ of the islands St. Paul and Amsterdam, by M. Fournier.—On the influence of stripping off the leaves of beet on production of sugar, by M. Corenwinder.

THURSDAY, DECEMBER 23, 1875

LORD DERBY ON THE ENDOWMENT OF SCIENTIFIC RESEARCH

WE do not think it possible to estimate too highly the value of Lord Derby's address last Friday at Edinburgh, and his statements as to the rapidly widening fields of science and the increasing value of the results of scientific research. We shall simply content ourselves with quoting the very remarkable views he put forth as to the duty of the State with regard to the encouragement of research, views which, when we consider the character of the speaker and his official position, must be regarded as of the greatest significance. After speaking of the all-absorbing nature of scientific research, of the necessity of complete devotion to a special department in order to achieve success, and of the "world-wide benefit" of scientific results, Lord Derby said :—

"Science, above all, needs leisure, and I hope it is not utopian to look forward to the possibility of a far ampler provision being made for its prosecution by competent persons than exists at present. I do not refer merely or principally to help from the State; though, speaking for myself, I should not grudge it in such a cause. But the spirit of patriotism which animated founders of schools and colleges and public benefactors of former days is not extinct; in some directions it is more flourishing than ever. An American banker lately gave half a million to help the poor of London; a well-known Scotch gentleman has given the same sum within the last few years in aid of the Kirk of Scotland; money is never wanting at either end of this island when men see their way to make a good use of it. When have schools, hospitals, public parks, museums, institutes been more abundant than at the present day? Science has no endowments, or next to none; but only because the interest in that class of subjects is comparatively new, and rich men, who want to do some good with their capital, have not looked much in that direction as yet. Is it too sanguine a hope that we may see individual liberality take a form which hitherto it has rarely taken? Who knows how many discoveries might be worked out, how many conquests of man over nature secured, if for, I do not say a numerous body, but even for some 50 or 100 picked men, such modest provision were made that they might be set apart, free from other cares, for the double duty of advancing and of diffusing science? Who can measure what has already been lost to England and to the world, when intellects capable of the highest kind of original work have been wasted, not by choice, but by necessity, on the common drudgery of every-day life? I know very well that to some extent that must continue to be the case; it is visionary to contemplate a state of society in which every man will find exactly the employment that suits him; in human life, as in nature, there will always be a vast apparent waste of power. But we may at least reduce that waste where we see it going on; original capacity is not so common that we can afford to throw it away, nor so difficult to discover that we may excuse ourselves by saying we did not see it. I am quite aware that endowments of all sorts are discountenanced by a certain class of thinkers, of whom I speak with respect, but who, I think, argue from the abuse of a thing against its use. The fact remains that the most enduring and valuable work done in the line of pure science will not bring a shilling to the man who does it; and while that is so (and one does not see how it can be otherwise), there seems nothing unreasonable in saying that society shall, in one way or another, make provision for those who are doing so much for society. Nor do I see that the risk of jobbing in such matters is great. Men who work to make money, or men who care for reputation of the popular sort, do not choose such pursuits as those of which I am speaking. And, making all allowance for the little jealousies and rivalries from which no profession is free, I believe that there is seldom any difficulty in picking out the best qualified candidates for professorships and appointments of that kind where there is an honest wish to find them. I go into no detail; I indicate no special plan. I had rather, for my own part, see action taken by the community than by the State, or, at least, I should wish to see the community largely helping the action of the State; but whatever is done, or whoever does it, I think that more liberal assistance in the prosecution of original scientific research is one of the recognised wants of our time. How far that assistance can be obtained by the utilisation of ancient endowments is a question partly of principle, partly of detail. I do not agree with the extreme views which have been put forward on either side in regard to it. I cannot follow the reasoning of those who say that the State has no right to divert endowments from one purpose to another. There must be a regulating power somewhere, else changes which, by common consent, lapse of time has made necessary could not be effected; and whether that power is vested in a Court of Justice or in a Commission, it is equally the power of the State. To my mind, so far as right is concerned, the Legislature may do what it chooses in regard to any endowment, without injustice, provided only that the rights of living individuals are respected. How far it is politic to use that power is another matter. Push its exercise too far, and you kill the bird that lays the golden eggs. Men give or leave funds, not for the promotion of useful public purposes in the abstract, but for some special form of public usefulness that has taken their fancy. You never hear of a fortune left to the Chancellor of the Exchequer to employ as he thinks best for the public service. One man cares for schools, another for hospitals, and so forth; and unless intending benefactors have a reasonable security that the general purpose for which they leave their money will be respected, the stream will soon dry up. More than that, I consider, they ought not to ask. Respect the founder's object, but use your own discretion as to the means; if you do not do the first, you will have no new endowments; if you neglect the last, those which you have will be of no use."

We need not add one word of our own in support of these views; the case on behalf of the endowment of research, which we have long advocated on the grounds stated by Lord Derby, could not be more forcibly put. It may, however, be useful to collect for reference the opinion of the country as expressed through the daily press.

The *Daily News* thus endorses Lord Derby's views :—

"The real advancement of science needs, as Lord Derby says, leisure, and the power and opportunity of purely disinterested study. In this sense all scientific men will agree with Lord Derby that science needs more help. We have, indeed, in England, some very illustrious living examples of men who not only teach, as a daily and laborious duty, the methods and results of scientific investigation, but who have themselves, in a precious and hard-earned leisure, carried that investigation far forward along paths hitherto untrodden. But it has occurred to every reader of their writings to ask what they might have added to the world's knowledge had they been able to devote their whole time and strength to their favourite pursuit. There is a growing conviction that investigation of this kind, as apart from teaching, ought to be encouraged by the State. Lord Derby would not grudge it help, even from national resources; but he throws out a suggestion which may be commended to the notice of men who, like the late member for Bridport, have money to leave, and are on the look-out for heirs. We have, as Lord Derby says, bequests of all kinds; and it would be a welcome sign that science had been made popular, even in a sense he would approve, if bequests of large sums to endow original research should come into fashion."

The *Daily Telegraph* says:—

"And here the speaker could not but touch on the question of the better endowment of scientific research, which he disposed of by heartily wishing that such benevolent people as give half a million to a charity, or to the Kirk of Scotland, would turn the stream of Pactolus upon the dry ground of natural science. There is no soil which would yield back more profitable harvests. A discovery in mechanics or physics benefits all mankind; and great investigations are undoubtedly kept in abeyance for want of the help which society does not, and the Government cannot, bestow. Lord Derby, indeed, expressed himself willing to advocate all that could be done in this direction by a Government; but his opinion is that the community must take up the question, if anything really large was to be hoped for, though something might, perhaps, be effected by the careful application of old endowments, upon which point the Lord Rector uttered some observations balanced so finely that a pinch of the dust of a 'dead founder' would turn his well-trimmed scales."

The *Globe* speaks as follows:—

"Valuable as were the hints suggested on what may be described as the conduct of intellectual life, still greater interest attaches to Lord Derby's observations on the subject of scientific research and University Reform. On the former topic scientific men have sometimes talked rather wildly of late, as if it were the duty of the State to provide an elaborate scheme for the endowment of science. Lord Derby did not accept this view; but he distinctly laid it down that the community has not yet realised the vastness of its obligations to science, and that, when it does so, much larger funds will be devoted to its encouragement than are now available. He also declared that, for his own part, he would not object to the State doing something to foster original research. These utterances will be eagerly fastened on by scientific men, but it may perhaps be questioned whether the difficulties in the way of definite action are not somewhat underrated. By what test would it be possible to select the men who should be supported for the purpose of extending the bounds of science? And if this difficulty were overcome, how could an assurance be given that the opportunities secured would be applied to the best advantage? Would it not be necessary to associate duties with the rights conferred on successful candidates? These and other obstacles may not be insuperable; but they will have to be thoroughly considered before a large additional expenditure is undertaken on behalf of science. Perhaps the best solution would be a generous endowment of scientific professorships—by private liberality, if possible—in connection with which there would be teaching to some slight extent, but not so much as would interfere with work of a high kind."

According to the *Hour*—

"Perhaps that which will seem to English readers the most important part of Lord Derby's address is that relative to the importance of scientific research."

The *Scotsman* has the following:—

"Lord Derby does not know much about science, but he knows enough to have a clear view of the truth that 'science, in the strict sense of the word, can never be popular.' He also sees plainly enough that, as a consequence of this, science as a pursuit can never pay. Nothing in his address is more important or more just than his plea for the endowment of science, coupled as it is with an expresson of his individual willingness that some aid should be given to science by the State. It is plain, too, that Lord Derby thinks that something might be got from our older endowments for this object, without doing injustice to anyone, living or dead."

The *Glasgow Herald* thus writes:—

"Scientific culture seems to command the largest share of Lord Derby's sympathies. Those who have the taste for the investigation of material objects 'have the satisfaction of knowing that while satisfying one of the deepest wants of their own nature, they are at the same time promoting, in the most effectual manner, the interests of mankind.' There is, in other words, the investigation of the unknown, and a service of utility rendered to mankind. Then, the charm of scientific studies to Lord Derby lies in their definiteness. The student is held down to the facts of nature; if he investigates them at all he must investigate them thoroughly. He knows nothing till he knows all that the facts reveal. Popular science is, to his mind, a misnomer. Science can never be popular, for its study involves leisure, careful industry, and patient waiting and watching. He is so convinced of the advantages of cultivating the study of nature that he would not be averse to a Government endowment."

It will thus be seen that public opinion, so far as we at present have been able to glean it, approves of the views expressed by Lord Derby; we cannot therefore doubt that Government will take an early opportunity of giving them practical effect.

AFRICAN HANDIWORK

Artes Africanae. By Dr. Georg Schweinfurth. With twenty-one lithographic plates. (London: Sampson Low and Co., 1875.)

THE title of this work may perhaps be thought too comprehensive, the author having, wisely as we think, confined himself to the arts of the negro tribes visited by him in the vicinity of the White Nile between the equator and about 12° north latitude.

Africa may be divided into three regions, corresponding to the movements of trade. In the northern half of the continent where Islamism and firearms have penetrated, home-made goods have been supplanted by European commodities and the last traces of native industry threaten shortly to disappear. An intermediate zone in which the cotton stuffs of Europe are made the chief articles of trade intervenes between this and the interior, where European goods are unknown and native arts are found in their most primitive condition. It is to a portion of this latter region that Dr. Schweinfurth's work relates.

The tribes of the White Nile were first visited by Consul Petherick in 1857-8, and many specimens of their arts which were brought home by him have since been

dispersed. A considerable number have. however, since found their way either into the Christy collection, or into Col. Lane Fox's Anthropological collection at Bethnal Green, and have been described in greater or less detail. But with the exception of a brief account of the war weapons of this people which was contributed by Mr. Petherick to the *Journal of the United Service Institution* in 1860, including numerous illustrations, no original account of their native arts has been published until the appearance of the present work.

The tribes referred to in this volume are named Dinka, Dyur, Bongo, Mittu, Niam Niam, Bellanda, Monbuttu, Sere, and Kred, and as a rule the same types of art with innumerable but closely-allied varieties pervade the whole of them. Imitation of natural forms, that invariable characteristic of primitive arts, is not less frequent here than amongst other savages; thus we find amongst the Bongo, bells and rattles in imitation of leguminous fruits, and iron thorns upon the heads of spears, both named and copied from the Makrigga, a thorny shrub of the district which no doubt was used and served as a model for these barbarous weapons before the introduction of iron. Notwithstanding the prevalence of iron, the Mittu and some other tribes still employ an arrow with a hard wood point or fire-shaft in preference to the iron ones, which carry only one-third the distance although with greater accuracy of flight.

The partiality for doubling certain objects without in most cases the least practicable utility being perceptible is noticed by the traveller as a characteristic of Central African art. Thus we find double points to roofs, double pipe-bowls, double lance-heads, double spoons, and double bells included amongst the objects illustrated. The art of the carpenter, as with most savages, appears to be confined to carving household utensils such as seats, tables, dishes, boxes, mortars, musical instruments, canoes, &c., out of a solid block; the joiner's art seems almost unknown, the only exception here recorded being a sleeping-bench of the Monbuttu tribe, in which the framework of Raphia stalks is fastened to the feet by pegs of hard wood. One of those curious transformations so common in savage art is seen in the case of the broad mushroom-headed club, "Bollong." This club has been described by Mr. Petherick, amongst the Dor tribe, as a weapon for cracking skulls. The broad head, which is obviously a monstrous development of the ordinary club head, appears to have suggested its employment as a seat by sticking the pointed handle into the ground and sitting on the head. Accordingly we find that amongst the Dinka, Dyoor, Madi, and Gani, the upper surface of the head has been made perfectly flat, in order to adapt it to this new use, whilst at the same time preserving its efficiency as a weapon. The wooden parrying-stick or shield, "Kwrr," constructed of one piece with a hollow for the hand carved out in the centre, has been noticed by Mr. Petherick amongst the Mundo, and is here figured as a Dinka weapon. Its close resemblance to the Australian parrying-shield, Tamarang, and to one from an Egyptian tomb, now in the Louvre at Paris, has been noticed by Col. Lane Fox in his catalogue of his collection at Bethnal Green. Dr. Schweinfurth compares it to a specimen from the Pacific Isles now in the Berlin Museum. Should this turn out to be correct, and not a mistaken locality, it will add another link to the area of distribution of this peculiar form of weapon. Parrying-sticks, without the hand hole, are undoubtedly employed in some of the Pacific Isles. The bow-shaped parrying-shield, "Dang," represented by Mr. Petherick, now in the Bethnal Green collection without a string, is here represented with a string attached, showing that although now used exclusively as a parrying weapon, it was without doubt derived from the bow, which it resembles, and that the curved ends have been retained for a totally different use from that which they served originally. The identity of this weapon with a Caffre implement figured in Wood's "Africa" is, however, doubtful, as it appears not unlikely the latter may be a musical instrument.

Several illustrations are given of the peculiar iron boomerang of the Niam Niam, here called "Pingah," but known as "Hunga Munga," or "Shanger Mangor," by the Musgu of Soudan, and Kulbeda in Upper Sennaar. The distribution of this class of weapon and its varieties has been traced by Col. Fox in his catalogue, where it is shown to be common to the greater part of the black races of mankind, including the Australians and the aborigines of Central India; but we have here some additional points of interest in connection with the African variety. We now learn from Dr. Schweinfurth that, like the Australian weapon, it is thrown by the Niam Niam, so as to rotate in a horizontal plane, which, though anticipated, has not been distinctly stated by former travellers. We learn also from this work that the wooden variety of this weapon, called "Trumbash," a name which is sometimes also applied to the iron variety, and which was first noticed by Sir Samuel Baker in Abyssinia, is in use amongst the Mohammedan negro tribes throughout the district between that country and Lake Tsad. This weapon, described as a flat two-edged projectile of wood, curved more or less sickle-like, and wider towards the point, is undoubtedly the original of the whole class, and from its resemblance to the Dravidian and Australian forms of it, affords one of several links which connect the arts of those black races of the southern hemisphere, which are supposed by Prof. Huxley, and by Prof. Haeckel after him, to have been derived from a now submerged paradise in the Indian Ocean.

To our knowledge of the iron-work of these tribes Dr. Schweinfurth also adds some important details, but it is remarkable that he should not have especially noticed the peculiar ogee-sectioned blade, sunk on alternate faces, which is such a characteristic feature of the iron implements of all Africa, from the Caffres on the south-east to the Fans on the west, and which, like the double bellows, connect them with the iron-workers of Sudia and Burmah. It is true that illustrations of this peculiar blade, so far as the shading enables us to judge, are given in the plate of Niam Niam spear-heads, but without comment. They are absent in the plate of Bongo spear-heads, and it would be interesting to know whether this is an accidental omission, or whether the Bongo form is in this respect an exception to the custom prevalent amongst other tribes of iron-workers.

The plates are well executed, and though not furnished with a scale, as is desirable in such works, the dimensions are given in most cases.

It might be suggested as an improvement to future travellers, that in the arrangement of the plates more attention should be paid to varieties, and that the several forms should be placed side by side according to their affinities. There is no point of so great interest to the scientific student of early culture as the allied varieties of form. As a rule with exceptions, it may be said that arts which are indigenous present greater varieties than those which are exotic, and hence the importance of studying minute differences, more especially in cases where, by means of gradual variation, transitions to other types or other uses may be traced. A few finished drawings are no doubt valuable in order to give a correct idea of the leading types; but for the varieties, outline drawings on a smaller scale in the style of the illustrations of "Demmin's History of Arms," are all that is needed, and enable these transitions to be given at a trifling cost. With these additions, and with due attention to such other matters relating to savage art as are suggested in the "Anthropological Notes and Queries," published by the British Association, we would earnestly commend the example of Dr. Schweinfurth to all travellers, for, as he truly says in his preface, "Hurry is needed: the destructive tendency of our industrial productions obtruding themselves upon all the nations of the earth menaces, sooner or later, to sweep away, even in Africa, the last remnants of indigenous arts." Of the utility of such a work as this no anthropologist or antiquary can doubt. There is, however, one remark of the author's to which we would draw special attention, and which he in this work reiterates with commendable emphasis:—"A people, as long as they are on the lowest step of their development, are far better characterised by their industrial products than they are either by their habits, which may be purely local, or by their own representations, which, rendered in their rude and unformed language, are often incorrectly interpreted by ourselves. If we possessed more of these tokens we should be in a position to comprehend better than we do the primitive condition of many a nation that has now reached a high degree of culture."

RECENT FRENCH EXPERIMENTAL PHYSIOLOGY

Physiologie Expérimentale. Travaux du Laboratoire de M. Marey. (Paris: G. Masson, 1876.)

UNDER the auspices of the Minister of Public Instruction of France are published from time to time volumes of the "Bibliothèque des Hautes Études." The work before us is one of these, and its value will be fully appreciated by any physiologist or physicist who has once glanced at its well illustrated pages. It contains several papers by M. Marey, mostly on points connected with the employment of the "graphic" method of depicting the magnitude and duration of dynamical phenomena both physical and physiological, and two by Dr. François-Franck on the anatomy and physiology of the vascular nerves of the head.

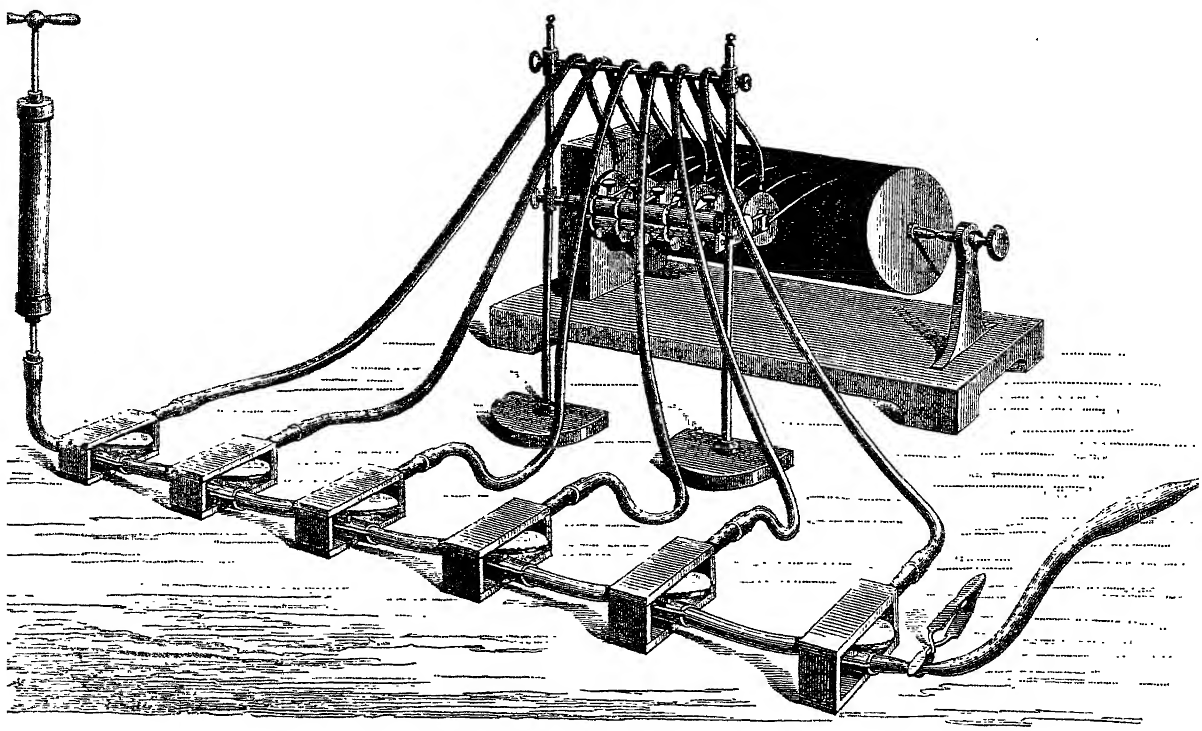

Fig. 1.

The most important of the memoirs by M. Marey is, in our estimation, that on "the movements of liquid waves, undertaken with a view of assisting in the theory of the pulse." Of this we will give a short account on the present occasion.

M. Marey's extraordinary mechanical skill has enabled him to devise and construct an apparatus by means of which he has been enabled to represent synchronously,

by the graphic method, the moment of origin and the conformation of the wave produced in every part of an india-rubber tube distended with fluid. A glance at the accompanying figure (Fig. 1.) will indicate the method employed. The wave is produced by the movement of the piston of the pump at the left side of the figure. It is transmitted along the continuous horizontal tube in the foreground, which is made to record the movements of six equidistant spots twenty centimetres apart, on the revolving drum, covered with smoked paper, in the background, by means of the delicate system of double "tambours," or elastic-covered drums and levers which have been introduced and so much employed by the author. The tubes connecting the tambours, being of the same material and of equal length, any error from irregularity in the rate of transmission along them is avoided. A pair of forceps, as in the figure, close the experimental tube just beyond the point of attachment of the last of the tambours.

When a positive wave, in other words, one of compression, is transmitted along this tube, thus arranged, it is seen that the levers rise one after the other, beginning at that nearest the piston; and that immediately the last one begins to rise, a second wave commences in the opposite direction. There is still more to be learnt from the curves recorded on the smoked cylinder, which are reproduced in Fig. 2, from an actual experiment. In this figure the six undulations are those of the six levers, the lowest being that of the portion of the tube nearest the piston, and the highest that of the furthest end. The trace of a chronograph vibrating fifty times a second is given below the lowest of the curves. Perpendiculars projected from the summits of each of the curves upon the chronograph trace would be separated by equal intervals if, during the different parts of its course, the rapidity of transmission of the wave were uniform. But it is seen from the figure under consideration that, although in traversing each 20 centimetres of the tube the wave takes about one-fiftieth of a second, and so travels at the rate of about 10 metres a second, nevertheless its rapidity is not absolutely uniform, being at its maximum at its orifice of entry, and after it has become slower again, slightly increasing in velocity in the neighbourhood of the closed end. There is therefore a double change in the velocity of the wave.

When it has reached the extremity of the tube the wave takes a reverse course, and returns through each of the recording drums to the place from which it started. This reflected wave is indicated by the down-turned arrows in Fig. 2; the direct one and its secondary companions having

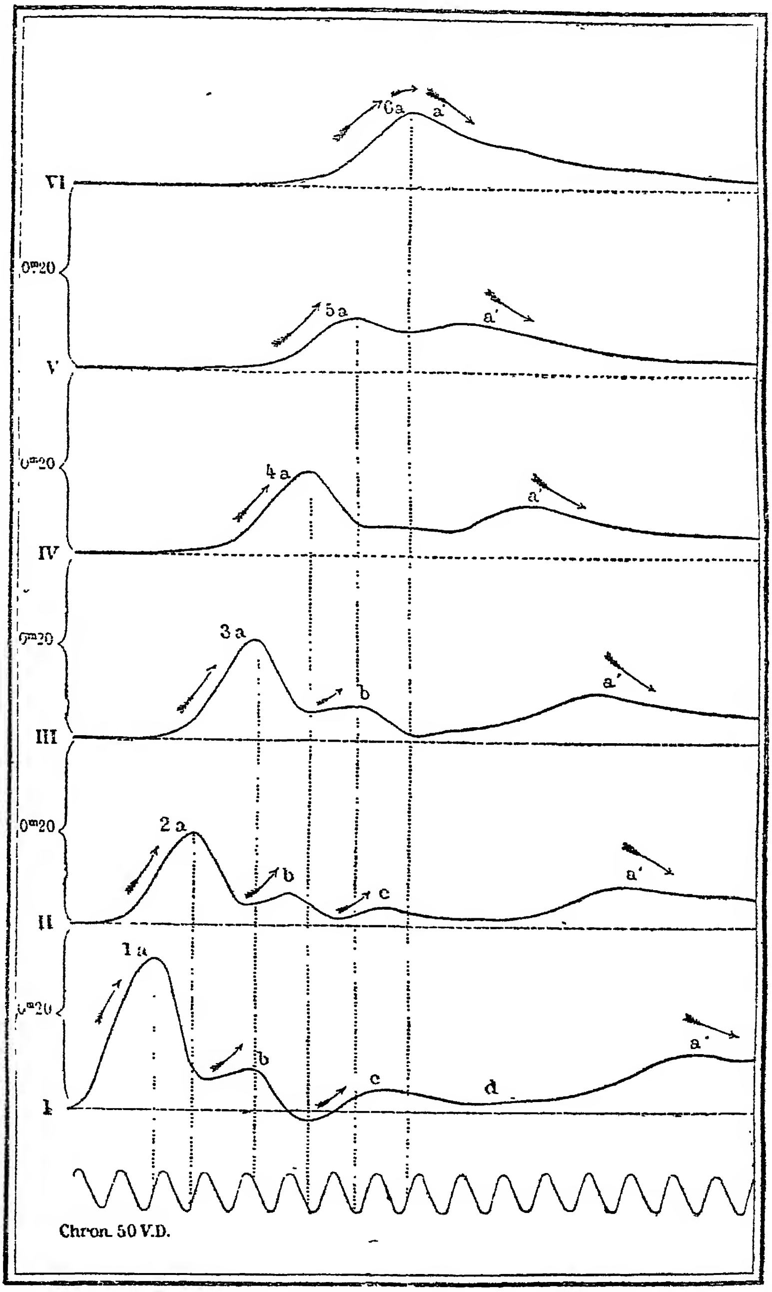

Fig. 2

upturned arrows above them. By varying the distance of the occluding forceps from the last recording tambour the time of commencement of the reflected wave can be similarly varied.

It is interesting to observe that in a paper on the movement of the pulse-wave in the human arte-

ries,* Mr. Garrod has shown that the pulse-wave augments its rapidity as it gets further from the heart, a result which is specially interesting in connection with those of M. Marey on the undulations in closed tubes, the blood system being similar in all respects.

With reference to the changes of the height of the undulation in different parts of its course, it can be proved that the wave has its maxima of intensity at its two ends, its minima in the intermediate part of its course. The wave also changes in form during its progress, this change consisting essentially in a diminution in its amplitude and an augmentation in its rapidity. This depends on the elasticity of the tube, which tends to distribute the pressure in the different parts of the liquid column.

It will be seen from Fig. 2 that the primary direct wave is followed by a more or less numerous series of secondary diminishing minor waves. They are dependent on the rapidity with which the liquid is forced into the elastic tube. The reflected wave may also give rise to secondary undulations. The whole of the foregoing results are represented in a most vivid manner by the translation of their results stereoscopically or into a figure of three dimensions, represented in Fig. 3. We have never before seen results of a similar kind similarly depicted.

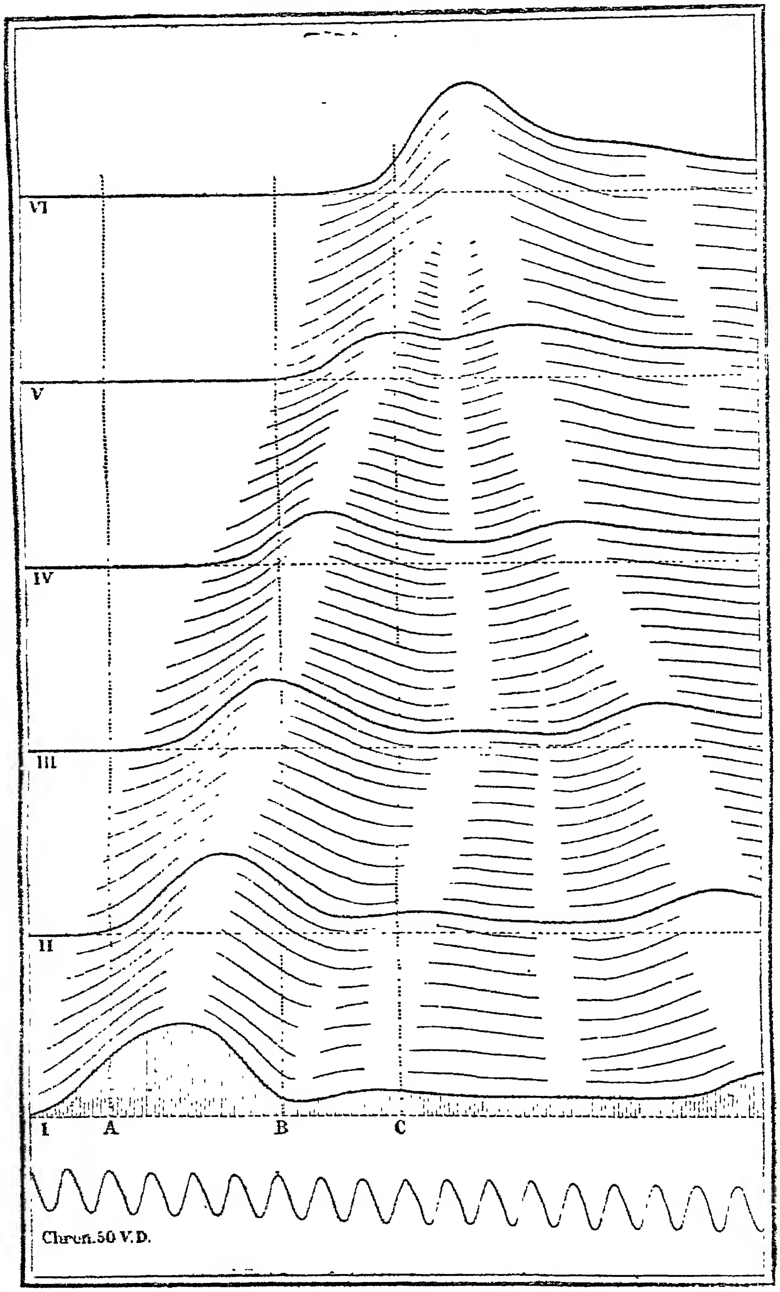

Fig. 3.

Among the other results arrived at by the employment of the same instrument, M. Marey has shown that *negative* waves, that is of absorption, obey exactly the same laws as do *positive* waves, or those of compression; also, in tubes opened at their distant end, if the aperture is large, no reflected wave is produced, at the same time that the intensity of the undulation diminishes from one to the other end, and its rapidity also gradually.

(*To be continued.*)

THE ARCTIC WORLD

The Arctic World: its Plants, Animals, and Natural Phenomena. (London and Edinburgh: Nelson and Sons, 1876.)

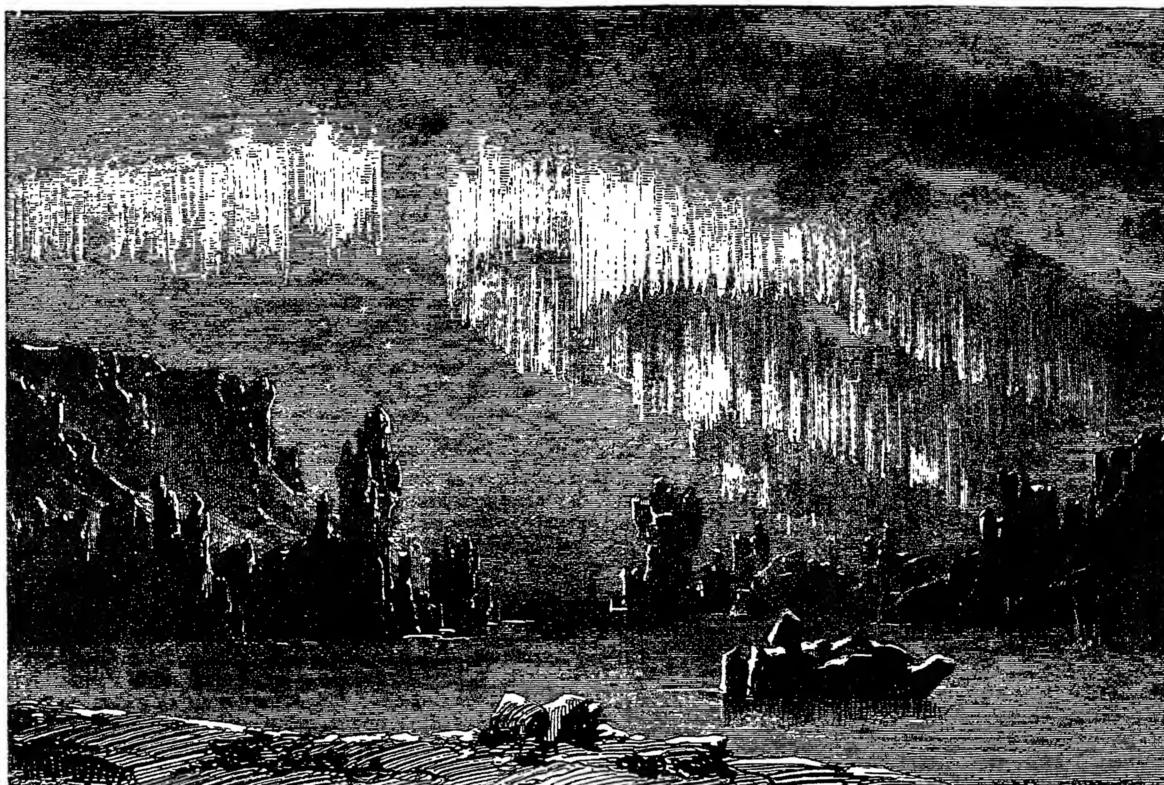
THE Messrs. Nelson have in the present work made a praiseworthy attempt at innovation on the usual style of drawing-room book; for that "The Arctic World" is meant mainly for the drawing-room table its whole appearance indicates. The work is something more than a mere picture-book, though its pictures are certainly a striking attraction. The compiler of the text has made an honest, and, we believe, remarkably successful, attempt to carry out the promise of the title-page, and present a satisfactory account of the physical phenomena, the plants, animals, people, and scenery of the entire round of the Arctic regions. There is really a great amount of solid and accurate and valuable information conveyed, information in itself calculated to interest in a high degree any healthy mind, and which the compiler has had skill enough to put into shape without detracting from its interest.

While we congratulate the publishers on their successful attempt to elevate the quality of drawing-room litera-

ture, we also rejoice, in the interests of science, that they think there is some chance of such a work becoming a commercial success; for thus, in the judgment of practical men, there exists a considerable public who are able to understand, appreciate, and enjoy a work which is largely scientific in its character. This is an additional sign of the general advance in intelligence which has been going on in recent years, and of the fact that the results of scientific research are gradually taking a place in the public estimation of equal importance with the results of literary effort. We sincerely wish "The Arctic World" an extensive circulation; the publishers certainly deserve to be rewarded for the venture they have made.

Although the text is of substantial value, still, the most striking feature in this beautifully got-up book is its pictures, which are most, if not all, of French workmanship, and are really beautiful in execution, with that touch of artistic exaggeration which the French manage to impart to the most commonplace woodcut. These pictures, upwards of 100 in number, render the work a most attractive one, and besides, of themselves, are calculated to convey not a little information concerning the Arctic regions, the varied life, animal and human, and scenery of which they represent with considerable fulness. They are in all respects so attractive, that they can be looked at over and over again without any diminution of interest.

In the first chapter the author points out briefly and



The Aurora Borealis.

forcibly the scientific and practical gains which may be expected from Arctic exploration, and which were fully set before the public in connection with the Arctic expedition, which no doubt is now upon or beyond the "threshold of the unknown region." He gives a short sketch of the geographical features of the Arctic region, of its surface in relation to snow and ice, and of the general character of life in the Polar World. In the second chapter an interesting account is given of some of the most striking phenomena tures of the region, the scenery, atmospheric phenomena, the aurora, and some of the most prominent astronomical features. The nature and formation of icebergs are pretty fully discussed in the next chapter, and the various forms of ice to be met with in the Arctic regions described; after which comes an interesting account of some of the forms of animal life to be met with in the Polar Seas, and the methods of capturing it. Then follows a well-written account of the most trustworthy researches on the nature and formation of snow and ice in connection with the constitution and movements of glaciers. Vegetable life is described in Chapter V., as also the connections, habits, and uses of the principal land-animals and birds. A slight divergence is made in Chapter VI., in order to give a brief account of Iceland its scenery, its physical phenomena, and the life and character of the people; this chapter is written in a tone that Capt. Burton would probably think too highly pitched. In the three succeeding chapters the characteristics and mode of life of the various people who inhabit the Arctic regions are set forth with considerable

fulness. The Eskimo, the Lapps, the Samojedes, the Ostraks, the Jakuts, the Tungusi, the Tchuktche, the principal groups of people in short that inhabit Arctic America, Europe, and Asia, all come in for detailed notice, and that in a manner calculated both to interest and instruct. It is the same with respect to all the other matters referred to in the work: we are too apt when thinking of the Arctic World to limit the term to Greenland or Arctic America at most, forgetting how much more the term includes. In the present work the whole region within the Arctic Circle, all round, is included, and its various features, phenomena, and life described with greater or

Kamtschatkans.

less minuteness. The last chapter contains a brief *résumé* of the course of Arctic discovery.

The work altogether is one of the most interesting and trustworthy of its kind we have had the pleasure to come across; we do not know of any similar book which gives a more satisfactory account of the principal features of the Arctic World. Boys and girls we are sure would consider it a treasure; and to all old boys and full-grown girls who desire "something fresh" both to read and to look at, we can heartily commend it.

OUR BOOK SHELF

Notes of Travel in South Africa. By Charles John Andersson. Edited by L. Lloyd. (London: Hurst and Blackett, 1875.)

THOSE who are acquainted with the late Mr. C. J. Andersson's "Lake N'gami," "The Okovango River"—discovered by him—or any of his other writings, will gladly avail themselves of the opportunity afforded by the "Notes of Travel" of again learning, from his own pen, other incidents in the short and far from uneventful career of the enterprising semi-Swedish traveller and fluent writer.

The posthumous "Notes" edited by Mr. Lloyd—who performed the same service with reference to another of Mr. Andersson's works, "The Lion and the Elephant"—contain, besides the descriptions of the habits of some few of the birds and animals of the districts in question, the account of the doings of the author during the last four or five years of his life, a period in which the political differences between the neighbouring South African tribes of Damaraland and Namaqua Land compelled him to devote more time to trade and the disputes which arose therefrom, than to geographical and biological research.

Not long after his marriage, in 1861, Mr. Andersson purchased of the Walwich Bay Mining Company, on the winding up of their affairs, their extensive establishment—Otjimbingue—in Damaraland, with the object of making it a trading station for cattle and ivory. In a war which arose between the Damaras and Namaquas Andersson found himself constrained to become the leader of the former; during this he sustained, from a bullet, a wound in the leg smashing the upper end of the right tibia and fibula, which was long in healing, and rendered him lame for the short remaining period of his life.

The great injury done to his trading operations, the loss of his stock, and the probability of further outbreaks, led the author, who was still suffering from his wound, and further incapacitated by repeated attacks of dysentery, in his enfeebled state, to entertain the idea of establishing favourable trading relations with the Portuguese settlers of Benguela, north of the river Cunené. With this object in view he left Cape Town, where he had spent some time on account of his health, in May 1866, once more for Damaraland. Namaqua marauders continued to harass him, and he started from Ondonga for the Cunené in May 1867. He reached that river in the middle of June; however, he never crossed it because of the bad treatment he received from the ferrymen and from his state of health, which will be best understood from his own note on the day following that on which he reached it. He died in the Ovampo wilderness, where he was buried by no one but a youthful and faithful attendant, Alex Ericson.

During his illness he spent much of his time in collecting the materials for a work on the ornithology of South-west Africa, a book which was to have been published in a profusely illustrated and otherwise costly form by Messrs. Day and Son. This important addition to our knowledge of the African avifauna the author never saw in print; but since his death it has been produced in a more unassuming form, under the able and careful editorship of Mr. J. H. Gurney, under the title of "The Birds of Damaraland;" now a standard volume of ornithological literature.

The notes on the habits and powers of the vulture will interest naturalists, as will the attempt to distinguish a second species of ostrich, said to differ from *Struthio camelus* in that the male bird is slightly larger, whilst the female is jet black, like the male, instead of greyish; and the young is of a sooty brown. *Machaerhampus anderssoni*, or Andersson's Perm obtained from Otjimbingue, is fully described, as are the Kori Bustard (*Eupodotis kori*), the Rufous-crested Bustard (*E. ruficrista*), Rupell's Bustard (*E. rupelli*), and a few other birds. Mr. Lloyd tells us in his preface that, among numerous papers, Andersson left behind him "Notices of several of the quadrupeds indigenous to Damaraland and the neighbouring countries." These it was his original intention to incorporate in the present work, but to preserve the continuity of the narrative they were, with the exception of a single chapter on the Leopard and its congeners, omitted, though not without hope that at some future

time they may be submitted to the public, as we wish they may be.

In conclusion, we may remark that, with the exception of a few descriptions of personal symptoms, which would have been much better left out, Mr. Andersson's "Notes on Travel in South Africa" forms an interesting and instructive volume to the general reader, as well as the student of geographical and natural science.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

A New Cetacean from New Zealand

I HAVE just received from Dr. Julius Von Haast of Canterbury, New Zealand, for presentation to the Zoological Society, an account of what appears to be a new species of Ziphioid Whale.

As far as can be at present ascertained, for, unfortunately, the heads only of three individuals, and these not in a perfect state, were obtained, it is nearly allied to the genus *Mesoplodon*, Gervais, but differs from the known species in the possession of a row of small pointed, conical, recurved teeth, about twenty in number, in the hinder part of the upper jaw, in addition to the usual single large tooth, placed near the middle of the ramus of the mandible. This is a very interesting circumstance as connecting the peculiar dentition of the ziphioids with that of the ordinary dolphins.

Another fact, new in the history of the Cetacea of this group, is that they belonged to a shoal of twenty-eight, all stranded together on one of the Chatham Islands, whereas all previously recorded examples have been either solitary or in pairs. It is evident that the attention which the naturalists of New Zealand are paying to the Cetacea, will throw much light on the history of the order, and it is to be hoped that they will persevere in collecting and preserving every specimen which may come within their reach. Dr. Haast's paper will be read at the next meeting of the Zoological Society. W. H. FLOWER

Evidences of Ancient Glaciers in Central France

MY attention has been recently called to a communication on the above subject which appeared in NATURE, vol. xiii. p. 31, from Dr. Hooker. Not having myself observed any traces of glacial action in the Mont Dore, and finding that M. l'Abbé Lecoq, whose examination of every portion of the district was most painstaking and exhaustive, has declared his conviction that no such traces exist, may I be permitted to remark that the evidence produced by Dr. Hooker does not appear very conclusive on the question? It consists of the occurrence of some large fragments of trachyte in the floor of the valley in which the Dordogne takes its rise, "the head of which occupies a noble amphitheatre immediately under the highest summit of Mont Dore," which "seen from a height above, were presumably huts, haystacks, *or glacially transported blocks*." The next day the doctor descended into the valley for a fuller examination of these blocks, and found himself "amongst a group of magnificent boulders *that had evidently been deposited* (?) *by an ancient glacier* which had flowed from the rocky amphitheatre at the head of the valley;" "others were seen further down the valley, its stream meandering among the blocks."

Now this description together with all that follows, and which I need not quote, strongly reminded me of a large assemblage of *débris* of trachytic rocks which on my last visit to the Mont Dore in 1860, I observed exactly in the position indicated by Dr. Hooker in the valley of the Dordogne, and which had been the result of a prodigious landslip or fall of a huge slice of the cliffs above, nearly a thousand feet high, forming the left flank of the valley as we look up it extending for upwards of half a mile. This landslip had occurred, if I remember rightly, in the previous winter, and was by no means an unprecedented occurrence, as the ruins of several older "eboulements" along the same line of cliffs attested. The summit of the cliffs consisted of a solid bed of trachyte perhaps fifty feet in thickness, and the action of frost on the waters infiltrated into the vertical joints of this rock tended to detach occasionally blocks of it which in large numbers, and many of them of enormous size, had evidently fallen from above on the floor of the valley. Some of these bore exactly the appearance of those described and figured by Dr. Hooker, and with every deference to his high authority, I cannot but suspect that they are the identical rocks which he, somewhat hastily, perhaps, concluded could only have been transported by "an ancient glacier descending from the neighbouring head of the valley." Should this prove to be the case, as no other evidence of the action of glaciers in the Mont Dore has been produced, it is presumable that M. Lecoq's view is correct, that none such are to be found. G. POULETT SCROPE

Fairlawn, Cobham, Surrey

Science Classes and Penny Lectures in Birmingham

IN NATURE, vol. xiii., p. 82, is an article on "The Manchester Science Lectures," in which it is stated that the popular lectures at the Midland Institute Birmingham "are chiefly frequented by the middle classes," while "at the Manchester lectures the class of persons present was chiefly working men for whom the lectures were designed.

This statement, although not absolutely incorrect, conveys quite a false impression respecting the Birmingham lectures; the fact being that the Midland Institute has two Departments, the "General" and the "Industrial," the former being designed for the middle classes, and the latter for artisans, &c. As the history of the popular scientific teaching at this Institute includes some instructive practical experience, a few reminiscences of the leading facts may be interesting.

The Institute commenced its working existence in October 1854 with three classes, one for Physics meeting on two evenings per week, one for Chemistry also on two evenings per week, and one on Popular Physiology and the Laws of Health meeting on one evening per week. These were all conducted by myself—then the only teacher of the Institute—at the rooms of the old Philosophical Institution, 7, Cannon Street. They were attended by men and boys, for the most part artisans and *bonâ fide* students. The first course on Chemistry comprised about 90 lectures, that on Physics about 130, and that on Physiology about 30 lectures.

The number of students and the general success of these lectures exceeded the expectations of the promoters of the Institute, and refuted the predictions of the large proportion of influential Birmingham men who loudly expressed their anticipations of failure.

Such was the beginning, but ere long we were threatened with a repetition of the old experience of the old Mechanics' Institution, and other similar efforts that had failed in Birmingham, and upon which failures these gloomy predictions were founded. The Chemistry class, which was the largest at first, sustained its numbers and attendance during what I may call the combustive stage of its existence, that is, so long as the three oft-quoted essentials of successful chemical lectures "the flash, the bang, and the stink," were maintained; but when we came to the metals, to mere precipitates, equations, analysis, &c., the numbers seriously declined.

The Physics class, which began more modestly, kept up its numbers rather better; there, the progress was from the heavy business of statics and dynamics, to the more wonderful phenomena of heat, light, and electricity. The physiology class was the smallest from the first, but held on pretty steadily to the end of the course.

On completing the first course of each subject we encountered a check that threatened our very existence. The numbers diminished, and this diminution became alarming with the third course on Physiology (which commenced before that of the other subjects). The alarming element was not merely the diminishing number of students, but the obvious cause of this diminution. We were evidently exhausting our raw material. The total number of Birmingham artisans who desired the amount of scientific instruction we offered them was but limited, and the majority of these had attended the first courses, and in the ordinary progress of normal generation they were not reproducible with a rapidity at all corresponding to the repetition of our courses of instruction. What was to be done?

This difficulty of course presented itself more forcibly to me than to anybody else as the facts were more directly before my eyes, and naturally led to serious reflections. To have shortened the courses of instruction, to have made them lighter and more popular, would have sacrificed our main object, seeing that I had already gone as far in that direction as sound instruction permitted. What then?

My own early experience suggested a solution. Might I not deliver some well advertised public scientific lectures of a sufficiently light and sensational character to captivate the intellect by the natural bait of wonderment? If so, the systematic classes might be fed by their means.

My first idea was, considering the poverty of the Institute at that time, to charge twopence or threepence for admission to such lectures, but on communicating my scheme to Mr. Arthur Ryland, the Vice-President of the Institute, he improved it materially by suggesting that the charge for such lectures should be one penny, and that they should be called "Penny Lectures."

The Council assented to this, and on Jan. 22, 1856, I commenced the first course of Twelve Penny Lectures in the Lecture Theatre, Cannon Street.

The lecture theatre was crowded throughout the course, which served its intended purpose of supplying an outline of the grasp of Physical Science. This course was followed by others. I continued them every Tuesday evening during above nine months of each year until July 1863, when I left Birmingham. They were always well attended but with some degree of fluctuation. The smallest attendance was during a course on the Birmingham manufactures, and the best attendance when subjects connected with combustion, electricity, or my own travelling experiences were treated and well illustrated.

I do not at all presume to describe these lectures as nearly equal to the Manchester lectures that have been lately delivered. They were necessarily extemporised, as may be supposed from the fact that, with the exception of an occasional volunteer (four or five lectures per annum), I delivered them all myself, and at the same time conducted the Lectures on Chemistry, Experimental Physics, Junior and Ladies' Classes, and the Practical Analytical Class in the Laboratory, besides being compelled to supplement my very small salary by writing newspaper articles.

I mention this to show how much may be done by small means. The Institute was so poor at its beginning that I was obliged to fit the lectures to the small stock of apparatus we possessed, and lecture on whatever subjects I could best illustrate. The average outlay upon illustrating these early lectures did not exceed three or four shillings each.

Nevertheless their object was fulfilled. The Penny Lectures fed the Science Classes, which without such aliment would have been starved and extinguished in their infancy. Their success led to the establishment of the "Penny Readings" of the Midland Institute in 1857 or 1858, which were, I believe, the first of these entertainments that have since become so popular and so much degenerated. These again were followed by the Penny Arithmetic Classes and the other Penny Classes which have since formed one of the leading and most important features of good work done and doing in Birmingham.

The egotism of the above narrative will possibly be pardoned, seeing that the experiences of the early struggles of the Science Classes of the Midland Institute have been so often repeated where similar efforts have been made, and are likely to be continued so long as the prevailing inefficiency or total absence of scientific instruction in our primary schools remains. The success of these Penny Lectures, in spite of all their shortcomings, in creating a demand for more thorough instruction indicates an available means of rendering science classes successful in other places. My advice to all concerned in the promotion of such classes is that they should make no compromise in reference to the classes themselves, by attempting to bring *in them* the subjects down to the level of present requirements of the majority, but that instead of this, they should, by means of very popular, attractive, aye, even sensational public penny lectures, excite curiosity, and create an interest in science among those they desire ultimately to teach.

Being now in the confessional I may as well admit that I practised several small illegitimate devices to keep my audiences together, one especially copied from the young lady who occupied "the thousand and one nights," that of leading the subject up to some amusing experiment just at the end of the lecture, and then discovering that it was time to conclude, and therefore that the experiment must be shown next Tuesday. The small boys who occupied the front seats and applauded all the explosions soon found me out, but they came next week nevertheless, and some of these who at first were blue-fire pupils only, ultimately joined the classes and became satisfactory students. Therefore the Penny Lecturer should not be too rigidly regardful of his own scientific dignity, but Barnumise to some extent, when he can thereby advance towards the high object he seeks to attain.

"Should this meet the eye" of any disconsolate projector and manager of a failing Mechanics' Institution or similar effort, let him try Penny Lectures forthwith, not musical or dramatic lectures, but lectures on the most wonderful of natural phenomena, including as much scientific explanation as the audience can digest, and at the same time let him prepare to supply the solid class instruction for which such lectures should ultimately create a demand. Belmont, Twickenham

Proposed Optical Barometer

I was led the other day to consider the possible effect of changes of barometric pressure on the ultimate destination of light passing through lighthouse refracting agents, and although I was satisfied that such changes cannot produce any effects of practical importance, the idea occurred to me that a glass prism might be used as a barometer. When a refracting prism is successively immersed in media of different refractive indices the ultimate angular deviation of the ray will, as is well known, depend in each case on the relative indices of the glass and the medium surrounding it at the time of the experiment. And as the refractive index of atmospheric air varies with its density, the amount of deviation of the refracted ray will be a measure of the density of the air, *i.e.* will give the means of ascertaining the reading of the barometer at the time.

If the ray of light were made to pass through a number of refracting and totally reflecting prisms the deviation would be increased. If with these prisms a microscope were combined the prisms might be used as a barometer. Or if the ray be received obliquely on a number of pieces of glass having parallel faces and slightly separated from each other, although there would be no angular deviation there would be horizontal displacement which would admit of being measured by a micrometer. How far such an application would be of practical value is certainly doubtful, as the effects of changes of temperature on the prism itself might interfere with the very limited range of the instrument. Or again, it is possible that easterly, westerly, or other currents—or perhaps differences in the hygrometric state of the atmosphere—may affect the index of refraction otherwise than by the mere changes of density which they produce. But if such be the case, the refracting prism will be useful in determining the existence and amount of such variations in the refrangibility of the atmosphere.

Edinburgh, Dec. 13 Thomas Stevenson

Seasonal Colour in Flowers

The "blue of the wild hyacinth" (see vol. xiii. p. 129) is anticipated by the yellow of the primrose, the daffodil, the marsh marigold, the coltsfoot, the lesser celandine (*Ranunculus Ficaria*), and especially the winter aconite. We may add as contemporaries the buttercup, the yellow deadnettle, and the cowslip. The furze blooms in autumn and winter, and the golden broom in spring; the dandelion and the groundsel flower during the greater part of the year. The "deep scarlet of our summer flowers," represented in Britain by the poppies and the pimpernel only, is accompanied by the no less vivid blue of the cornflower, the wild chicory, the viper's bugloss (*Echium*), whose blossoms change from red to blue as they approach maturity, the flax, and the various campanulas. I say nothing of white flowers; but it is worth notice that the hepatica, bugle (*Ajuga*), and milkwort (*Polygala*), vary to almost precisely the same shades of blue, white, and pink, at quite different seasons. Hatfield, Dec. 17

Glands of the Cherry Laurel

The nectariferous glands on the back of the leaf of the cherry laurel (vol. xiii. p. 107) are present also, I believe, in all the Drupaceæ. The position is not in all cases the same; but when the glands are not found on the back of the leaf, they may be seen on the petiole. Ants may often be found drinking this leaf-honey; and I heard, two or three years ago, that the same attraction had brought many hive-bees to the laurels in a garden at Sidmouth. E. H.

OUR ASTRONOMICAL COLUMN

Variable Stars.—Nos. 2065-67 of the "Astronomische Nachrichten" contain another of Prof. Schönfeld's

important contributions to our knowledge of the variable stars, the eighth of a series commenced in No. 1628, ten years since. The observations discussed in the last communication were chiefly made in 1874, but there are also observations of several objects to the middle of the present year. In the comparisons of the observed epochs of maxima and minima with those calculated, the elements in Schönfeld's second Catalogue (Manheim, 1875), which should be in the hands of every observer of variable stars, have been employed, while in a few cases new elements are given.

Mira Ceti was at minimum 1874, Nov. 20 (mag. 8·6), and at maximum 1875, March 4 (mag. 2·5), the latter being about eight days later than is deduced from Argelander's formula of sines.—T Tauri, the star adjoining the variable nebula in Taurus (Hind, 1852), has exhibited irregular fluctuations between the years 1868 and 1875; previous to 1868 it had occasionally been as bright as 9·5, but according to Schönfeld's observations since that year, it has not been higher than 10·3, while at a maximum, 1871 Nov. 25, it was only 12·0, and at another very certain one, 1874 Feb. 10, it was 11·7. Schönfeld states that the nebula of 1852 was invisible in the Manheim refractor (6·5 inches aperture) during the whole period 1868-75, while the small nebula detected by Mr. Otto Struve immediately preceding this was only occasionally glimpsed. This spot requires to be closely watched with large instruments.—U Geminorum was satisfactorily observed at a maximum, 1874 Feb. 4·4 (mag. 9·6), 111 days after the preceding one; another maximum may be expected at the beginning of January next, or possibly in the last days of the present month; since the discovery of this star in 1855, it has shown variation of period between about 70 and 150 days.

R Crateris, the star following α, which Sir John Herschel describes (Cape Obs., p. 448) as of "a most intense and curious colour," and "scarlet, almost blood colour," has exhibited during the last ten years a slight variation estimated from 8·2 to 8·9 mag., but the observations have not afforded any epoch to assist in determination of elements.—S Virginis has been twice observed by Schönfeld at minimum viz., 1874, April 20 (mag. 12·5), and 1875, April 26 (mag. 12·4), which he believes are the first minima yet secured; at certain maxima this star becomes distinctly visible without the telescope (mag. 5·7).—χ Cygni attained a maximum 1874, Nov. 9, mag. 4·7, or about midway between ϕ and η Cygni; this epoch is upwards of two months later than the date assigned by Argelander's formula in the Bonn Observations, vol. vii., but the extreme difference between the formula and observation appears to have occurred in 1870, when it exceeded three months; the star must be near a maximum at the present time.—R Vulpeculæ: the further observations support the addition of the term depending on E^2 introduced in Schönfeld's last catalogue; he remarks that a uniform period would involve differences from the observed epochs amounting to twenty-two days, while these epochs are uncertain to three days at the most.—S Pegasi. This star, detected by Mr. Marth at Malta, 1864, Nov. 24, when its magnitude was 8·3, was at maximum 1874, July 8 (mag. 7.3): it must not be confounded with the star which first appeared upon our list of variables as S Pegasi, the insertion of which probably arose from an error of observation. The position of the variable for 1876·0 is in R.A., 23h. 13m. 46s; N.P.D., 81° 48′·8.

The following are Greenwich times of geocentric minima of Algol according to the third elements of Schönfeld (Der Lichtwandel des Sterns Algol in Perseus. Manheim, 1870).

		d.	h.	m.			d.	h.	m.

					,,	,,	22	7	20

The next maximum of Mira Ceti may be expected about January 17.

THE MINOR PLANETS.—M. Bossert has calculated elements of the small planet discovered by M. Paul Henry at Paris, Nov. 2, from which it appears the planet is not identical with No. 98, Dike, as surmised by Prof. Tietjen, and the actual number in this group, therefore, stands at 157. The best orbit of Dike is that of MM. Lœwy and Tisserand (*Comptes Rendus*, 1872, Feb. 19), and is subjoined with M. Bossert's for No. 152, for the sake of comparison.

	No. 98, Dike.	No. 152.
	° ′ ″	° ′ ″
Longitude of perihelion	240 35 34	80 0 3
Ascending node	41 43 42	41 28 49
Inclination	13 53 18	12 10 13
Angle of excentricity	13 47 30	4 42 59
Log. semi-axis major	0·446639	0·49582
Long. from equinox of	1868·0	1875·0

Circular No. 37, issued by Prof. Tietjen, contains ephemerides of Sylvia, Austria, No. 148 with elements from two months' observations, No. 150, No. 151 from elements founded on three weeks' observations, No. 152, No. 153, and No. 156: a circular orbit of the latter places the ascending node in 253° 52′, with an inclination of 4° 42′.

COGGIA'S COMET, 1874.—Dr. Schmidt, Director of the Observatory at Athens, publishes the first portion of the results of his observations on the appearance of the great comet of 1874, between May 3 and July 23, when he believes to have glimpsed the tail for the last time. The observations refer to the brightness of the nucleus as viewed in the telescope, and of the head of the comet seen with the naked eye, the apparent length of the tail, and semi-diameter of the coma; the measures are not reduced to actual values, in the absence of a complete ephemeris from good elements. On June 9 and subsequently the nucleus was always remarked to be yellow, and the mean of its apparent diameters, given by Dr. Schmidt, would be, for the earth's mean distance, about 0″·65, or 290 miles, as we find by taking the distance of the comet from the earth, deduced from one of the best parabolic orbits.

HUMAN ANATOMY AS A PART OF THE BIOLOGICAL CURRICULUM

WE would draw the attention of our readers to the following "minute" from Cambridge, dated Dec. 2:—

"The Board of Natural Sciences Studies report that the study of human anatomy in the University is at a disadvantage in consequence of its not occupying a more prominent and definite position in the Natural Sciences Tripos. It is found from experience that medical students who are candidates for the Natural Sciences Tripos relinquish the study of human anatomy until after the examination for the Tripos, and many are therefore deterred from making the attempt to obtain a degree with honours. Further, the more distinct recognition of human anatomy in the examination for the Tripos cannot fail to elevate the character of the teaching and study of it in the University as a branch of science, especially as it is contemplated by the Board that the subject of human anatomy shall include the mechanism of the human body, the comparison of its parts with those of lower animals, its development, &c. In proposing this addition to the subjects of the Natural Sciences Tripos it is not intended to add to the number of subjects with which students are expected to be acquainted; but the subjects represented in the examination are now so numerous and extensive that they have become practically, to a large extent, alternative, and the additional subject would, it is thought, prove attractive to a large number of students. The addition would also help to maintain the connection between the schools of Natural Science and Medicine,

The two days allowed for the examination in practical work in the second part of the examination is scarcely sufficient, and as the number of candidates increases, more time will certainly be required. The Board recommends some alterations in and additions to the regulations for the Natural Sciences Tripos, which will accomplish the object it has in view."

The Biological Schools of the older Universities, on account of their recent origin, are still in a far from settled state. Men who have had a previous education in some other medical school enter as undergraduates, and on more than a single occasion these have had the opportunity of demonstrating to the less highly educated of their year how great is the value of a knowledge of human anatomy, and how excellent a scientific training it forms.

The Board of Natural Science Studies at Cambridge mention as the first claim in favour of the greater stress which it desires to lay on anatomy, that medical students suffer from its omission, and are tempted to delay their special work. We are not among those who believe that the Universities will ever form good medical schools. The advantage of the University curriculum is that it prolongs the *higher* education through the period during which the mind is acquiring its reasoning powers, and, as a result, tends to strengthen these by continually varying the material to be reasoned on. Except as far as the production of teachers of the subjects it inculcates are concerned, it has not, and ought not to have, any direct ulterior objects in view. If medicine is to be specially studied we see no limits to the extension of the subjects embraced within it. The practice of medicine by most is hardly more than a trade, and why, as such, it should be more highly favoured than any other special training it is difficult to understand.

The arguments in favour of making human anatomy a part of the biological education are of a very different nature, and are insuperable. The study of zoology may be commenced at either end, with the simplest protozoa, or with a foundation of human anatomy. Both of these have their advantages. A glance at the previous education of those who are, at the present day, devoting themselves to the subject, shows that almost all who commenced it after having mastered human anatomy, have devoted themselves to the vertebrate sub-kingdom; whilst those who have commenced without any or with but little knowledge of anthropotomy, have taken to the invertebrata. The intricacy of the higher forms, and the standard of comparison afforded by the structure of the human frame, naturally leads to a comparison of this with those of its closest allies, and consequently places the vertebrata in a more favourable position for investigation. It also helps to develop a greater interest in human anatomy from the light thrown on it by those of less elaborate organisation.

The student who commences with the lowest sub-kingdoms has to acquire his training as well as his facts from the simpler forms, amongst which there is so little correlation that he is led to lay little stress on that general uniformity of type which seems to him to detract from the interest of a group apparently presenting so little variety among its different members.

Under the existing system, therefore, the tendency of the University education is to develop invertebrate rather than vertebrate zoologists, and this condition is capable of being modified in the direction of improvement by the introduction of human anatomy into the biological curriculum; for then those who take up such subjects might have the opportunity of acquiring the knowledge of vertebrate anatomy to an extent which would place them in a position that would prevent them from laying themselves open to the correction, by any anthropotomist, of their otherwise shallow information on vertebrate structure.

As to the character of the human anatomy which is required by the student of biology, it is a mistake to suppose that it is exactly that needed by the surgeon or medical man. In almost all manuals of the subject great stress has to be laid on relational anatomy, because this is the aspect of the subject required by them. Nevertheless a very fair and biologically valuable knowledge of the structure of the human body can be acquired without any necessity for so much time being spent in the mastery of the exact relations, through the whole of their course, of vessels and nerves. A thorough training in osteology, the disposition of the various viscera and nerve centres, and the structure of the organs of sense, together with a comparatively slight acquaintance with the exact course followed by each nerve, artery, and vein, is all that is required by the majority of comparative anatomists. Upon such a basis any special regional relationships might be mastered in a short time with but little difficulty, and if the student afterwards commenced a medical training, he would do so on a footing of peculiar advantage.

The latter part of the report above quoted attracts attention in another direction also. From it we learn that "the subjects represented in the examination are now so numerous and extensive that they have become practically to a large extent alternative." This we very much regret, and we are convinced that this tendency in the direction of the system adopted at Oxford will be as little satisfactory as it has proved in that University. It has the effect of turning out a number of narrow specialists, instead of, as it ought to do, starting the student in some definite direction with a fund of general information, which he will find invaluable after he has taken his degree.

THE BIRDS OF THE PELEW ISLANDS*

THE eighth part of the "Journal des Muséum Godeffroy," which has been lately issued at Hamburg, contains an interesting article upon the Birds of the Pelew Islands, from the pen of the well-known ornithologist, Dr. Otto Finsch, of Bremen. This group of islands, until recently almost unknown to naturalists, has of late years been visited by several collectors in the employment of the House of Godeffroy, who have transmitted to Europe full series of specimens of its natural productions. Dr. Finsch, in conjunction with Dr. Hartlaub, has already published various notices of these collections, and given descriptions of several new and most interesting species which they contained. The present memoir gives a *résumé* of the previous articles, and adds a complete account of all that is yet known concerning the ornithology of this far-removed group of islands. The total number of species of birds as yet ascertained to occur within their limits is fifty-six, of which twelve are peculiar to the group, and are not known to be found elsewhere. Perhaps one of the most remarkable facts connected with the ornithology of the Pelew Islands is the occurrence of a Jungle Fowl (*Gallus bankiva*)—being the species generally recognised as the original of our domestic fowl—in a wild state. It is possible, however, that this may be an introduction. It is singular also to note that the Nicobar Pigeon (*Calœnas nicobarica*) has spread thus far to the west. Noteworthy again is the entire absence, so far as is hitherto known, of parrots and finches in these islands. Dr. Finsch's excellent text furnishes complete details upon these and other points of interest, and contains full authorities for the occurrence of all the species attributed to the avifauna of the Pelew Islands. Five well-executed coloured plates give illustrations of some of the rarer species and adorn the work. Of the physical features of these islands an account has already appeared in a former number of the same journal, together with an excellent map of the group.

* "Zur Ornithologie der Südsee-Inseln." I. Die Vögel der Palau-Gruppe. Von Dr. Otto Finsch in Bremen. "Journal des Muséum Godeffroy," Heft viii., 1875.

THE VOYAGE OF THE "CHEVERT" TO NEW GUINEA

MR. WILLIAM MACLEAY, of Sydney has, in a letter to the *Sydney Herald*, given an account of his expedition to New Guinea, an abstract of which, though so small in its results, will no doubt interest our readers.

The *Chevert* sailed from Port Jackson on the 18th of May last with a crew of twenty, together with a doctor, four zoological and three botanical collectors, Captain Onslow, and Mr. Macleay. The ship was fitted up chiefly with the object of making collections in all branches of Natural History in the islands of Torres Straits and in New Guinea.

The voyage from Sydney to Cape York occupied a month, five days being spent in the Palm Islands, and six at Cape Grenville. On the 4th of June a stoppage was made at Brookes Island, and on the next day on the north-west of the North Barnard Isles, in the latter case with the object of getting a species of *Ptiloris* peculiar to the island, and Mr. Masters was so fortunate as to procure a male and two female specimens in the course of the afternoon. The next stage was Fitzroy Island, where a few birds were obtained; but much progress was prevented by the dense brushwood, which was also found in Palm Island.

On the next day the *Chevert* anchored off a low wooded sandbank, marked on the chart "Low Wooded Isle." It was surrounded by an extensive coral reef, the first seen on the voyage. They afterwards reached Turtle Reef, opposite the Endeavour River, passing a belt of country on the mainland which looks very promising. A belt of low land near the coast was backed up by steep hills of about 2,000 feet elevation, the whole densely wooded, with numerous landslips, showing a dark red soil. On June 8th, Number 4 Howick Group was reached, after passing a mainland which consisted, for a long distance back, of bare sandhills with elevated patches, forming Capes Bedford, Flattery, and Lookout. The next stage was Flinders Island, near which the land is very rough and rocky. Two days took them to Cape Grenville, where they supplied themselves with water. The weather being stormy and wet, not many specimens were procured. The land in the neighbourhood is the most barren that can be imagined. The rock is a kind of metamorphic sandstone, with sometimes a sub-horizontal stratification, quite vertical on the hills, with sharp laminated edges. The vegetation is scanty, the lower hills being clothed with coarse grass, dwarf grevilleas, &c.; the higher ranges being thinly clothed with acacias, banksias, and pandanus; the declivities and gullies alone being densely wooded; whilst near the water's edge the mangrove predominates. The natives are tolerably numerous, and for Australians above the average, well grown and developed. They know a little English, can appreciate tobacco and biscuits, and are good workers. They adopt the practice of cutting the ear-lobe into thin strips, as do the natives of Cape York, the islands of the Torres Straits, and New Guinea.

On the 18th of June, after sailing through Albany Passage, the *Chevert* anchored in Mud Bay. The settlement of Somerset, of which some years ago the Government had hopes, has proved unsuccessful, except as a pearl fishery, on which occupation about 700 men are employed. The fishing-ground lies almost entirely to the west of Cape York, and extends from Endeavour Straits and the Gulf of Carpentaria northwards to the very shores of New Guinea. Diving dresses are much employed in the fishery.

The vessel was detained in Mud Bay till June 26th for the Sydney mail. Not much collecting-work was accomplished in the densely-wooded, but *pauvre* neighbourhood, which is entirely composed of a very hard ferruginous sandstone. She then took a course due north to Warrior Island, a distance of sixty miles, stopping off the Sue Islands, where the anchorage is perfectly covered with masses of the young pearl shells. Warrior Island is a mere sandbank of small extent, and without vegetation; but it is the birthplace and home of the strongest, most numerous, and most adventurous of the races inhabiting the Torres Straits, who closely resemble the inhabitants of New Guinea.

On June 28th the *Chevert* proceeded on its course to New Guinea, making for the entrance to the Katow River. They dropped anchor 1½ miles from the mouth of that river, and the village of Mohatta. The following morning they were visited by two canoes with about twelve men in each. In one was Maino, the head-man of the village, in the other Owta, the head-man of a village three miles further west. They came on board with the utmost confidence, though they could never have seen so big a vessel before. It was explained to them, through interpreters, that the visit was a friendly one, with no other object than the collection of specimens; both Maino and Owta expressing a desire to assist, and inviting the crew ashore. Shortly afterwards twenty-two of the men landed in the fishing and surf boats, and were received at the village by the elder members of the tribe seated in a circle upon a large piece of new matting. They would not join in the company and participate in the smoking; those forming the circle consequently arose, perhaps not the best pleased.

The village consists of seven houses, exactly like those described by Jukes in the voyage of the *Fly*. Each house is ninety or 100 feet long, elevated about 6 feet from the ground, and covered with a thick thatch. The ends are open, and on each side are the sleeping places of the inmates. Each house holding about 50 people, so the population of the village must have been about 350. The houses are built near the sea, and are everywhere surrounded by mud, filth, and stench. The people are powerful and well made, jet black, with straight foreheads and Jewish noses, the projecting jaws of the Australian being absent. The hair is woolly, but grows in small tufts, which, when long, form close, compact ringlets; and it is not uncommon for the people, not here only, but at Warrior and Darnley Islands, to cut off their hair when thus grown into ringlets, and convert it into a wig for their own use. The men are quite naked; some being marked like the Australians with seams on the shoulders, all cutting the lobes of their ears into fantastic shapes and piercing the rim all round, and ornamenting it with coloured wool or fibre. They seem fond of ornaments of birds' feathers for the head, and necklets of pearl-shell. The women are kept from the view of strangers, but they are in no way beautiful. They are the hewers of wood and drawers of water. Their clothing is a scanty loin-covering, with ornaments of cassowary feathers round the knees and ankles.

Almost the only weapons of defence are bamboo bows and four-feet arrows. They use kava, said to be obtained some distance up the country. They are great navigators, their canoes, of great size, being formed of excavated trunks of large coral trees (*Erythrina*). Their supply of animal food is chiefly from pigs, which, both wild and tame, are numerous.

The appearance of the country is the same everywhere. In some places the mangrove seems to grow out into the sea; in others, as at Mohatta, there is a beach closely belted by cocoa-nut palms, and behind, everywhere the same absolutely level mud flat, without the slightest apparent rise as far as the eye can reach, and all densely covered with trees of all sizes and kinds, never reaching more than three or four feet above the sea and river level. The driest spots have been selected by the natives for their banana and taro plantations. They also cultivate yams, sago, and bread-fruit.

All efforts to penetrate the jungle proving ineffectual, an attempt was made to navigate the river in a steam launch and surf boat. At its mouth the Katow is about 200 yards wide, rapidly narrowing to 60 yards, and soon to 30 yards. For the first two miles Mr. Macleay and his party, accompanied by Maino and Owta, passed through a dense forest of mangrove, beyond which the river was edged by a palm nearly 50 feet in height. Behind these was the lofty and interminable forest. After ascending the river for between eight and nine miles they were abruptly stopped by a tree of great size which had fallen, or been felled, across the river. They had to return in order to obtain instruments for removing the obstruction. As they in this however never succeeded, they had to return to Warrior Island, whence they made for Darnley Island, at which place some successful dredging was accomplished. This they left on Aug. 13 for Hall Sound, on the east side of the Gulf of Papua, which they reached after much difficulty from adverse winds. The ship's captain declined to go further on this account. Yule Island forms the sea face of this Sound, and the opening on the north side between the island and the main is merely a shallow sandbank. The anchor was dropped close to the north-west point of the island, opposite the residence of Signor D'Albertis, the enthusiastic Italian naturalist, which can be seen perched on the side of a clear hill, about 100 feet above the water. Signor D'Albertis had established himself on Yule Island some months previously, in this his second expedition to New Guinea, and though, as Mr. Macleay tells us, he has encountered serious difficulties from the desertion of most of his men, the loss of his boat, and robbery by the natives, he still persists in holding his ground and prosecuting the object of his wanderings—the collection of objects of natural history. Assuredly if pluck, per-

severance, and determination can command success, Signor D'Albertis ought to be successful.

The island is about six miles long, picturesque, and healthy-looking. The soil is rich, and the plantations of the natives are numerous. The geological formation consists entirely of a calcareous sedimentary rock, containing numerous remains closely resembling recent forms. The appearance of the opposite shore of New Guinea is very different from that at Katow. Mangrove swamps are intersected by salt-water creeks, with low ranges of well-wooded open forests behind; beyond which the country seemed to become very rough and mountainous, with a stupendous mountain chain, on a clear day distinctly visible from the magnificent peak of Mount Yule on the west, to Mount Owen Stanley on the east. The natives of the country hereabouts are light-coloured, of medium size and active. Their hair is not woolly, and is generally worn long, being tied up in a chignon behind. They do not use tobacco, but chew the betel leaf. They wear a very tight belt, carrying a small piece of cloth. They seem to be timid and inoffensive, greedy and thievish. The women appear to be the rulers, and they are far from reticent in the presence of strangers. Some of the younger ones are tolerably good-looking; they wear showy loin dresses, and are tattooed about the breasts and belly. Their villages and houses are clean, and generally on sloping ground; they have a house in every village for the reception of guests; their mutual relations seem most friendly. They pay considerable attention to cookery, and manufacture pottery, cloths, and nets of excellent quality.

Mr. Macleay remained on Yule Island until Sept. 2, collecting and exploring. No Birds of Paradise were obtained, although many plumes were seen in the hands of natives. No Tree Kangaroo nor Cassowary was seen. He then, on account of adverse winds, returned to Cape York, and so terminated this unsuccessful attempt to explore New Guinea.

It may be mentioned that Dr. James, the surgeon, Mr. Knight, one of the botanists, and Mr. Pollard, one of the taxidermists from the *Chevert*, have undertaken an independent expedition to New Guinea on their own account, which though so much more unassuming than the one above described, may on that account have greater chance of success.

NOTES

DR. GEORGE BENNETT, of Sydney, has been in correspondence with Signor D'Albertis, the Italian naturalist now residing on Yule Island, off S.E. New Guinea. From him we learn that Sig. D'Albertis is on most friendly terms with the islanders; that he has made several excursions on to the main land, though in so doing he has been much delayed on account of his boat having been stolen by four of his own men. He afterwards, however, managed to purchase a canoe, and has visited five villages, the language of the natives of which he can now speak pretty well. On the coast he finds a fauna and flora much resembling North Australia, but inland, on the mountains, the Papuan vegetation predominates. He has succeeded in obtaining a perfect specimen of his new bird of paradise, *Paridisea raggiana*, and has shot a second specimen of the ground tree-kangaroo, *Dorcopis luctuosa*. His health is excellent; but an Italian companion has suffered from fever and slight sunstroke.

LIEUT. CAMERON has earned a high place as an explorer by the work which he has so successfully and so quietly accomplished. It will be remembered that Cameron was sent out in 1873 to find Livingstone, whose fate was then unknown. On his way to Tanganyika he learnt the fate of the great traveller, but continued westwards and determined to carry out an exploration on his own account. After surveying a great part of Lake Tanganyika and discovering what he thought was likely to prove an outlet to the westward, he proceeded to the Lualaba for the purpose of finding out whether that river is connected with the Congo or the Nile system. The latest news that Sir Henry Rawlinson had to announce in his address to the Geographical Society about a month ago was that at the end of May 1874, Cameron had finally left Ujiji for the West. The telegrams just received are very brief, and announce that he came out at Benguela and reached Loanda on Nov. 19, with fifty-seven followers, "all well." Cameron was forced by adverse circumstances to abandon the Congo route, and followed the watersheds between the Zambesi and Congo. He has thus accomplished the rare feat of marching right across the continent, and will no doubt bring home many additions to our knowledge of central tropical Africa.

THE Professorship of Physiology in the University of Glasgow will be vacant at the end of the present session on account of the resignation of Dr. Andrew Buchanan.

WE have received from Prof. Mohn, Christiania, a printed paper giving a brief *résumé* of the meteorology of Norway for 1874. Monthly results of temperature are stated for forty-one stations, and of rainfall for thirty stations, and these results are compared with averages of previous years for those stations at which observations have been continued for some time. These forty-one stations show an increase in the number of the stations of previous years, and we have much satisfaction in learning that, as the result of a recent special grant by the Norwegian Government, the stations have still further increased to fifty, and that each of them has been furnished with minimum thermometers and with new thermometer screws. Of the stations sixteen are supplied with Fortin's barometer, sixteen with the Kew barometer, thirty-one with wind-vanes and velocity-plates, thirty-seven with rain-gauges, thirty-two with dry and wet bulb hygrometers, nine of the coldest stations with hair hygrometers, and all of the fifty with aneroids. In Prof. Mohn's energetic and able hands highly valuable results may be looked for from these changes and additions in the further development of the meteorology of Norway, which plays so prominent a part in the meteorology of Europe.

THE *American Naturalist*—the recognised organ of intercommunication between naturalists in America—will pass, at the commencement of the coming year, into the hands of Messrs. H. O. Houghton and Co., of Cambridge, Mass. It will still be under the able editorship of Dr. A. S. Packard, jun., who will be assisted by a number of eminent men of science, in all departments. Indeed, the list of expected contributors for 1876 is a very strong one. The amount of matter in each number will be increased, and articles will be introduced of a more popular character than heretofore. We are glad to take this opportunity of again calling the attention of English naturalists to this excellent periodical.

M. DUMAS, the distinguished Perpetual Secretary of the French Academy of Sciences, has been elected a member of the Académie Française in room of the late M. Guizot. Science has now two representatives amongst the grandees of French literature—M. Claude Bernard and M. Dumas.

SIR HENRY RAWLINSON, President of the Geographical Society, has been elected a foreign member of the Geographical Society of Paris.

THE *Pall Mall Gazette* is informed that Mr. Max Müller has been asked to accept a professorship at Florence, at the highest salary ever offered to a professor in Italy.

A TELEGRAM dated Adelaide, the 18th inst., states that Mr. Giles's exploring expedition (see vol. xii. pp. 135, 194), fitted out by the Hon. Thos. Elder, M.L.C., has arrived at Perth, Western Australia, direct from Adelaide. This is the third expedition that has crossed Central Australia within the last two years. The first was that under Col. Warburton, from the telegraph line westwards, generally between 20° and 21° S. lat.; then Mr. Forrest crossed from Perth to the telegraph line by a route about 5° farther south. Mr. Giles's route, we believe, has been much farther south than Mr. Forrest's; judging from previous news, probably about 100 miles from the south coast.

A TELEGRAM from Naples, Dec. 19, states that Prof. Palmieri reports from the observatory near Vesuvius that fire has appeared in the interior of the crater, and expresses his opinion that an eruption of long duration may be expected. A volume of black smoke rose from the volcano on the morning of the 19th. A telegram of the 20th states that the fire in the crater is gradually increasing in strength, and that the instruments of the observatory are in motion.

A REUTER'S telegram of Dec. 21 states that the New York papers publish advices from Porto Rico stating that the town of Arecivo in that island had been wholly destroyed by an earthquake. Only two churches and six houses are stated to be left standing.

DURING the recent heavy floods, the low-level districts of Somersetshire have been submerged beyond precedent, so that it has been possible to sail across country for twenty miles. Many farms and cottages had to be abandoned, and for the first time the railways beyond Bridgwater were covered with several feet of water. One of the results of the flood was the driving from their haunts of great numbers of rats, some of which might have been seen by railway passengers to have taken refuge in willows and other trees along the line. Deserted houses were also taken possession of. In one case a labourer, on proceeding to his cottage by boat to obtain some necessary articles, was about getting into the bedroom window, when he found the room swarming with starving rats, whose demonstrations were so threatening that had he not made a hasty retreat there was every probability he would have been eaten up alive.

THE third annual dinner of the students of the Royal School of Mines took place on Friday the 19th inst., at the St. James's Hall Restaurant. In spite of the unavoidable absence of many who had expressed their intention of being present, the students, associates, and professors mustered to the number of nearly sixty.

A COMMITTEE was appointed some time ago by the Geographical Society of Paris to arrange for the erection of a building for its special use. A large sum of money has been collected, partly by loans, partly by private subscription and grants from the Society. Further proceedings have, however, been stopped, the Prefet of the Seine having intimated his intention to erect an establishment in which several of the learned societies of Paris are to have meeting rooms and libraries, and in which collections will be located at the expense of the city.

A *Daily News* telegram announces that the Italian Geographical Society has resolved that its exploring expedition to equatorial Africa shall start at the end of next January, so as to reach Ankober, the capital of the Kingdom of Shoan, before the rainy season. From Ankober, the expedition will penetrate the Galla country, in a south-west direction, towards the Victoria Nyanza Basin. Subscriptions for defraying the expenses will be received by the Italian Geographical Society in Rome.

THE Admiralty have made arrangements with Mr. Allen Young, the experienced Arctic voyager, to communicate with the entrance of Smith's Sound in the summer of 1876, in hopes of obtaining some information of the proceedings of the Arctic expedition.

IN Nos. 2 and 3 (1875) of Guido Cora's *Cosmos*, just to hand, is the first instalment of a paper, by Giacome Bove, giving an account of a journey to Borneo; Sarawak and Labuan were visited, and an ascent of Kini Balu is described. In continuation of the papers on recent expeditions to New Guinea a useful *résumé* of our knowledge of the island at the end of 1875 is given; there are also letters from Beccari, D'Albertis, and L. Cambiaso of the *Vettor Pisano*. Two maps illustrate these New Guinea papers.

IN accordance with the will of Prof. Jungken, of Berlin, the *London Medical Record* states, his collection of scientific works and all his surgical instruments have been presented by his widow to the Augusta Hospital, and a letter of thanks has been sent to her by the Empress Augusta. The Royal Saxon Academy of Sciences at Leipzig has also received a donation from the late Dr. Hermann Härtel of 30,000 marks, to be expended in helping German students to prosecute scientific inquiries.

AT the annual meeting of the Eastbourne Natural History Society on the 8th ult. the Secretary read a satisfactory report. The President, Mr. F. C. S. Roper, announced that ninety-one additions had been made to the fauna and flora of the district during the year.

IN the form of a supplement to the December number of the *Journal of Botany*, Mr. W. B. Hemsley publishes an "Outline of the Flora of Sussex," a list of all Phanerogams and Vascular Cryptogams known to occur within the county, with their authorities.

THE *Garden* announces an addition to its attractions in the form of a "coloured plate (full-page size) of a beautiful or rare flower or fruit, of proved value for our gardens, and executed in the best style of art." The aim is to illustrate, as nearly as may be in their natural colours, the finest of new flowers and fruits. The specimens which we have seen are really beautiful, and the enterprise deserves encouragement.

M. H. GIFFARD has reported on the Paris balloon accident to which we referred last week. He finds that during the process of inflation the net and the canvas got frozen together, the consequence being that during dilatation of the latter, the net could not yield freely, and therefore exerted pressure on the canvas, which broke suddenly near the valve. Precautions will be taken in future to prevent a similar occurrence.

AN examination will be held at Clare College, Cambridge, on March 28 and three following days, when a scholarship in Natural Science of the annual value of 60*l* for two years will be offered for competition. Particulars by application to the tutor, the Rev. W. Raynes. A Natural Science Scholarship at Caius College, of the same value, will be offered for competition on April 4. Particulars from the Rev. N. M. Ferrers, tutor of Gonville and Caius College.

THE Cambridge University Natural Science Club commenced the October Term by the formation of a new code of rules. The officers for the term were—President, A. J. Jukes Browne, B.A.; Vice-president, J. F. M. H. Stone; Hon. Sec., A. F. Buxton. Six papers have been read during the Term, usually followed by interesting discussions—"On the evolution of fossil forms," by A. J. Jukes Browne, B.A. (St. John's); "The motion of glaciers," by T. W. Bridge (Trinity); "Darwin's Insectivorous Plants," by J. F. M. H. Stone (St. Peter's); "Huxley's classification of animals," by A. F. Buxton (Trinity); "'Typical' number of somites in arthropoda," by A. M. Marshall, B.A. (St. John's); "Molecular energy," by E. B. Sargant (Trinity). There were sixteen members in residence.

THE fourth number of volume ii. of the Cincinnati *Quarterly Journal of Science*, edited by S. A. Miller and L. M. Hosea, has lately been issued, and, we regret to learn, closes the series of this publication. During the short period of its existence it has been the medium of presenting a number of original scientific papers especially relating to the palæontology of the Mississippi Valley, which will render it a necessary work of geological and zoological reference.

A ROMAN Society has commenced excavations quite close to the monument of Minerva Medica. They have come upon some very interesting things, among which are the paintings that

adorned a columbary. The Roman archæologists and artists believe that these paintings are of the Augustan age, and are of great value both to science and art. In making preparations for constructing the central hall in the Conservatory Palace at the Capitol, a ground-plan has been discovered supposed to be that of the Temple of the Capitoline Jupiter, to which Dionysius gave a surface of 4,000 square feet. In the same place has been found a column of large size, which appears to belong to the Temple of Jupiter Optimus Maximus. Excavations in other places have brought to light additional fragments of antiquarian interest.

THE Secretary of the Interior, in his annual report to the President of the United States, commends in high terms the work of the Geological and Geographical Survey of the Territories, and presents the following brief summary of the results for the season of 1875:—The survey under Dr. Hayden continued its labours of the two preceding years in the Territory of Colorado. The field of work during the past season was the southern and western portions of said Territory, and including a belt, fifteen miles in width, of the northern border of New Mexico and the eastern border of Utah. The survey was divided into seven parties, four of which were devoted to topographical and geological labours, one to primary triangulation, one to photographic work, and one to the transportation of supplies. The survey of the southern and south-western portions of Colorado has been completed, so as to make six sheets of physical atlas, designed by this Department, leaving unexplored only the north-western corner thereof, which can be surveyed by a single party during the coming year. The districts explored in the past season were not so mountainous as those of the previous years, but were quite remote from settlements, and in perhaps the most inaccessible regions of this continent. The total area surveyed is about 30,000 square miles, portions of which were very rugged. Much of this area is drained by the Colorado river, and is mainly a plateau country cut in every direction by deep gorges or canons, the sides of which show, for geological investigations, admirable sections of the strata forming the earth's crust. The topography of the district surveyed was elaborated in detail by the aid of the plane-table. The exploration of the remarkable prehistoric ruins of Southern Colorado, glimpses of which were obtained the preceding season, was continued with great success. They were traced down the canons to the Colorado river in New Mexico, Utah, and Arizona, and their connection established with the cliff cities of the Moquis of the latter Territory. Hundreds of cave-dwellings, of curious architecture and many miles from water, were found in the sides of the gorges, and the ruins of extensive towns discovered in the adjacent plains, indicating the former existence of a people far more numerous and advanced in the arts of civilization than their supposed descendants of the present day. Of these ruins many interesting sketches, plans, and photographs were made, and a valuable collecion of flint weapons, earthenware and other specimens, was gathered. The materials thus obtained will enable the survey to present an exhaustive report on this interesting subject. The photographer of the survey obtained a series of mountain views on plates twenty-four inches long by twenty wide, or larger by several inches than any landscape photographs ever before taken in this country.

A FRENCH clerical journal, quoted by the *Revue Scientifique*, maintains that the tolling of the church bell is of much greater efficacy than the use of lightning-rods in warding off the effects of a thunder-storm, and advises the faithful to resort to the former means in preference to the latter.

THE *Revue Scientifique* announces the death, at Zurich, of the chemist Prof. E. Kopp, "one of the creators of the atomic theory."

THE Institution of Naval Architects has issued a list of subjects on which communications are desired.

THE American Institute of Mining Engineers held a meeting at Cleveland, Ohio, October 26–28. Its proximity to several of the large iron and steel works and the interest taken by its President, Prof. A. L. Holley, in the details of the Bessemer process, caused the meeting to be more especially devoted to that class of subjects. Prof. Holley in his opening address referred to several improvements which ought to be made in the iron and steel manufactures. Among the papers of scientific interest relating to mining subjects was a mention by Mr. Charles A. Ashburner of the discovery of coal-beds in the Vespertine sandstone of Pennsylvania. Mr. Ashburner is one of the assistant geologists of the Second Geological Survey of Pennsylvania. There have been a few scattered instances of discoveries of coal in the Vespertine rocks, and such beds have been designated as false coal-measures. The present discovery may, however, serve to modify our notions as to that sub-carboniferous formation. In a tunnel passing through Sideling Hill, Huntingdon County, Penn., in cutting the Vespertine sandstones, there were found not less than nineteen beds of coal; their thickness varies from one to thirteen inches; collectively they would make a thickness of four feet. The coarseness and false bedding of the Vespertine strata indicate a period of frequent agitation and numerous local currents; but the presence of coal-beds shows that considerable spaces of repose must have intervened, and that the changes were slowly effected.

AT the meeting of the Norfolk and Norwich Naturalists' Society, on Nov. 30, the Secretary read a short paper from Dr. Lowe on the occurrence of a rare microscopic fresh-water Alga (*Clathrocystis æruginosa*, Hen.) at Anmer, near Lynn. In June 1870 Dr. Lowe discovered a large quantity of it in the lake at Sandringham in the form of a green scum. In October of the present year he again discovered it growing in a pond at Anmer, two miles from Sandringham, his attention being attracted by the peculiar scum which he at once recognised as *Clathrocystis*. It seems probable that it has recently been introduced at Anmer by the agency of wild fowl.

THE additions to the Zoological Society's Gardens during the past week include a Haste's Apteryx (*Apteryx hastei*) from New Zealand, presented by Baron Ferdinand von Muller; a Marginated Parrakeet (*Tanygnathus marginatus*) from the Philippine Isles, presented by Master Hugh Sutton; two Bengal Leopard Cats (*Felis bengalensis*) from Cashmere, presented by Mr. W. A. Cuthell; a Bay Antelope (*Cephalophus dorsalis*) from W. Africa, received in exchange; an Ocelot (*Felis pardalis*) from S. America, a Hoffmann's Sloth *Cholopus hoffmanni*) from Panama, a Duck Falcon (*Falco anatum*) captured at sea, purchased; a pair of Peacock Pheasants (*Polypectron chinquis*) from Burmah, deposited.

SCIENTIFIC SERIALS

Jahrbücher für wissenschaftliche Botanik. Herausgegeben von Dr. N. Pringsheim. Band x. Heft 11.—In the present number of Pringsheim's well-known and valuable year-books there are four papers, all of them of considerable interest. The first is by Dr. J. Reinke, of Göttingen—Contributions to the anatomy of the secreting organs, occurring especially on the serrations of certain foliage-leaves. It has been observed that in many plants the serrations of the leaves act as glands and secrete in many instances a mucilaginous substance, and in others resin, or a mixture of mucilage and resin, called blastocolla by Hanstein. Reinke has carefully examined the structure of these secreting organs in a large number of dicotyledonous plants, but has not made any exhaustive micro-chemical investigation of the secretions themselves. His observations show that the serrations of the leaves of Dicotyledons are in general the bearers of peculiar organs of secretion, whose activity may cease even while the leaf is in the bud, or at a later period. *Æsculus* and plants with

spiny leaves apparently have no such secreting organs. In respect to the secretion itself, it is in the bud either a fluid mucilage or resin, while in the full-grown leaf it is only a watery or somewhat mucilaginous fluid. The paper is illustrated by two plates, on which are figured the glands of *Prunus avium*, *Kerria japonica*, *Vicia faba*, *Betula alba*, *Corylus avellana*, *Evonymus japonicus*, *Ribes multiflorum*, *Epilobium Dodonæi*, *Catalpa syringæfolia*, *Clerodendron fragrans*, and *Viola odorata*. —The second paper, on the process of fertilisation in the Basidiomycetes, is by Dr. Max Reess. Every day renders it more and more probable that the receptacles, or fruit-bearers, of the Basidiomycetes are, like the sporocarps of the Ascomycetes, the result of the fertilisation of a carpogonium. The researches of Reess now under consideration, those of Van Tieghem, and lastly, those of Dr. Eduard Eidam, in the *Botanische Zeitung*, 1875, p. 649, all tend in the one direction, and lead us to look with very great caution on the results obtained recently by Mr. Worthington Smith, and published in the *Gardener's Chronicle* for October. Reess has examined the early stages of *Coprinus stercorarius*, Bulliard, which develops rapidly, and could be easily obtained. The ripe spores of *Coprinus stercorarius* are ellipsoidal in shape, pointed towards each pole, and average eleven mic. mill. long by six mic. mill. broad, having a brown episporum. Germination begins by the protrusion of the endosporium in the form of a colourless papilla at one, rarely at both, the poles of the cell. The process is a rapid one, and at the ordinary temperature of a room occurs in from four to five hours after sowing. The mycelia rapidly develops and branches frequently, so that in three or four days the mycelia from a single spore will form a patch from 1½ to 2 mill. in circumference. At first the mycelium is formed of a single much-branched cell filled with colourless homogeneous protoplasm, numerous vacuoles forming in the older parts as branching proceeds. At the end of the second day numerous transverse walls appear in the mycelium, and a little later the hyphæ are seen to anastómose. In from three to four days after the germination of the spores, special bearers of minute rod-like cells appear. They are more or less long cylindrical cells with protoplasm, and they bear at their ends, or sometimes at the side, the short, straight rod-like cells. These grow until they have attained a certain length, then they divide, and the upper one drops off, a process which may be repeated two or three times, so that at about the end of two days, when the entire protoplasm of the bearers has disappeared, the process stops, and then the bearers themselves may fall off. When this occurs a little pile of about fifty to sixty rod-like cells may be noticed. These rod-like cells might be confounded with conidia, but further observation has shown that they cannot germinate, and there is now no doubt whatever that they are *spermatia*, and therefore male cells. The youngest stage of the fruit-bearer is a thick, more or less irregularly-shaped hypha thread, densely filled with protoplasm, and resembling the earliest stage of the carpogonium of Ascobolus. The next stage is the fertilisation by means of the spermatia which attach themselves to the branching sacklike structure, and as the spermatia at once lose their contents, the empty wall contrasts strongly with the protoplasm of the carpogonium. After fertilisation the carpogonium becomes more and more tortuous and branched. The spermatia of Coprinus are therefore male cells; their bearer the antheridium, while their function is the fertilisation of the carpogonium. As a consequence of fertilisation the carpogonium develops into the fruit-bearer of the fungus. The process described by Reess will thus be seen to have a very close resemblance to the fertilisation of the Florideæ, such as Nemalion and Batrachospermum.—The third paper is on the "Germination of the spores of *Cyathus striatus*, Willd., one of the Gasteromycetes," by Dr. R. Hesse, with one plate. The spores germinate by the protrusion of the endosporium at one, rarely at both, poles, a single hypha thread three or four times the length of the spore being formed. Transverse walls then appear, and the free end of the thread separates into a number of small cells, but the further history of these minute cells has not been studied. —The fourth and last paper in this number is "On the development of certain flowers with especial reference to the theory of Interposition," by Dr. A. B. Frank, with three plates. The author gives the results of his researches on plants belonging to the natural orders Papilionaceæ, Geraniaceæ and Oxalidaceæ, Malvaceæ, and Primulaceæ. Many important observations are made in reference to the order of succession of the parts of the flowers, the development of diplostemonous flowers, and of flowers with superposed stamens. The paper is however not one that can be usefully abstracted. Altogether this number of Pringsheim's *Jahrbuch* maintains its well-known high standard of excellence, and is well illustrated.

THE first part of the twenty-fifth volume of Von Siebold and Kölliker's *Zeitschrift fur Wissenschaftliche Zoologie* (Nov. 1874) contains an article of 100 pages by E. Ehlers, of Erlangen, on the vertical distribution of the marine chætophorous annelids, based on the specimens secured in the *Porcupine* Expedition. In the same article is included M. Claparède's report on the chætophorous annelids brought home by the *Lightning*. The forms are carefully described, new species are added, and the results are excellently tabulated. It is concluded that all the families of polychætous annelids which are known as littoral inhabitants on the Atlantic coasts of Europe, excepting the Telethusæ and Hermellidæ, are represented in the deep-sea fauna; that beyond the littoral region a greater or less depth does not influence the character of the annelid fauna; that temperature influences it just in the same manner as temperature influences the littoral annelids. Four very excellent plates, chiefly of annelid appendages, are given.—Karl Möbius gives a detailed account of the anatomy of the Rotifer *Brachionus plicatilis*.—Dr. F. C. Noll describes *Kochlorine hamata*, a new genus and species of boring Cirripede, boring into Haliotis and other shells, differing from Cryptophialus and Alcippe in lying free in the artificial cavity in the shell, and in other important particulars. —The second part (March 1875) opens with a contribution by W. Repiachoff to the embryology of *Tendra zostericola*.—Prof. Ranke describes minutely the supposed organs of hearing in *Acridium cœrulescens* and the eyes of the leech.—Dr. Claus describes the shell-glands of Daphnia, identifying them with the segmental organs of annelids, and with the kidneys of vertebrates. —Dr. H. Dewitz writes on the structure and development of the sting and the ovipositor in several common Hymenoptera and the Grasshopper, which he calls *Locusta viridissima*, instead of using the generic name Gryllus.—O. Bütschli contributes some "preliminary observations" on the first steps of development in Nematodes and Snails.—Dr. von Willemoes-Suhm's third letter from the *Challenger* concludes the number.—The third part (May 1875) contains as its *pièce de résistance* a very valuable memoir, by Dr. C. Claus, on the development, organisation, and systematic position of the Argulidæ. *Argulus foliaceus* is the species chiefly described, both in its development and adult state. Dr. Claus concludes that it is useless to describe a distinct species of Argulus for every fish on which it is parasitic. It is established that *Argulus foliaceus* is parasitic on a great variety of fishes, also on toads and tadpoles, and even on the Axolotl. It appears that Argulus reproduces itself not only in early spring but also in summer and autumn with great freedom. For many reasons Dr. Claus places the Argulidæ among the Copepoda, and constitutes them a sub-order under the name Branchiura.—Dr. L. Stieda describes the structure of the central nervous system of Axolotl; the brain he asserts to be of a more completely embryonic type than any whose structure has been carefully examined.—E. Metschnikoff describes the early development of Geophilus. He finds that its larva differs from those of Chilognathous Myriopods in having its yelk-mass inside instead of outside the alimentary canal.—Oscar Grimm gives an account of the results of his dredgings in the Caspian Sea last year, resulting in the discovery of eighty new species.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie Nov. 1.—Dr. Hann contributes an article on the meteorology of the Punjab, founded on the reports made by Mr. Neil for 1871, and by Mr. Calthrop for 1872.—Prof. Buys Ballot gives a table showing the tension of aqueous vapour at eighteen places in Russia for each month. It appears that at all stations the tension is below the average from November to April, and above it from May to September, and at some places in October. The influence of height, latitude, longitude, and proximity of the sea is plainly indicated by the table.

Journal de Physique, October.—In this number M. Penaud describes some researches on aviation, and apparatus for mechanical flight, for which a prize was recently awarded him by the Paris Academy.—Some experiments by M. Moreau are given as showing that a fish with swimming bladder undergoes variations of interior pressure, and that it adapts itself to different heights not by a mechanical action exercised on the bladder by means of its muscles, but by changing the quantity of air contained in the organ.—The penetration of electricity into badly-conducting substances has been sufficiently demonstrated, but there is still a good deal of confusion as to the mode of its action. M. Neyreneuf here endeavours to give precision to ideas

on the subject. He finds, *inter alia*, that in the case of a compound insulating plate between two armatures, the electrification of the two extreme plates is the same as that of a single plate (*i.e.* positive on the side of the positive armature, negative on the side of the negative), and the *persistent* electrification of the intermediate plates is also the same; but at the moment of separation these plates may appear positive and negative on both their faces.—M. Righi contributes a mathematical note on the laws of electromotive forces, and there is the usual amount of matter abstracted from other serials.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Dec. 9.—On the Development and *Lepas fascicularis* and the "Archizoëa" of Cirripedia, by the late R. von Willemöes-Suhm, Ph.D. The author shows that the *Archizoëa gigas* of Dohrn is the nauplius of *Lepas australis*, a form closely allied to *L. fascicularis*. The life history of the latter is described.

Preliminary remarks on the Development of some Pelagic Decapoda, by the late R. von Willemöes-Suhm, Ph.D. The genera described are *Amphion*, *Sergestes*, and *Leucifer*. The first passes through a true Zoëa stage, *Amphion* itself being, as Dohrn has shown, adult. The larvæ of *Leucifer* and *Sergestes* pass through an *Amphion* stage. The form *Elaphocaris* of Dohrn is proved to be the larva of a *Sergestes*. The form *Erichthina* of Dana is proved to be the larva of a *Leucifer*.

Dec. 16.—On the Structure and Development of the Skull in the Batrachia, by W. K. Parker, F.R.S. The author makes some corrections in his memoir on the skull of the frog, specially showing that the hyoid arch does not coalesce with the mandibular. The skull of *Dactylethra* and *Pipa* are described. The indications of vertebral segmentation in the cephalic part of the notochord are demonstrated in a manner which has much theoretical interest in relation with the theory of Goethe and Oken.

On the development of the spinal nerves in Selachians, by F. M. Balfour, B.A. The author shows that both the roots of the spinal nerves arise as outgrowths from the involuted epiblast of the neural canal, the posterior first, and by the more complicated process.

Chemical Society, Dec. 16.—Prof. Abel, F.R.S., president, in the chair.—Dr. C. R. A. Wright read a paper by himself and Mr. G. H. Beckett, on narcotine, cotarnine, and hydrocotarnine (Part iii.), in which the authors brought forward experimental evidence of the constitutional formula for hemipinic acid, opianic acid, and meconin.—Dr. H. E. Armstrong then gave an account of researches by Mr. Harrow and himself, on the action of alkaline sulphites on the haloid derivatives of phenol, and on the action of nitric acid on tribromophenol.—Mr. E. Neison subsequently made a communication on the sebates of the alcohol series, after which papers were read by the Secretary, on the compounds of ether with anhydrous metallic chlorides, by Mr. P. P. Bedem, and observations on variations in the composition of river waters, by Mr. J. Andrews.

Royal Astronomical Society, Dec. 11, 1875.—Prof. Adams President in the Chair.—Mr. Burton read a paper on the Southern nebulæ 30 (Bode) Doradûs and the nebulæ about η Argus. Mr. Burton had while stationed at Rodriguez on the Transit of Venus Expedition made drawings of these nebulæ with a 12½ inch silver on glass reflector, and on his return had compared them with Sir John Herschel's drawings. After a careful comparison he was not disposed to think that there had been any great change in either of the nebulæ since the date of Sir John Herschel's observations.—Mr. Ellery, of the Melbourne Observatory, described the observations which they had made of the same nebulæ with their great Melbourne 4-feet reflector. He was inclined to think that rapid change could be traced not only in the details of the nebulæ but also in the relative positions and magnitudes of the stars which appeared to be involved in them.—Mr. Ellery also read a paper on the results of some experiments with Huygen's parabolic pendulum for obtaining uniform rotation. The instrument he had used consisted of a heavy weight or bob attached by a thin flexible band of watch-spring steel to the upper part of a piece of metal cut into the form of the evolute of a parabola. This was attached to the upper part of a revolving axis so that the contrivance formed a conical pendulum, in which when the rate of motion was increased the bob or pendulum flew away from the axis and wound the watch-spring band round the evolute of the parabola. He found that with this contrivance a very uniform rate of motion was obtained, and it seemed to be independent of the weight which was placed on the bob of the pendulum and of variations in the driving power used.—A paper by Mr. With on the structure of Coggia's Comet was read. On the night of the 8th July, 1874, an oscilatory motion of the fan-shaped jet in front of the nucleus was observed. The fan seemed to tilt over from the preceding towards the following side and then for an instant appeared sharply defined, then it became nebulous and all appearance of structure vanished. These pulsations and appearances of structure occurred several times at intervals of from three to eight seconds.—Mr. Ranyard read a paper on the duplicate structure of Coggia's Comet. He showed two drawings each made on July 14, 1874, the one by Mrs. Newall with the great refractor at Gateshead, and the other by Mr. With at Hereford. Both drawings showed that on that evening there were two faint parabolic arcs, which intersected one another in front of the nucleus. The axes of the arcs were parallel to one another, and were separated by a distance of about 1°. During the earlier evenings of July the parabolic arcs within the envelope of the comet had been drawn by several observers as double and overlapping, but the axes of the two sets of parabolic arcs were much less separated than those of the arcs visible on the evening of the 14th. Mr. Ranyard suggested that possibly a disruption was going on similar in character to the disruption which took place in Biela's comet as it approached perihelion in 1846.—Father Perry showed some photographs of the transit of Venus which had been sent to him from Manilla. They appeared to show the body of Venus projected on a bright back-ground outside the sun's limb. It was suggested, however, from other evidence, that the photographs must have been taken from drawings. Lord Lindsay and Mr. Brothers, after an examination of the photographs, both inclined to the latter view.

Meteorological Society, Dec. 15.—Dr. R. J. Mann, president, in the chair.—William Ellis, F.R.A.S., Kaufmann J. Marks, Thomas Read, and Philip Wright, F.C.S., were elected Fellows of the Society. The following papers were read:—On the registration of sunshine, by R. H. Scott, F.R.S. This paper is on the continuous record of sunshine and rainfall obtained at Kew for September 1875; the latter by Beckley's rain-gauge, the former by a method originally proposed by Mr. J. F. Campbell, of Islay, F.G.S. This consists in the use of a sphere of glass to concentrate the sun's rays, and a strip of cardboard is placed on a frame concentric with the sphere and distant from it by its own focal length. The sun when it shines burns a hole in the cardboard, the length of the trace being regulated by the duration of the sunshine. It remains to be proved whether such a record is of real practical value, as it affords no measure of the heat of the sun.—On the rainfall at Calcutta, by R. Strachan. These observations were made at the Office of the Surveyor-General, and extend over a period of twenty-eight years, viz., from 1847 to 1874. The most rain falls in July, but the heaviest downfalls are most frequent in June, and heavy downfalls are more frequent in August than in July. The greatest number of days of rain is in July, but the number is almost the same for August. December has the least frequency and amount of rain. The dry season includes November to April, during which on an average 6·04 inches of rain fall, on 12 days out of 181, or 1 out of 15 days. The wet season is from May to October inclusive, during which 61·60 inches of rain fall, on 84 days out of 184, or about 1 in 2 days. There is therefore ten times as much rain in the wet season as in the dry, and nearly seven times as many rainy days. The mean annual rainfall is 67·64 inches on 96 days.—On the use of the rotatory thermometer (*Thermomètre fronde*) on board ship, by R. H. Scott, F.R.S. This paper showed that the mean of 76 days' observations made by Capt. Heggum, of the *Rozelle*, on a voyage from Liverpool to Calcutta only differed by $-0°\cdot4$ from the mean of the observations made in the ordinary way.—On the moon's influence in connection with our extremes of temperature, by George D. Brumham.—Mr. Scott exhibited a complete set of instruments, with thermometer screen, &c., as used at the Russian meteorological stations.

Anthropological Institute, Dec. 14.—Col. A. Lane-Fox, president, in the chair.—Mr. M. J. Walhouse read a paper on the belief in Bhutas—devil and ghost—worship in Western India. Although the lower castes and classes in India acknowledge and reverence the Brahminical gods, their familiar household cultus is much more especially addressed to inferior super-

natural beings analogous to the evil spirits, devils, ghosts, and goblins of European superstition. According to Hindu doctrine there are ten classes of such beings, the first seven of which are demons created aboriginally with the world or by acts of the higher gods on whom they wait as attendants or servants receiving some share of their worship, and avenging any omission or neglect of ceremonies due. Though not invariably, they are for the most part evilly-disposed towards human kind. But the last three classes of whom the paper more particularly treated, are exclusively of human origin, being malignant discontented individuals, wandering in an intermediate state between a heaven and a hell, intent upon mischief and annoyance to mortals, chiefly by means of possession and wicked inspiration, every aspect of which ancient ideas as well as of the old doctrine of transmigration they exemplify and illustrate. They are known by the name of Bhūta. The author went on to show how most of the evils and misfortunes of life were attributable to the Bhūta influence; death from violence, evil possession, diseases in families and in cattle, stone throwing, &c. He then described the priestly use of those supposed powers, the cure of diseases, the conduct of festivals, and dances. It was also pointed out how close was the similarity between the occurrences under Bhūta influence and the prevalence of a belief among European nations in witchcraft, demoniacal possessions, "levitations," ghosts, invisible poweis, dancing manias, and the like. The Bhūta emples and ceremonies were also described and compared with those of the Todas and other hill tribes. The paper contained accounts of several well authenticated trials consequent on Bhūta interference and punishment. A series of Bhūta (Turanian) gods was exhibited by the author as illustrative of the wide difference between Turanian and Aryan art.—Mr. Groom Napier read a paper on the localities whence the tin and gold of the ancients were derived; and a paper by Mr. Bertram F. Hartshorne on the Weddas of Ceylon, was also read.

Royal Microscopical Society, Nov. 24.—The president, Mr. H. C. Sorby, F.R.S., described and exhibited his new contrivance for measuring the position of the absorption bands in spectra. The new apparatus and its principle of action may thus be described:—When polarised light passes along the line of the principal axis of quartz, it does not suffer double refraction and depolarisation, but *circular* polarisation. The result is that when the quartz is $1\frac{1}{2}$ inch thick, and placed between two Nicol's prisms, the spectrum of the light transmitted through it exhibits seven well defined black bands, which gradually move up or down the field of the spectrum on rotating one of the Nicols, returning to the same place at each half-revolution. In order to make use of this property in measuring the wave-lengths of different parts of any spectrum, the lower Nicol is permanently fixed in a mounting connected with an ivory circle, each half of which is divided into ten large divisions, and these again into five smaller, so that it is easy to read off to the $\frac{1}{100}$ part of a half revolution. This of course corresponds to $\frac{1}{100}$ of the intervals between any two of the seven bands. Placing the circle at the zero point, the other Nicol's prism can be rotated until the bright line of sodium is all but invisible in the centre of total interference of the second band, counting from the red end. The position of all the other bands is then also definite and constant. By using a diffraction spectroscope the wave-lengths of all the bands and of each $\frac{1}{10}$ interval can be calculated and arranged in a table and the smaller intervals can be filled up by interpolation. There is then no difficulty in determining the wave-length of the centre of any well-marked absorption band seen in the spectrum of any substance which is compared side by side with that of the quartz; for which purpose the binocular form of apparatus described by Mr. Sorby is the most convenient. The number of the band counting from the red end is easily seen, and the fractional interval is easily measured by rotating the ivory circle until the centres of the bands are made to exactly coincide. In the case of well-marked absorption-bands consecutive readings differ by only what is equivalent to one-millionth of a millimètre of wave-length, and the means of several observations differ considerably less than that. By proper attention to the illumination of both spectra there appears to be no serious difficulty in measuring the position of well-defined absorption-bands to within one-millionth of a millimètre of wave-length, which is quite as near as appears to be necessary in the case of the spectra for which the instrument is designed.

Geologists' Association, Dec. 3.—Mr. Wm. Carruthers, F.R.S., president, in the chair.—On quartz, chalcedony, agate, flint, chert, jasper, and other forms of silica geologically considered, by Prof. T. Rupert Jones, F.R.S. After noting a few of the salient mineralogical features of quartz, pointing out the difference in specific gravity between fused quartz (2·2) and ordinary quartz (2·6), the author passed on to chalcedony, which bears a similar relation to quartz that barley-sugar does to sugar-candy. No definite crystallised structure can be observed; but a fibrous appearance may generally be noted, at right angles to the planes of deposit, which latter often render the mass flaky. In some specimens this fibrous structure gradually becomes stronger, close-set, minute, crystalline prisms being visible in the fracture, and these pass into regular quartz crystals. The sub-crystalline structure of chalcedony is not yet thoroughly worked out. On account of the unequal resistance of some chalcedonies in agates to the action of hydrofluoric acid, by which certain layers are eaten away, cut agates have been prepared in slabs which take printer's ink and give impressions of their concentric structure, and of the channels of infiltration (See Transact. R. Acad. Vienna, &c.). Speaking of the formation of the angles in "fortification-agates," the author was inclined to accept the hypothesis of the chalcedonic silica having replaced calcite or a zeolite; a portion of an agate, comprising flat transverse layers of chalcedony, with quartz and calcite, being exhibited in illustration. The porous nature of agates, and the facilities thus afforded for the absorption of colouring matter, artificially introduced, were alluded to as connected with the minute prismatic structure. The properties of flint are somewhat different; it is less translucent, more conchoidal in fracture, and never fibrous in structure. Aggregations of silica were stated to be present in every limestone, either in the form of common flint or as hornstone, or some variety of chert, and were regarded by the author as being due to the replacement of carbonate of lime by silica. But as this mineral rarely succeeds calcite (crystallised calcic carbonate) as a pseudomorph, it is only the amorphous, or detrital, carbonate of lime of the organisms constituting the limestone that becomes changed into, or replaced by, silica (as flint), and not the crystallised material of Echinodermatal structures (whether spines, plates, stems, or ossicles), nor of *Inoceramus*, *Ostrea*, *Terebratula*, &c. These latter, however, in some cases are replaced by *orbicular silex*. When such unchanged organisms are abundantly present in flint, or when they have left cavities after removal by water, or when other partially altered organisms abound in the flint, it appears coarse-grained and is called "chert." The fine calcareous detritus which filled the internal canal of encrinital stems, the perforations of echinite tests, the parasitical borings of oyster-shells and belemmites, the tubules of sponges, the cavities of sea-urchins, shells, foraminifera, &c., has been changed, atom by atom, into exquisite silicious casts of such hollows and interiors, and are exposed to light by the natural or artificial removal of the calcareous enclosure. In some beds of chalk the pseudomorphosis of the limestone has taken place near and around Sponges; elsewhere, without Sponges, large masses of Polyzoan Chalk have been silicified (France, Maestricht, &c.); also Orbitoidal and Nummulitic limestones (West Indies, Alps, &c.) Freshwater limestones (Paris, Asia Minor, &c.) Encrinital limestone (Carboniferous, Britain, and Tasmania). The white surface of a fresh chalkflint, of whatever shape it may be, shows by its rough subreticular surface, dotted with unchanged microzoa and fragments of shells, the extent of the creeping pseudomorphic change between the nodule and the matrix, and the replacement by silica has been through just so much chalk or other limestone as the nodule or tabular mass represents in size. Even some vertical flint-veins in chalk the author believes to consist of the two altered walls of a fissure, which has been traversed by water with silex in solution; for chalk fossils remain sometimes *in situ* in such vein flint. The author believed that in the south of England, at least, it is rare for sponge-structure to be itself converted into flint. This substance represents the calcareous mud filling the cavities of the sponge, the tissue having generally been lost, or remaining only as a ferruginous stain. Hollows in flints due to the removal of involved sponge-tissue have been lined, by infiltration, with either quartz-crystals or mammillary chalcedony. The specks, blotches, lines, and some other markings apparent on weathered flint, the author thinks, in many cases, arise from differences in the texture of the flint, due to the various organic substances inhabiting or buried in the calcareous mud now represented by pseudomorphic silex. Among such organisms, he suggests that the recent thread-like Foraminifera (*Botellina*, &c.) of the Atlantic ooze may have had their analogies in the Cretaceous mud, giving rise to some straight and cross-lined markings on the weathered surfaces of broken flint, and somewhat similar,

but raised, figures on the outside of nodules. Siliceous sinter, both stalagmitic and granular, resulting from hot siliciferous springs, as in Iceland, New Zealand, Colorado, &c., was next noticed; and it was suggested that some of the flint in the Purbeck "cap" at Portland may have been siliceous sinter. Hyalite and opal and its varieties were alluded to. The orbicular silex of "beekite" was exhibited, and referred to the deposition of silica around angular fragments of limestone, which at the same time it has replaced to some thickness. The origin of the "potato-stones," or siliceous geodes, in the Triassic beds of Somersetshire is similarly pseudomorphic. In some honestones we have extremely fine compact sand cemented by silica; thus approaching one of the two very different kinds of "chert;" other kinds belong to siliceous schists and altered argillaceous rocks. Jaspers the author was disposed to view, for the most part as altered argillaceous rocks; though some are opaque chalcedonies. Beds of shell and clay may be traced into iron-flint (Eisenkiesel) and other jaspery rocks. In Griqualand-west, South Africa, there are miles of bedded jaspers, highly contorted, varying in colour and character according to the nature of the original clays and sand-rocks, which were crushed and folded by lateral pressure, and altered by the accompanying hydrothermal agency (See G. W. Stow's sections). Such jaspers, lydites, and jaspery schists have great geological importance in many parts of the world, inasmuch they hold up the surface of the country by resisting denudation.

CAMBRIDGE

Philosophical Society, Nov. 15.—Mr. Trotter said that since reading his paper "On some Waterholes in the Gorner Glacier," his attention had been called to a passage in Agassiz (Nouvelles Etudes sur les Glaciers, Paris, 1847, p. 101), in which a similar phenomenon was described as having been first observed by Dr. F. Keller. There could be no doubt that the description in Agassiz referred to the same phenomenon as had been described by Mr. Trotter, and that therefore these holes had been first noticed by Dr. Keller, and described in 1847. Mr. Trotter however thought Dr. Keller's explanation of the phenomenon unsatisfactory, and adhered to his own as contained in the paper in question.—The following communications were made:—(1) By Mr. F. M. Balfour on the behaviour of Nucleus during Segmentation. The following observations were made upon the eggs of Scyllium and Pristiurus. At a late stage of the segmentation of these eggs most of the segments contain nuclei, but in some of them there is to be seen in the place of the nucleus a peculiar body. This has the shape of two cones with their bases in apposition. In each cone a series of striæ radiate from the apex to the base; and between the two is an irregular row of granules. From the apex of the cone there further diverge into the protoplasm of the cell a series of lines. The author regards these peculiar bodies as metamorphosed nuclei in the act of dividing. He points out that the simple division of the nucleus, as well as its complete disappearance, accompanied by the formation of two fresh nuclei, are well authenticated modes of behaviour of the nucleus during cell division. These two processes can only be connected on the supposition that in the second case the two fresh nuclei are formed from the matter of the old nucleus. The author considers that there exist in Selachians modes of behaviour of the nucleus intermediate between the two extremes mentioned above, and points out that in the peculiar striation of the body he described there are indications of the streaming out of its matter into the surrounding protoplasm; while on the other hand it never completely vanishes. It therefore affords an instance where part of the matter of the nucleus divides and part streams out into the protoplasm of the cell to be again collected to assist in the formation of two fresh nuclei. The author further states that he has found other bodies intermediate between the cone-like bodies mentioned above and true nuclei; and regards these also as nuclei in the act of division, where a still larger bulk of the protoplasm of the nucleus becomes divided and a smaller part rises with the surrounding protoplasm.—(2) By Mr. Foster, On the effects of Upas Antiar on the Heart. A summary of this paper will be found in the Proceedings of the Society.

PARIS

Academy of Sciences, Dec. 13.—M. Frémy in the chair.—The following papers were read:—On the laws of magnetic induction, by M. Jamin.—On the theory of refining of glass, by M. Frémy.—On the heat of dissolution of precipitates, and other little soluble substances, by M. Berthelot.—Researches on sulphines, by M. Cahours.—Atmospheric perturbations of the hot season of 1875; inundations in the south of France, by M. Belgrand.—Note accompanying the presentation of micrometric plates, for measurement of solar images, by M. Janssen.—Report on reclamations with reference to the decree given on request of the Governor of Algeria, concerning importation into Algeria of fruit and forest trees from France, by MM. Dumas, Blanchard, and others. The Commission think a line should be drawn through the points Phylloxera has reached in a northward direction, and that the exportation should be authorised of all plants accompanied with an authentic certificate stating they are from territory at least 40 to 50 kilometres north of this line.—On the temperature of elevated layers of the atmosphere, by M. Mendeleeff.—Exposition of a new method for the resolution of numerical equations of all degrees (first part), by M. Lalanne.—On destruction of the vegetable matter mixed with wool, by MM. Barral and Salvetat. They give lists of substances which destroy and those which do not destroy the vegetable fibre. The first action of the former is to remove part of the water from the fibre and carbonise it.—Researches on the constitution of fibroin and of silk, by MM. Schutzenberger and Bourgeois.—Comparative study of instantaneous and continuous electric currents in the case of uni-polar excitation, by M. Chauveau.—On a fish of the Lake of Tiberias, the *Chromis paterfamilias*, which incubates its eggs in the buccal cavity, by M. Lortet. The male fish sucks in the eggs from a sandy hollow (where the female has deposited them) and passes them in among the folds of his branchiæ, where they go through the usual stages.—Researches on the respiratory apparatus and mode of respiration of certain Brachyouran Crustaceans (land crabs), by M. Jobert.—Lithological examination of green chalk sand, by M. Meunier.—On the discussion of a system of simultaneous linear equations, by M. Meray.—On the calorific intensity of solar radiation and its absorption by the terrestrial atmosphere, by M. Crova.—On the action of flames in presence of electrified bodies, by M. Douliot.—Note on the sulphocyanates of the radicals of acids, by M. Miquel.—On the saccharification of amylaceous matters, by M. Bondonneau.—Influence of stripping off the leaves, on the weight and saccharine richness of beet, by MM. Champion and Pellet.—On the embryogeny of Tunicata of the group of Luciæ, by M. Giard.—Meteorological observations in a balloon, by M. Tissandier. This voyage was made on Nov. 29. At 1,500 m. a remarkable bank of ice-crystals (in whirling motion) was passed through. The balloon rose to 1,776 m., and from about 1,100 m. upwards, a rise of temperature was observed.

THURSDAY, DECEMBER 30, 1875

MONTEIRO'S ANGOLA

Angola and the River Congo. By Joachim John Monteiro. Two vols., with map and illustrations. (London: Macmillan and Co., 1875.)

ALTHOUGH Angola is one of the oldest, if not the oldest, European colony in Africa, there are probably few other discovered regions in that continent about which English readers at least know so little, and we suspect that the Portuguese themselves know even less about its people, its productions, and its physical geography. And yet it is about four hundred years since the Portuguese planted their first colony on the coast. True there are a number of memoirs of old date, in Portuguese and in English, relating to the country, including the narrative of quaint Andrew Battell, who was for years a prisoner in Angola; but these are all pre-scientific. Recent travellers have told us a good deal about the lower Congo, and Burton, as we recently noticed, made brief visits to some of the Portuguese settlements further south, and in his own way has told us much worth knowing. Henceforth, however, there can be no doubt that Mr. Monteiro's work will be regarded as the authority on the country, more especially when it is supplemented by the various memoirs on the natural history of Angola which he has contributed to the proceedings of the Linnean and other societies, and to scientific journals. Mr. Monteiro spent many years in the country, evidently in connection with mining operations, and during that time had opportunities of visiting and exploring most if not all of the principal districts from the Congo to Mossamedes, frequently penetrating many miles inland. Mr. Monteiro is an Associate of the Royal School of Mines, and his work proves him to be well qualified not only for geographical exploration, but for the investigation of the natural history and physical conditions of a country. He is evidently quite at home in geology, zoology, botany, and meteorology, and has a skilled eye for the points which a traveller ought to note in the natives whom he visits. To the natural history of the country, our naturalist readers no doubt know, Mr. Monteiro has made several important contributions. On the Portuguese settlements and colonists, on the various native tribes, on the geographical and physical features, and on the natural history of Angola the work before us contains such abundant information, that no one but a specialist need go further to obtain a satisfactory knowledge of the country in all its aspects. Mr. Monteiro writes in a simple, straightforward style, indulges but little in speculation, conjecture, or moralising, and every page is so full of interesting and important facts, clearly told, that the reader will feel constantly in a state of satisfied enjoyment. Most of the information in the work has been obtained at first hand; in the few instances where it is otherwise Mr. Monteiro is careful to point out the source and its value. So far as a full and trustworthy account of Angola is concerned, it seems to us that it would be difficult to supersede the work before us.

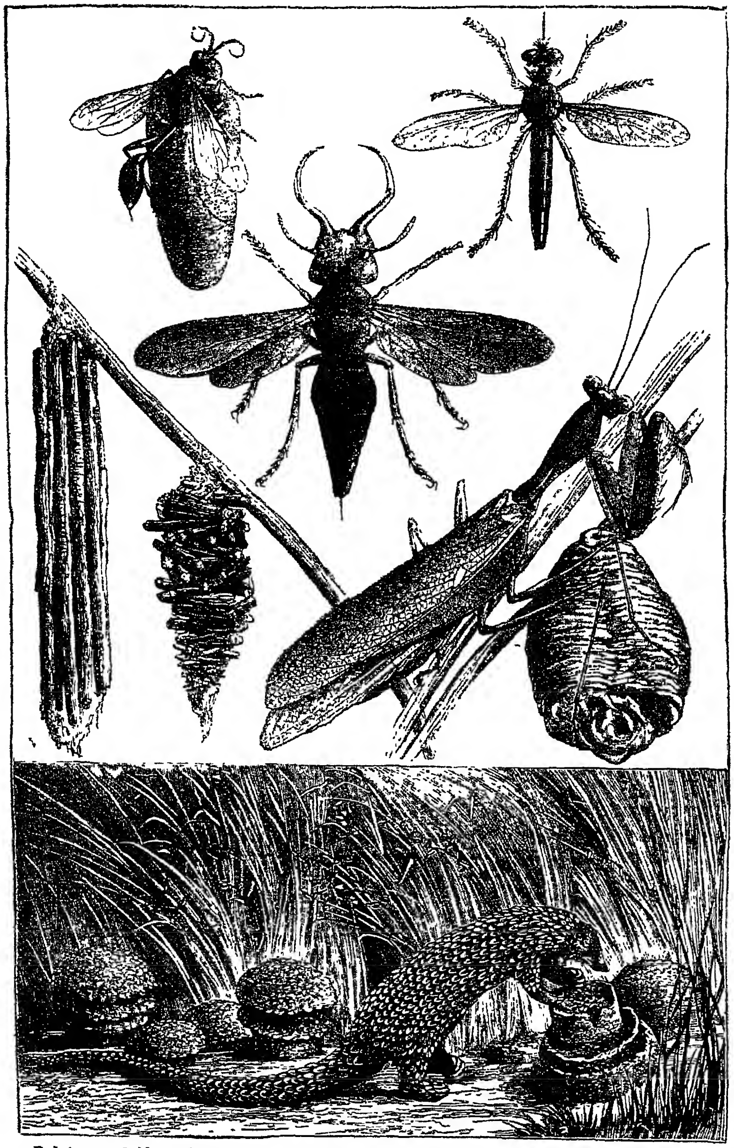
The name Angola Mr. Monteiro applies to all the country from the Congo to Mossamedes, a distance of about nine degrees of latitude. On the north, however, the Portuguese possessions extend no farther than Ambriz, a good many miles south of the Congo, while on the south they extend as far as Cape Frio in 18° 20′ S. lat. The author chooses the Congo as the northern boundary, that being the strong natural limit of the climate, fauna, and ethnology of the region. Chapter I. contains a brief account of the history of Angola to the beginning of the present century, translated from the Portuguese of Feo Cardozo. Throughout the work Mr. Monteiro gives an account of all the principal Portuguese settlements along the coast, and has frequent occasion to refer to the inland districts presided over by a *chefe* or sub-governor. The general impression left on the reader will be one of utter mismanagement, pusillanimity, and oppression. The country as a whole is a fine one, capable of extensive development in many directions, and might be made an extremely valuable possession to Portugal, if the most ordinary care were bestowed upon it. The officials are all underpaid, and with very few exceptions are as corrupt as can well be imagined. The poor natives are plundered on all hands, and a country which might be made to add materially to the resources of the world, is almost entirely profitless through being in the hands of a people too ignorant and too lazy to turn it to any account.

There are a considerable number of tribes scattered up and down the region described by Mr. Monteiro. These tribes vary considerably in language, customs, physique, and intelligence, none of them, however, standing very high in the last-mentioned attribute. The author had many opportunities of studying the natives of Angola, and the ethnologist will find much valuable information in the work. Mr. Monteiro has but a poor opinion of the capacity of the African, and but little hope for his future. He believes that all the efforts hitherto made to elevate and civilise him have failed, and his conclusions on the subject coincide essentially with those of Burton and with those of most other authorities who have examined it dispassionately. Unless under the judicious superintendence of the white man, Mr. Monteiro does not believe there is any hope of the negro ever attaining to any considerable degree of civilisation; and as whites can flourish in very few parts of Africa, "the negro must ever remain as he has always been, and as he is at the present day." Moreover, any advantages which the negro has hitherto derived from the white races have been more than counterbalanced "by the creation of an amount of vice and immorality unknown to the negro in his native or unsophisticated state." Many, no doubt, will be inclined to think that Mr. Monteiro takes much too hopeless a view of the future of Africa and Africans. It is certainly hard to believe that no means will ever be discovered of developing the resources of a country which might be made to yield so much. No doubt, if this is ever to be accomplished, it must be mostly by means of native labour under white superintendence. But with the author's general conclusions on the African question we have no doubt that all who have dispassionately considered must in the main agree. Angola itself is on the whole a comparatively healthy region, and, with ordinary care, Europeans need have little difficulty in getting acclimatised. On this subject, Mr. Monteiro gives some valuable hints; he is of the same opinion as Capt. Burton as to the use of stimulants in tropical countries; from his own experience and from observa-

tions, he infers that their judiciously moderate use is indispensable to complete health.

With regard to the almost hopeless stupidity of the negro, the author gives a curious instance. He employed a number of natives while mining malachite at Bembe. He says :—

"It was great trouble to teach the natives the use of the pick and shovel, and the wheelbarrow was a special difficulty and stumbling-block ;—when not carrying it on



Pelopœus spirifex and nest—Devil of the road (*Synagris cornuta*)—*Dasylus sp.*—Caterpillars' nests—Mantis and nest—*Manis multiscutatum* and Ants' nests.

their heads, which they always did when it was empty, two or three would carry it ; but the most amusing manner in which I saw it used, was once where a black was holding up the handles, but not pushing at all, whilst another in front was walking backward, and turning the wheel round towards him with his hands."

The following bold and ingenious theory as to the character of the native Africans is at least worthy of consideration :—

"The character of the negro is principally distinguished not so much by the presence of positively bad, as by the absence of good qualities, and of feelings and emotions that we can hardly understand or realise to be wanting in human nature. It is hardly correct to describe the negro intellect as debased and sunken, but rather as belonging to an arrested stage. There is nothing inconsistent in this it is, on the contrary, perfectly consistent with what we have seen to be their physical nature. It would be very singular indeed if a peculiar adaptation for resisting so perfectly the malignant influences of the climate of tropical Africa, the result of an inferior physical organisation, was unaccompanied by a corresponding inferiority of mental constitution. It is only on the theory of 'Natural Selection, or the survival of the fittest' to resist the baneful influence of the climate through successive and thousands of generations—the 'fittest' being those of greatest physical insensibility—that the present fever-resisting, miasma-proof negro has been produced, and his character can only be explained in the corresponding and accompanying retardation or arrest of development of his intellect."

In his second chapter the author gives a very clear account of the physical conditions of Angola, whose aspect, productions, and climate present considerable variety both north and south, and from west to east. Contrary to the generally received opinion, Mr. Monteiro doubts whether the Congo, with its vast body of water and rapid current, drains any large extent of country in an easterly direction to the interior, beyond the first rapids. He is inclined to believe that the river, or its principal affluent, after going in a N.E. direction for a comparatively short distance, bends to the southward and will be found to run for many degrees in that direction. It would be vain to theorise on the question, which happily may be set at rest by Lieut. Cameron, who is expected to arrive in this country in a week or two ; the information he must have obtained about the watersheds between the Zambesi and the Congo may enable us to form some notion of the upper course and approximate length of the river. Mr. Monteiro's general conclusion seems, however, at present a very probable one. "From the few and insignificant streams traversing Angola to the coast, which at most only reach sufficiently far inland to have their source at the third elevation or central plateau, it would seem that a great central depression or fall drains the waters of this part of Africa in either an easterly or southerly direction."

The alternation of swamp and dense forest which is characteristic of so much of the West Coast of Africa, ends completely on arriving at the River Congo, and a total change, Mr. Monteiro tells us, to the comparatively arid country of Angola takes place.

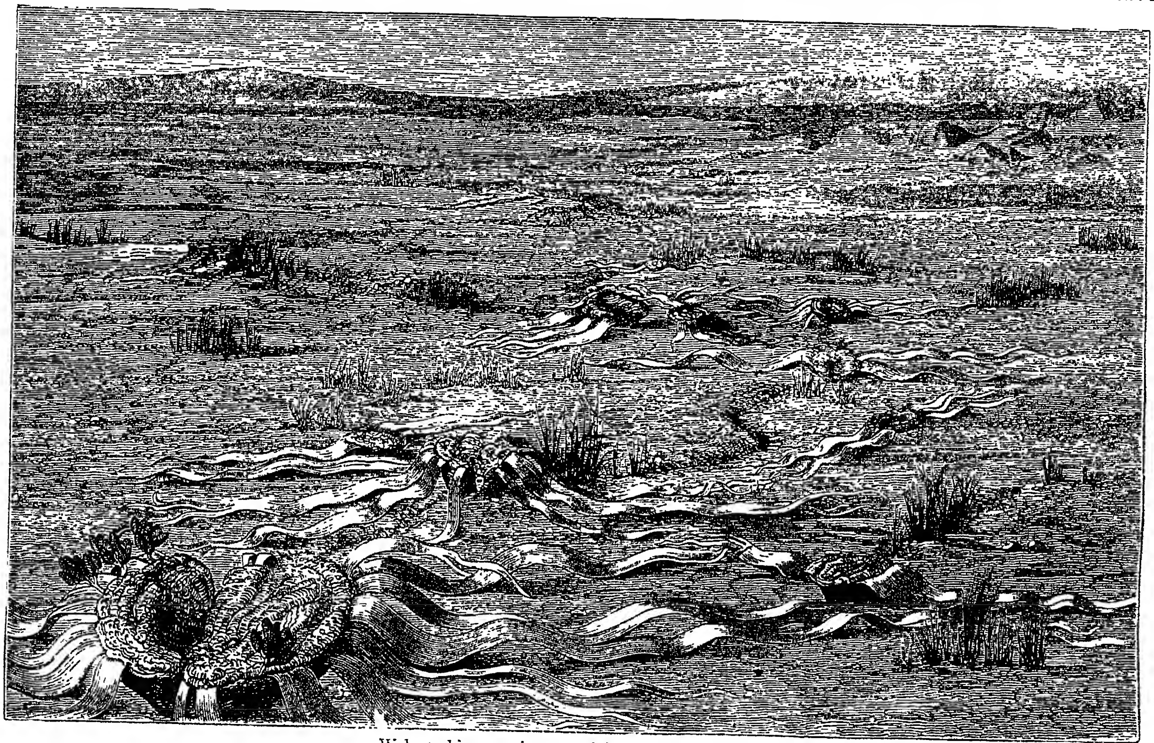
"I may say that, without exception, from the River

Congo to Mossamedes no dense forest is seen from the sea, and from thence not a single tree, it is said, for hundreds of miles to the Orange River. A little mangrove, lining the insignificant rivers and low places in their vicinity, is all that varies the open scrub, of which the giant Adansonios and Euphorbias have taken, as it were, exclusive possession. Nowhere on the coast is seen more than an indication of the wonderful vegetation, or varied beauty and fertility, which generally begins at a distance of from thirty to sixty miles inland.

"At this distance, a ridge or hilly range runs along the whole length of Angola, forming the first elevation; a second elevation succeeds it at about an equal distance; and a third, at perhaps twice the distance again, lands us on the central high plateau of Africa."

Each of these successive elevations is accompanied by a corresponding change in the character of the vegetation. This varied vegetation Mr. Monteiro describes with considerable minuteness as he makes his way from the Congo to Mossamedes, stopping at many places to make minute explorations of the country around. As we have said, Mr. Monteiro has chosen the Congo as the northern boundary of Angola, because it presents a well-marked line of division in respect of climate, fauna, nature, and customs, between Angola and the rest of the west coast. He refers to some very remarkable facts in confirmation of this. The Congo is the southern limit of the gorilla and of several species of monkeys and even of birds, butterflies, and insects. He says truly that it would well repay a naturalist to investigate the number of species the Congo cuts off; it is a pity he had not time to undertake the work himself; no one could be more competent.

With regard to the universal fetishism of the natives,



Welwitschias growing in a plain near Mossamedes.

Mr. Monteiro gives abundant information, much of which we are sure will shed a new light on this degrading and depressing superstition. It seems almost impossible to eradicate it. Many of the Angolan tribes were converted and educated by the old Portuguese missionaries, and to this day many of the tribes transmit the "trick," as Mr. Monteiro calls it, of reading and writing. But this seems to have had no effect in abolishing fetishism, but on the contrary has rather furnished it with new materials on which to flourish. In some respects fetishism seems to resemble the Polynesian "tabu." "Fetish" is often used as equivalent to *charm* or *magic*, and many objects are used by the natives to carry about with them to be used as charms against evil, and in some places rude houses are built as a dwelling for a fetish, who may be represented by a rude image. But besides this it is possible to fetish a person, or thing, or animal, in the same way as in some of the Pacific Islands certain objects may be tabu. Certain animals are fetish, and these a native dare not injure; and indeed it seems possible and easy to render anything whatever fetish, and once at least Mr. Monteiro took legitimate advantage of the custom for his own protection. Their fetishes have, however, no power for good or evil over the white man, who belongs to another and more powerful god than do the natives, who themselves received the idea of God or Creator from the Portuguese missionaries.

The Celis and Mucelis, tribes dwelling inland from Nova Redondo to the north of Benguella, are, Mr. Monteiro believes, the only cannibals in Angola; the Quinbundos, a superior tribe to the south of the Quanza, are not so, "though a traveller who made a few days' trip up the river has asserted they are." The natives on the Quanza and to the south for many miles are great bee-

keepers, constructing hives which they keep in trees. Some families possess as many as 300 or 400 hives.

About Mossamedes the *Welwitschia mirabilis* is found growing, and the country about the river San Nicolau, 14° S. lat., seems to be its northern limit. Mr. Monteiro sent home specimens of the plant, flower, and cones, which supplied Dr. Hooker with some of the materials for his monograph on the plant.

It is impossible in our limited space to give any adequate idea of the abundant information contained in these volumes; we can only assure our readers that if they wish for satisfactory information about the country, the people, the fauna, the flora, the geology, the mineralogy of Angola, they will find it here. While an excellent idea of the country as a whole will be obtained, the author gives minute details of a very large number of animals and plants, of the geology of certain parts, and as to the various minerals which may be obtained, and especially concerning the various tribes, their characteristics, customs, implements, and other matters. The numerous illustrations add not a little to the value of the work.

WORKS ON THE BLOWPIPE

An Introduction to the Use of the Mouth-Blowpipe. By Dr. Theodore Scheerer and H. F. Blanford, F.G.S. Third Edition. (London: Frederick Norgate, 1875.)

Pyrology; or, Fire Chemistry. By Major W. A. Ross, R.A. (London: E. and F. N. Spon, 1875.)

THE first of these volumes is a third edition of a well-known little work, the second edition of which was published in 1864. We think that it still holds its place as the best elementary book on the application of the blowpipe to the determination of minerals, although but few changes have been made in the text.

Major Ross's work on "Pyrology" is an imposing volume illustrated with coloured lithographs. The preface looks more like an article in a well-known daily paper than the opening of a scientific treatise, for in the space of a few pages the names of Neri, Cassius, Pattinson, Herbert Spencer, Bacon, Sir W. Hamilton, Hume, Kant, Mrs. Marcet, Walpole, Bonaparte, Grimaldo, and Hook are alluded to, often in a flippant and tiresome way. The introduction is much in the same style, and we are told that "precisely the same operations of the mind are necessary to analyse a murder or a miracle as a mineral," and that "the general, the detective or the logician deduces probabilities from facts . . . and the physicist or pyrologist has first to elicit facts, which he calls reactions, from which probabilities are concluded." A passage which occurs on page 10 deserves notice. In it the author states that "the various spectra in the orange, green, violet, and indigo, &c., are due to the vapour of substances composed of combinations of hydrogen, oxygen and carbon, and thus that such lines seen in the solar spectrum should scarcely without further evidence be, as they now generally are, attributed to the vapour of burning terrestrial metals in the solar photosphere, but that our metals should rather be supposed to be composed of these elements in different proportions." Spectroscopists will hardly consider the evidence he adduces in support of this hypothesis to be satisfactory, for it rests on no better foundation than the fact that when small fragments of zinc, lead, silver, aluminium and other metals are heated before the blowpipe flame in a bead of phosphoric acid each metal with the exception of tin, gold, platinum, and mercury is decomposed into a brick-red oxide, a brownish black gelatinous mass, and bubbles of some gas which smells like phosphuretted hydrogen.

An interesting and careful history of the use of the blowpipe is then given, at the conclusion of which the author alludes to his own labours, and after a careful examination of the work, we are convinced that we shall best do him justice by stating the principal observations that he claims as his own. These are—a method of detecting soda by means of the orange colour which is imparted to the "pure pyrochrome of boric acid." Potash, on the other hand, being detected by the blue colour produced by breathing on a bead of boric acid which has been blown into a thin vesicle, and in which the mineral has been fused. The separation and detection of "lime and the alkaline earths" by fusion in a bead of boric acid, when the oxides congest into small balls which float in the clear bead. The use of phosphoric acid as a solvent for certain metals, such as platinum and gold, and the adoption of sheet aluminium as a support, which, among other advantages, facilitates the roasting of arsenides and sulphides. In addition to these there are between thirty and forty other "novelties" which space will not permit us to enumerate.

The nomenclature employed in the work is rather bewildering; for instance, a flame having a conical shape is termed "a pyrocone;" a non-luminous flame tinged with colour "a pyrochrome;" and the crystallisation of substances from a state of fusion, is called "crystallignation." It will be evident that such terms become almost irritating when combined into words like "Ellychnine Pyrocone," which means a candle flame tinged with colour.

The tables for blowpipe analysis constitute a "Pyro-qualitative Indicating Chart," which Major Ross has divided into fourteen columns. Taking nickel, to which he specially directs attention as showing the merits of the table, we find that its reactions are described under three heads. First, with phosphoric acid an amber brown bead or, with little of the substance, an orange bead is produced. Second, with boric acid a bead containing green fragments is obtained in the O.P. (oxyhydrogen pyrocone), and metallic fragments in the H.P. (hydrocarbonous pyrocone), and third, when the substance is heated on an aluminium fusing tray in a "charcoal mortar" before the O.P. a green hairy mass is produced. Anyone familiar with blowpipe work will be able at once to compare mentally these directions with Plattner's concise and well-known tables which, by the by, are printed in the appendix. In addition to the well known reagents he employs many of unknown or uncertain composition, such as potassic tungstic borate, mangani cobalt solution, and thus complicates effects. We may give the following as an example of the author's chemistry:—"Sulphides are instantly detected upon it (aluminium foil) by fusing them with a small fragment of soda, and saturating the hot mass with a drop or two of water, when an inky black,

disgusting smelling precipitate of sodium sulphide is produced." It will be new to chemists that *sodium sulphide* is a black substance insoluble in water. There are a few well executed coloured lithographs, but the woodcuts, of which there are about forty, are very rough.

So much care and labour have evidently been bestowed on the preparation of the book, that we regret to be compelled to speak of it in terms of but faint praise. It is the work of an earnest enthusiast who has discovered some pretty reactions which might have at once become generally useful, had they been set forth in a clear and concise form.

THE ROCKS AND MINERALS IN THE MELBOURNE MUSEUM

A Descriptive Catalogue of the Specimens in the Industrial and Technological Museum, Melbourne. By G. H. F. Ulrich, M.E., F.G.S. (Melbourne, 1875.)

THE value of the collection of rock-specimens and minerals in the Museum at Melbourne will be much enhanced by the publication of this descriptive catalogue, which has been drawn up by Mr. Ulrich somewhat upon the model of the catalogue illustrating the collections in the Museum of Practical Geology in London. We learn from Mr. Newberry's preface that it originally formed part of the Report of the Museum presented to Parliament in 1874, and it is now reprinted with a view of making it more generally useful. Judging from the catalogue itself, we should say that the collection of rocks and minerals from the province of Victoria must be of an exhaustive character; the varieties are abundant, and embrace rocks of nearly every known description.

In drawing up this catalogue, the author has not neglected the geological conditions under which the specimens have been originally found; and along with the several varieties of granitic, plutonic, volcanic and sedimentary rock-specimens are also described the distribution and characteristics of the masses from which the specimens have been collected, together with their economic uses. In this part of his work the author has availed himself of the maps and reports of Mr. Selwyn, late Director of the Geological Survey of Victoria—whose important and successful operations in the field were brought to a close about seven years ago, by a sudden fit of parsimoniousness on the part of the Colonial Legislature. In describing the rocks, Mr. Ulrich has adopted the system of classification laid down by Zirkel in his *Petrographie* modified by the views of Von Cotta and other petrologists. But, however valuable such a classification may be when it is in the power of the observer to have constant recurrence to the aid of chemical analysis, we consider that for the field petrologist it is only occasionally available. The nice distinctions between the several species of plagioclastic felspars are only to be determined by laboratory analysis, and for the ordinary observer a classification founded on the presence or absence of quartz amongst the felspathic rocks; and on the determination of hornblende, as against augite as the basis of the pyrosenic rocks is sufficient. Daily experience, aided by microscopic examination, tends to show that definite species amongst rocks are but limited in number, and have little connection with geological age. On this ground we object to such terms as "diabase," with its several varieties mentioned in the *Table of Mixed Felspar Rocks*, as well as "anamesite," "felspar basalt," &c., though resting on the high authority of Dr. F. Zirkel; such being simply varieties of basalt or dolerite.

Again (in p. 24), several specimens are described under the head of "porphyrite," with its varieties, in all of which quartz-grains are present. Now, if this term means anything different from "porphyry," it means a *quartzless* porphyry, as its author, Naumann, proposed. Zirkel's definition is "quartzfreier orthoklas Porphyr." The presence of free silica, therefore, renders the name inapplicable; and although the matter is of little consequence, we refer to it to show the confusion which has arisen by the introduction into petrology of an objectionable name, and its use in a different sense from that intended by the original proposer.

Those portions of the catalogue relating to the occurrence of gold will be found of much interest, and must prove useful to colonists and adventurers in search of the precious metal. The upper Silurian strata rest discordantly on the lower—as in the British Isles—and in these latter are very numerous "veins, lodes, or reefs of quartz," which traverse the beds, varying from one inch to above 100 feet in breadth. According to Mr. R. Brough Smyth's statistics for 1874, the number of these actually proved to be gold-bearing amounted to 3,367, which was being constantly added to owing to the energy of the mining population. These reefs are the original source of the gold, which is extracted directly from the quartz, but more frequently from the detrital strata derived from the denudation of the Silurian rocks, and now arranged in three divisions of "Drift," of which the oldest is the most auriferous. Associated with the gold grains are minerals and precious stones in such variety and profusion as is only granted to a few favoured spots, amongst which we notice the diamond, ruby, sapphire, topaz, zircon, garnet, amethyst, Cairngorm, opal, &c., besides metallic ores, all jostling each other amidst the stones, clay, and sand which would conceal their charms from the unpractised eye.

On the whole, the volume before us affords a remarkable illustration of the similarity of the materials which enter into the composition of the earth's crust all over the world, or at least in widely separated districts. Here at the Antipodes we have a series of rock-specimens exemplifying the rock-formations of Victoria, nearly every one of which finds its representative in the British Islands. We find similar granites, felstones, porphyries, diorites, mica-traps, dolerites, basalts, schists, serpentines and quartzites, sandstones, slates and limestones, and even the rare "nepheline-basalt" of Philip Island and Port Ray has its representative in the Wolf Rock, off the coast of Cornwall, as Mr. Allport has recently determined. As regards the drawing up of the catalogue, the most scrupulous care has evidently been exercised, both in determining the nature of the specimens themselves, and in identifying their localities; while a very good idea of the geological structure of the colony may be obtained from a perusal of its pages.

OUR BOOK SHELF

A Monograph of the Trogonidæ; or, Family of Trogons. By John Gould, F.R.S., &c. (London: Published by the Author, 1875.)

THE completion of a second edition of Mr. Gould's "Monograph of the Trogons," is an event which ought not to pass by without a notice in this Journal. The first edition of this work, published in 1838, was one of the earliest of Mr. Gould's magnificent series. Of its fellow Monograph, that of the Toucans, a second edition was issued some time since, and the present work is a worthy companion to it. During the thirty-seven years which have elapsed since the publication of the first edition of the "Monograph of Trogons," Mr. Gould, as his brother ornithologists know full well, has by no means neglected the subject, but has from time to time brought forward descriptions of new species that have come to his knowledge from the more thorough exploration of the tropics that has of late years taken place. From these, and other sources, the number of known Trogons, which at the time of the first Monograph was thirty-four only, has now been increased to forty-six, of the whole of which splendid life-sized pictures, according to Mr. Gould's wonted practice, are given in the present volume.

Like the Parrots, the Trogons are widely diffused through the tropics of both hemispheres. Though not so strongly marked in general characters as the Psittacidæ the Trogonidæ are separated from all other known birds by the peculiar conformation of their feet, having the first and second toes permanently turned backwards, which is not the case in any other form of the class "Aves." Like the Parrots, too, the Trogons are most numerous in the New World, thirty-three out of the forty-six species being peculiar to Central and Southern America, whilst eleven are found in the Indian region, and two only in Africa. As regards habits and mode of life, there appears to be much similarity in the Trogons of all three continents. They are universally forest-haunting birds, inactive in habits, short in flight and feeding, whether their prey be insect or fruit, mostly upon the wing. Their brilliant colours offer the most remarkable compounds of emerald green and various shades of crimson and golden yellow, as will be sufficiently apparent to anyone who turns over Mr. Gould's splendidly-coloured plates. We must indeed congratulate the author on the energy and success with which, prompted by the pure love of science, he has brought out a second edition of one of the first of his many important ornithological works.

Geologie der Kohlenlager, von Dr. Hermann Mietzsch, Geolog der Landesuntersuchung im Königreiche Sachsen. (Leipzig, 1875).

FOR those to whom the magnificent work of Geinitz, Fleck, and Hartig, *Die Steinkohlen Deutschlands*, is inaccessible, the smaller treatise before us will prove acceptable. From the practical acquaintance of his subject gained in his professional duties, Dr. H. Mietzsch was well fitted to produce a treatise on the physical properties of coal and the phenomena connected with its place amongst the strata; while, with the industry which generally characterises German authors, he has made himself acquainted with what has been written on the subject by French and English writers, as well as those of his own fatherland, and has woven the whole into a connected account of the history of coal-mining, the properties of coal, and the conditions under which it has been found in various countries and periods, as well as the structure and mode of formation of coal-fields and coal-basins. The work is illustrated by twenty-five woodcuts, and appears to bring the subject well up to the present state of our knowledge. E. H.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Evidences of Ancient Glaciers in Central France

WERE this a question concerning volcanic phenomena, with which Mr. Scrope is as familiar as I am with glacial ones, I might be disposed to defer to his opinion. As it is, having only his assertion that I have mistaken the results of a recent landslip (*i.e.* a spot where there are no traces of landslip, and to which no landslip could have reached) for time-worn and weathered glacier-transported blocks, I ask the readers of NATURE to pause before disposing of my powers of observation as summarily as Mr. Scrope does; remembering that the history of all glacial phenomena, from scratched boulders to lake-basins, has been successively overlooked, denied, and misinterpreted, before being understood and accepted.

The landslip to which Mr. Scrope refers, and which he describes as having occurred in 1859, under cliffs nearly a thousand feet high "on the left flank of the valley looking upwards," is in a very different position from that of the blocks to which I have directed attention. There are no cliffs whatever such as Mr. Scrope describes on the left flank of the valley anywhere near their position, nor for half a mile above it. The left flank of the valley for half a mile above them forms a very gentle slope indeed, and rises but a very few hundred feet above its floor, without cliff or rock protruding on its surface.

On the other hand, the evidences of old ice action in the Mont Dore district, and elsewhere in Central France, are as conclusive as in Western Scotland, M. l'Abbé Lecoq notwithstanding, for whose labour in his own line of research I have as high a regard as I have for Mr. Scrope's.

J. D. HOOKER

Sir Thomas Millington and the Sexuality of Plants

The letter of your anonymous correspondent "A. B. C.," in your issue for Dec. 16, hardly seems to need a reply, inasmuch as he has added nothing whatever to the solution of the question raised in mine, whether any writings of Sir Thomas Millington are in existence which confirm the alleged discovery by him of the sexuality of plants. From the silence of your correspondent on this point, as well as of the two writers referred to in my letter, I infer that no such writings are, at all events, readily accessible. There are, however, some statements by your correspondent which cannot be allowed to pass uncorrected.

First, as to the bibliographical matter: "A. B. C." says "there is no such thing" as a second edition of Grew's book—a somewhat rash assertion in the face of the fact that the words "The 2nd edition" are printed on the title-pages of three out of the four books which make up "The Anatomy of Plants," first published as a whole in 1682. The facts of the case are these: In 1672 Grew published a small volume under the title "The Anatomy of Vegetables begun, with a general Account of Vegetation founded thereon;" in 1682, a much larger work entitled "The Anatomy of Plants begun, with a general Account of Vegetation founded thereupon," a portion of which is a reprint of the earlier work. I fail to see why I should be held up to reproach as having almost committed a literary crime in referring to the larger as "a second edition" of the smaller work.

Now as to the more important matter. Without bringing forward a tittle of fresh evidence, "A. B. C." makes the confident assertion that it is "also clear enough" that Millington is entitled to be described as the discoverer of the sexuality of plants. In singular juxtaposition with this assertion he quotes a paragraph from Sprengel in which some half-dozen illustrious botanists are named in this connection, but Millington is not even mentioned! The preceding quotation from Grew is made to appear as if it owed its inspiration to Millington; whereas, after the graceful reference to his friend the Savilian Professor, Grew commences his account with these words:—"The sum therefore of my thoughts concerning this matter is as follows." It would seem as if, at the close of the seventeenth century, fresh insight into the phenomena of fertilisation was being gained by a number of botanists in both England and Germany; but "A. B. C." has established no right to express an opinion in so *ex cathedrâ* a style in favour of Millington's sole claim to the discovery. For evidence

that the observations of Kamerer of Nürnberg (Camerarius) anticipated by two years the publication of Ray's "Historia Plantarum," I must refer him and any of your readers who are interested in the subject to Sachs's "Geschichte der Botanik."

Linnæus ("Amœnitates," vol. i. pp. 329, 330) thus sums up the relative merits of Millington, Grew, Ray, and Camerarius: "Thomas Millington, eques Anglus, Professor Savilianus, primus videtur, qui insigni cura in hanc veritatem eruendam incubuit, viamque aperuit experientissimo Grewio. Nehemias Grew, in anatome Plantarum, sexus diversitatem et fecundationem plantarum per farinam mascule scrutari conatus est; cujus *hypothesibus*, album addidit calculum temporis sui botanicus eximius Rajus. Rudolphus Jacobus Camerarius primus perspicue *demonstravit* sexum et generationem, quamvis non dubii fuit ipse expers de hac veritate, quod si moverant experimenta quæ fecerat in Cannabe."

Now as to Theophrastus. Your correspondent makes much of the "prolifick virtue" ascribed to the pollen-grains by Grew. No one, however, can have read the writings of the early Greek and Roman naturalists without having learned, that not only did they distinguish male and female flowers, but also ascribed a "prolific virtue" to the pollen. Without troubling your readers with a Greek quotation, let us hear what a commentator on Theophrastus says:—"Theophrastus ait, fructum in palma feminæ perdurare nunquam posse nisi florem maris cum pulvere super eam concusserint;" and again: "In palma maris et fœminæ coitus sit;" or again, Pliny: "Adeoque est veneris intellectus, ut coitus etiam excogitatus sit ab homine ex maribus, flore, et lanugine, interim vero tantum pulvere insperso feminis."

I hardly think your readers generally will agree with "A. B. C." in his opinion that "time, paper, and ink are wasted" in a discussion of a historical point of some interest.

Dec. 24 ALFRED W. BENNETT

Saw-fish Inhabiting Fresh Water

IN NATURE, vol. xiii. p. 107, Mr. Wood, of Manila, writes on "Saw-fish inhabiting fresh water," in the Laguna de Baij, Luzon, as on something curious and new. But this fact was known long ago; not only do sharks live in fresh water there, but also elsewhere on the globe. As one who mentions the saw-fish in the Laguna de Baij, I only name the famous de la Gironnière ("Aventures d'un Gentilhomme Breton," 1857). He says, p. 102: "Deux poissons de mer se sont acclimatés dans les eaux douces du lac: le *requin* et la *scie*. Le premier est heureusement assez rare, mais le second est très abondant."

The species of saw-fish mentioned is *Pristis perrotetti*, a species of very wide distribution; it has been collected in the Atlantic (West Indies), in the Indian Ocean (Zambesi), in the China Sea (Borneo), &c.

When on Luzon in the year 1872, I succeeded in procuring a series of specimens on the spot, which I brought home; they are from two to three feet long, but I saw, myself, at the fish-market of St. Cruz a specimen of about twenty feet in length. Quantities are to be seen on every market day in St. Cruz, the flesh being very cheap on account of its bad and dry quality, and only the poor mountaineers like it as food.

I took some trouble to get those smaller specimens home, because I fancied that they might possibly differ from the marine specimens (Bay of Manila). But an accurate comparison showed no difference at all, and therefore the changed conditions seem to have had no influence on the external features of the species.

The saw-fishes are said to fight violently with the crocodiles, which occur in large quantities in the Laguna, and I do not doubt the fact. A. B. MEYER

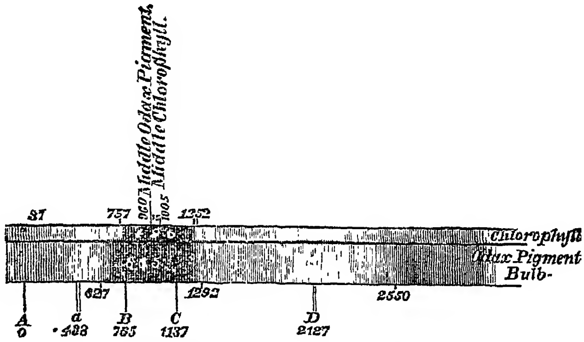
Dresden, Dec. 23

Spectrum of Fish-pigment

I HAVE lately observed the spectrum of a pigment-colour found under the scales in fins and tail, mouth and eyes, of a small smelt-like fish found in St. Vincent's Gulf, S.A. They are commonly known as the Weed fish, but Mr. Waterhouse, our Curator, informs me they are the *Odax radiatus*, *O. frenatus*, *O. Richardsonii*. These fish are perfect little gems for colour, being of a bright blue green (nearly blue) in *O. Richardsonii*, and about the eye most splendid; black centre, brilliant orange ring, outside of which is a most brilliant turquoise blue ring set in deep brown.

Finding this colouring matter stained paper, I examined the scales and fins by spectroscope, and noticed a deep band that appeared to correspond with the deep band of chlorophyll. I send a sketch of the respective spectra and a bulb and tube of the pigment in solution, which, with the pieces of tail and fins, I trust you will receive in good condition. I do not place much faith in it remaining clear and brilliant; the heat of the ship may possibly destroy or alter it. You will notice the solution is rather bluer than chlorophyll. This pigment is nitrogenous, is destroyed by heat, chlorine, acetic acid, alkalis, ammonia, and alcohol. It is soluble in water and sea-water. Sulphuric acid precipitates it with albumen of fish, but does not destroy colour. Light bleaches it. Its chemical properties are therefore distinct from those of chlorophyll.

I consider some interest attaches to this from the fact of the Parrot-fish (*Labrichths Richardsonii*) being marked with blue stripes containing the same colouring matter; also the scales and parts in Odax coloured orange give a green tint almost identical in shade to chlorophyll. This yellow or orange does not give



Spectra with kerosine flame on edge of Odax pigment and comparison with chlorophyll.

Dividing the Solar spectrum into 10,000 parts from A. bright kerosine flame on edge gives as above. The chlorophyll band is rather lighter in the centre; when solution is dilute it divides into two fine lines. Width of strong band, 495.

The Odax Pigment does not resolve into two lines. The centres of these two great bands Odax Chlorophyll are only forty-five apart. Width of band, 665; rather nebulous, especialy at end of greatest refraction. Some very faint bands occur each side of D, and continue to end of nebulosity to 2,550. The bulb gives the above figure. The tube a much narrower band, but centre coincides with bulb.

any band or interfere with the spectrum of the pigment, except so far as its mere colour and general absorption at blue end arising from such colour.

Now as chlorophyll has been said to be found in some infusoriæ, which I doubt, it is just possible that this or similar colouring matter is taken for it. I have been rather curious in examining animal greens in shells, and a native green silk we have here, also in the Emu egg-shell, but cannot find the slightest trace of chlorophyll band, and until I met with this I concluded no animal green yielded any band that could be mistaken for chlorophyll, and that therefore the spectroscope was an unerring test for distinguishing between vegetable and animal organisms. This spectrum of Odax pigment, which possibly I may find in other species of fish, Actiniadæ or Medusæ, many of which are beautifully coloured, is therefore so far of interest. I trust these remarks may be interesting and lead to some inquiry in this direction.

The dry pieces of fins and tail, also a piece of stained paper, will show well if mounted in balsam. If the colour is not deep enough, cross the layers one over the other until sufficient depth of shade is obtained. I use half-inch object glass in microscope except for scales and spots, when I use quarter, and shut out all other light; single scales then show the bands well.

GEORGE FRANCIS

Laboratory Institute, Adelaide, Oct. 9

Function of the Ocelli of Hymenopterous Insects

MY brother, Fritz Müller (Itajahy, Prov. St. Catharine, South Brazil), in his letters to me, has repeatedly started the question whether the size of the ocelli of hymenopterous insects is not dependent on their nocturnal habits. He supports this opinion by the following observations:—

1. *Apoica pallida*, one of the social wasps of Brazil, in the daytime rests quietly in its nest, which resembles the nest of our *Polistes gallica*, but is attached to the twig of a tree. During the evening it looks after flowers, and, whether sitting on them, and sucking their honey, or flying about in the moon-light, by its moonlike colour it is protected from its enemies. It differs from the allied species, which have diurnal habits, in the largeness of its ocelli.

2. One of the solitary Apidæ of Itajahy, belonging to the family of Andrenidæ (*Eophila matutina*, F. and H. Müller) has the singular habit of visiting flowers exclusively in the twilight of earliest morning, and is also provided with unusually large ocelli.

3. A species of *Dorylidæ*, probably belonging to the genus *Labidus*, found, Oct. 1875, by my brother's daughter Anna, late in the evening, flying towards the candle-light, is likewise remarkable for strikingly large ocelli. Concerning *Dorylus*, Gerstaecker says: Ocelli large, bladdered ("Ocellen gross, blasig"); and Westwood (Introduct. vol. ii., p. 216), "Mr. Burchell has informed me that the African species of Dorylus is nocturnal in its habits."

Can any of your readers give further information about the function of the ocelli? HERMANN MÜLLER

Lippstadt, Dec. 18

The House-fly

SOME months ago there were several notices in NATURE as to the death of house-flies, caused by a parasitic fungus. One instance only has come under my observation.

Certainly not later than the first week of last October I saw a fly standing dead on the outside of the pane of my window, surrounded with a small cloud of dust. After a day or two the fly fell off; but the curious part of the matter is that at this moment (Dec. 20), the dust is still on the window-pane. The spaces where the legs were are left sharp and clear, and the cloud, thickest close around them and under the place of the body, thins out gradually round to the distance of above an inch. Looked at through the window-glass (I cannot get at the outside), a pocket-lens resolves it into nothing more than coarser dust, presenting much the appearance of iron filings round the pole of a magnet, in the manner it diverges from the centre. Can any microscopist inform me, through NATURE, whether the fungus actually takes root on the glass, or by what means it has been able to maintain its adherence through the many drenchings of rain and snow to which the window has been exposed during this stormy season? M. E.

Mountfield, Sussex, Dec. 20

The true Nature of Lichens

The writer of the criticism on "Haeckel's History of Creation," in NATURE, vol. xiii. p. 121, will confer a favour on British Lichenologists if he will explain what he means by asserting that "the true nature of Lichens has been cleared up" of late years. W. LAUDER LINDSAY

[The reviewer referred to the investigations of Prof. Schwendener, of Basel: "Untersuchungen über den Flechtenthallus" (Nägeli's *Beiträge zur wiss. Botanik*, 1868), and "Eröterungen zur Gonidienfrage" (*Flora*, May, 1872). A translation of the latter paper appeared in the *Quarterly Journal of Microscopical Science* (vol. xiii. p. 235). See also "A *resumé* of recent views respecting the Nature of Lichens," by Mr. Archer (*ibid*, 1873, p. 217), and "Sexual Reproduction of Thallophytes," by Prof. Thiselton Dyer, in the same journal for last July, p. 296.—ED.]

The Boomerang

TRUSTWORTHY information respecting the performance of the boomerang is a *desideratum*. Reports from professed eye-witnesses as to its behaviour are frequently highly sensational and perplexing. It has been seen, so it is said, to strike an object with great violence and then to return to the hand of the projector! That its rapid rotation round the shortest axis passing through its centre of gravity should, as in the gyroscope, tend to make it keep its original plane of rotation, is clear. That its progressive force being expended before its rotatory force, it should tend to fall in the direction of the least resistance, *i.e.* to return on its path, need not be doubted. But striking an object with violence must, one would suppose, change its plane of rotation; and then there would be no disposition to return on its path. In the notice in last week's NATURE of "Artes Africanæ" it is stated that the African boomerang is thrown so as to rotate in a horizontal plane; in which case, except by accident, there would be no tendency to return to the thrower, a mode of action supposed to be proper to the boomerang. Many know the toy boomerang made of card-board, "V" shaped, with one limb shorter than the other, say four and two and-a-half inches respectively. When this toy is laid on the smooth cover of a book held at an inclination of about 60°, and when the shorter limb projecting just beyond the edge of the book is struck with a smart fillip of the finger so as to project it rotating rapidly at an upward angle of 60°, the toy will reach the further side of a room and return; but of course if it strikes anything its plane of rotation is changed and it falls irregularly. HENRY H. HIGGINS

OUR ASTRONOMICAL COLUMN

SMALL STAR WITH GREAT PROPER MOTION.—In vol. v. of the Madras Observations, Taylor mentions having observed in 1838 or 1839 a star of the 9th magnitude near to Brisbane 3458 (which appears not to have been found), the position of which, by three observations, is thus given for 1840:—R.A. 11h. 5m. 25·71s, N.P.D. 118° 59′ 12″·62.

Argelander twice observed a star of the same magnitude (Oeltzen, Nos. 11237-8) in zones 374 and 377, 1851 April 22 and 28, the mean place of which for 1850 is in R.A. 11h. 5m. 50·98s, N.P.D. 119° 1′ 52″·95. Assuming the identity of the stars observed by Taylor and Argelander, of which there can be little doubt, the comparison of positions for 1840 and 1850, taking the date of opposition of the star in 1838 as about the epoch of Taylor's observations, unfortunately not stated, shows an annual proper motion of − 0·293s in R.A., and of − 2″·74 in N.P.D., or 4″·72 in arc of great circle in the direction 305°·5. If this amount of proper motion is confirmed, it will be fourth in order of magnitude of the great proper motions of stars yet satisfactorily ascertained, and the list will then stand as follows:—

	Proper Motion in Arc of great Circle.		Direction of Motion.		Magnitude.
	″		°		
Groombridge 1830...	7·05	...	145·0	...	7
61 Cygni ...	5·21	...	51·8	...	5½
Lalande 21185 ...	4·75	...	186·6	...	7
Taylor's star ...	4·73	...	305·5	...	9
ε Indi ...	4·63	...	124·8	...	5½
Lalande 21258 ...	4·40	...	282·4	...	8½
40 Eridani ...	4·09	...	212·0	...	4½
μ Cassiopeæ ...	3·83	...	115·3	...	5½
α Centauri ...	3·81	...	276·6	...	1

Lalande 21185, is "Argelander's second star" of Prof. Winnecke, and No. 21258 is the star called "Argelander's third" by Dr. Krüger.

If Taylor's observations of the star of ninth magnitude were made in 1839, it should be third on the above list, but the precise amount of proper motion must remain for comparison of Argelander's position obtained in 1851, with future observations, it may be hoped early in the next year.

The N.P.D. of Brisbane 3458 mentioned above, agrees exactly with that of Lacaille 4641, but the R.A. differs 1m. 8s.; the magnitudes are the same.

THE SECOND COMET OF 1702.—The first comet of this year does not figure in our catalogues of cometary orbits, no observations properly so-called having been obtained. In Europe the tail only was seen by Maraldi and Bianchini at the end of February and beginning of March. The second comet of 1702 was observed at Berlin, Paris, and Rome, in the last ten days of April and beginning of May, and orbits have been calculated by Lacaille and Burckhardt; the latter reduced the observations anew, but it does not appear what data he had besides those

published in the "Memoirs of the Paris Academy." It is singular that the original observations of this comet, given in "Francisci Blanchini Veronensis Astronomicæ ac Geographicæ Observationes selectæ" (Verona, 1737) have not, so far as we can discover, been fully calculated. The volume is not mentioned amongst those consulted by Pingré, in the preparation of his great work, the "Cométographie," and is probably rare. A preliminary reduction of these observations exhibits considerable difference from Burckhardt's parabola, and in presence of the suspicious indications of ellipticity, small inclination and direct motion, it may result that Bianchini's observations may be sufficient to add another comet of short period to those already known—at least so far as to render probable its having moved in an elliptical orbit of small extent, at the time it was observed, which is about all that can be said in the case of the comet of 1766, or of the first comet of 1743. It is certain that it must have been very near to the earth shortly before Bianchini discovered the comet on April 20. In a short time we may have more to say respecting the movements of this body.

THE TOTAL SOLAR ECLIPSE of 1999, AUGUST 11.—In NATURE, vol. xii. p. 213, were given the elements of the eclipse of 1927, June 28, which will be total in the north of England, though only for nine or ten seconds even on the central line; it is the first total eclipse that will be visible in these islands during the ensuing century, and there is only one other eclipse that can be witnessed in its totality in England before the year 2000. It is that of 1999, August 11, of which we proceed to give some account.

The elements of the eclipse are as follows:—

Conjunction in R.A. 1999, Aug. 10, at 22h. 50m. 8s. G.M.T.

R.A.	140° 46′ 31″
Moon's hourly motion in R.A.	35 29
Sun's " " "	2 22
Moon's declination	15 50 11 N.
Sun's "	15 19 49 N.
Moon's hourly motion in decl.	7 44 S.
Sun's " " "	0 44 S.
Moon's horizontal parallax	58 43
Sun's " "	9
Moon's true semi-diameter	16 0
Sun's " "	15 47

The sidereal time at Greenwich mean noon on Aug. 11 is 9h. 18m. 2·0s., and the equation of time 5m. 16s. subtractive from mean time.

The central eclipse begins 21h. 29·4m. in long. 64° 49′ W., lat. 41° 11′ N.; central with sun on meridian in long. 18° 47′ E., lat. 46° 47′ N.; central eclipse ends 0h. 34·8m. in long. 87° 33′ E., lat. 17° 31′ N.

So far as regards this country the most favourable locality for observation will be in the vicinity of St. Ives, in Cornwall, which place is almost exactly on the line of central eclipse. Taking the position of St. Ives in long. 5° 26′ W., lat. 50° 12′ we find—

	h. m. s.	
Beginning of totality August 11 at	9 47 42	A.M. local time.
Ending " " "	9 49 42	" "

The duration of total eclipse is therefore 2·m.

The sun's apparent altitude at this time is 47°.

If we found equations of reduction upon this direct calculation for St. Ives, we shall have the following expressions by means of which anyone who is curious in the matter may examine the durations for such places as fall within the total eclipse:—

$$\text{Cos. } w = 70{\cdot}8267 - [2{\cdot}12739] \sin. l + [1{\cdot}70001] \cos. l, \cos. (L + 11^\circ\, 55'{\cdot}6)$$
$$t = 23\text{h. } 19\text{m. } 48\text{s.} \mp [1{\cdot}78051] \sin. w - [3{\cdot}27551] \sin. l$$
$$+ [3{\cdot}92586] \cos. l, \cos. (L - 114^\circ\, 40'{\cdot}1).$$

In these formulæ l is the geocentric latitude, L the longitude from Greenwich taken *negative*, and t the Greenwich mean time of beginning or ending, according as the upper or lower sign is employed; the quantities within the square brackets are logarithms.

For that portion of the zone of totality falling upon English ground we have—

Long. W.	Lat. North Limit.	Central Eclipse.	South Limit.
2° 30′	... 50° 35′·9	... 50° 8′·2	... 49° 40′·5
3 30	... 50 38·2	... 50 10·5	... 49 42·8
4 30	... 50 40·4	... 50 12·6	... 49 45·0
5 30	... 50 42·2	... 50 14·5	... 49 46·9

These results may be expected to prove pretty near the true ones, being derived from elements of the lunar motions which represent with considerable precision the circumstance of the total eclipse in England in 1715, and the annular eclipse of 1737, which was well observed at Edinburgh by Lord Aberdour and Maclaurin.

THE ZODIACAL LIGHT.—This phenomenon presented itself rather conspicuously in the neighbourhood of London on the evening of the 23rd inst., though the vaporous condition of atmosphere seriously interfered with any attempt to trace its outlines satisfactorily. The southern border of the light appeared to be better defined than the northern one, and the latter seemed to be slightly curved.

*THE THEORY OF "STREAM LINES" IN RELATION TO THE RESISTANCE OF SHIPS**

IV.

SUPPLEMENTARY NOTES.—A.

THE proposition, that the flow of fluid through a tortuous pipe when its ends are in the same straight line, does not tend to push the pipe endways, can be treated in several ways, of which only one is given in the text of the address; but it may be interesting to some readers to trace some of the other ways of viewing the question.

First let us take the case of a right-angled bend in a pipe (that is to say where the direction of a pipe is altered through a right-angle by a curve of greater or less radius; a bend of this sort is shown in Fig. 29), and assume that the fluid in it at A is flowing

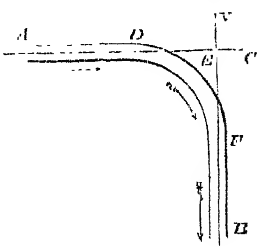


FIG. 29.

from A towards C. I propose at present to deal only with those forces or tendencies which act more or less powerfully in the direction of the original motion of the fluid, namely along the line AC.

I must here remind you that I am dealing with this matter entirely independently of hydrostatic pressure. Perhaps to some it will be difficult to dissociate the idea of hydrostatic pressure from a fluid in a pipe. This difficulty might be got over by assuming that the pipe is immersed in a fluid of the same density and head as the fluid within it. There will thus be hydrostatic equilibrium between the fluid within and without the pipe, the only difference being that the fluid inside the pipe is assumed to be in rapid motion, and thus to subject the pipe independently to any stresses properly incidental to that motion of the fluid within it.

The sole work that has to be done in the present case, is that of deflecting the current of fluid to a course at right angles to its original course AC; and, regarding these forces as resolvable throughout into two sets of components, the one at right angles to the line AC, the other parallel to it, it is of the latter alone that account is to be taken. Manifestly the sum of these components is measured by the circumstance that it is precisely sufficient to entirely destroy the forward momentum of the fluid that flows

* Address to the Mechanical Section of the British Association, Bristol, August 25, 1875; by William Froude, C.E., M.A., F.R.S., President of the Section. Revised and extended by the author. Continued from p. 133.

along the pipe at A towards the bend. This force is administered to the fluid by the curved portion of the pipe at the bend DEF; and as the pipe is assumed to be rigid, the work of arresting the forward velocity of the fluid throws a forward stress on the pipe in a direction parallel to the line AC.

Let us now assume that to the right-angled bend AB we attach rigidly a second right-angled bend, BG, as shown in Fig. 30, in such a manner that the termination of this second bend

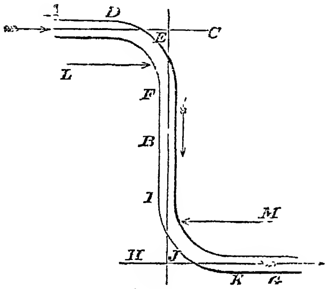

FIG. 30.

at G is parallel to the commencement of the first bend at A. Here I will again, for the present, deal only with the forces in a direction parallel to the line AC.

The fluid at B has no velocity in the direction of the line AC, and at G it has a velocity in that direction equal to the velocity which it had at A. To give it this velocity in a forward direction (I mean forward in its original direction of motion), to establish this forward momentum, requires the application of a force in the direction HG; and this force is administered to the fluid by the curved portion of the pipe at the bend IJK; and as the pipe is assumed to be rigid, the duty of establishing the forward velocity of the fluid throws a rearward stress on the pipe in the direction GH. Now as the forward momentum given to the fluid between B and G in the line GH is exactly the same as the momentum destroyed between A and B in the line AC, it follows that the rearward stress thrown on the pipe at the bend IJK is exactly equal to the forward stress thrown on the pipe at the bend DEF. Hence it will be seen that the forces acting on the rigid pipe AG, treated as a whole, balance, so far as relates to the forces parallel to the line AC, the original line of motion of the fluid—the forward stress acting on the pipe at the bend DEF being balanced by the equal rearward stress acting on the pipe at the bend IJK. These two of the forces acting on the pipe are shown by the arrows L and M, which, it must be remembered, are the only forces which act in a direction parallel to the line AC.

It will have been seen that the measure of these forces is the amount of forward momentum of the fluid which is destroyed or created; and from this it will be inferred that the forces will be the same, no matter what is the radius of the curve of the pipe, inasmuch as the curvature of the pipe does not affect the amount of the forward momentum that has to be destroyed or replaced in the fluid.

Let us next take the case of a bend in a pipe that is not a right angle, as shown in Fig. 31; and here, as before, I only

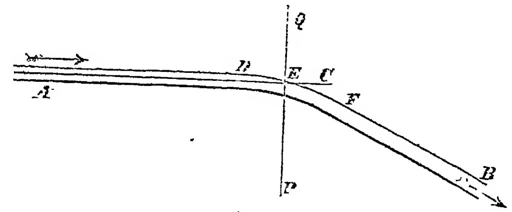

FIG. 31.

propose to deal with the forces that operate in a direction parallel to the line AC, that is, of the original motion of the fluid. Now in this case the forward motion of the fluid is not, as in the instance of the right-angled bend, entirely destroyed in its progress from A to A; only a portion of the forward motion is checked, and the same portion of the forward momentum destroyed; and the force by which it is destroyed is administered to the fluid by the curved portion of the pipe at the bend DEF, and, as in the former case, constitutes a forward stress on the pipe in the direction of the line AC, which will bear the same ratio to the stress which would follow from the destruction of the whole, as the portion destroyed bears to the whole forward momentum.

Suppose to this bend we attach rigidly another bend BG, of same angle, as shown in Fig. 32, so that the termination of this

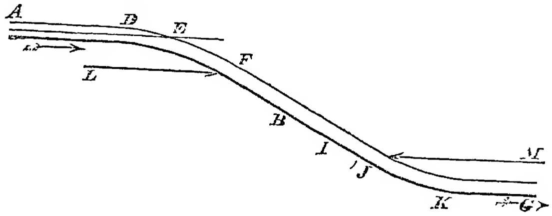

FIG. 32.

second bend at G is parallel to the commencement of the first bend at A. Here, in the portion of the pipe BG, that part of the forward velocity which was taken away has to be again given to the fluid; this requires force, which is administered to the fluid by the curved part IJK of the pipe. There is thus thrown on the pipe a rearward stress represented by M. The force required in the bend between B and G to reinstate completely the forward velocity, is evidently the same in amount as the force required in the bend between A and B to destroy in part the forward velocity.

It follows, therefore, that the two stresses on the pipe, represented by the arrows L and M, which indicate the forces acting on the pipe, are equal and opposite to one another, and these are the only forces acting on the rigid pipe in a direction parallel to the line AC or the original motion of the fluid at A. It follows, therefore, that in case of two right-angled bends rigidly connected, or in the case of two connected equal-angled bends of any other angle, the stresses brought on the pipe by the flow of the fluid will not tend to move the pipe bodily endways.

It will be seen also by this reasoning that the forces we have referred to do not depend on the curvature of the pipes, but are simply measured by the amount of the forward momentum of the fluid and the extent to which that momentum is modified by the total of the deflection which the course of the fluid experiences in passing the bend, or, in other words, by the angle of the bend. And from this reasoning it becomes apparent that by

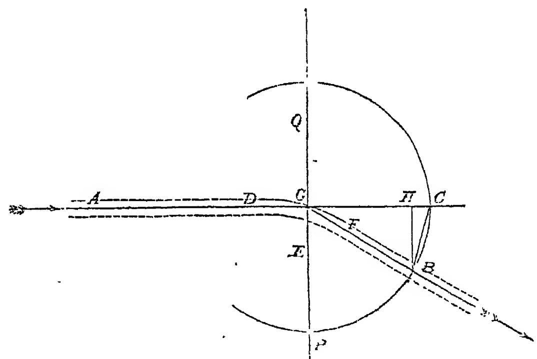

FIG. 33.

Let AGB = angle of bend.
Let GC = force required to destroy the whole momentum of fluid in line AC.
" = tension which would be put on pipe AD by a right-angled bend.
Then HC = force required to destroy momentum lost at the bend in the line AC.
And HB = force required to establish momentum acquired at bend in line QP.
∴ BC = total force acting on pipe.
This force must be in equilibrium with the tensions of pipe along BG and AC.
∴ the tension of pipe = GC or GB.
i.e. = the tension of pipe when the bend is right angled.
Therefore the tension of the bent pipe is constant for a given velocity of flow, whatever be the angle of the bend.

whatever bends or combinations of bends we divert the course of a stream of fluid in a pipe, provided the combination be such as to restore the stream to its original direction, the aggregate of the forces in one direction required to destroy forward momen-

tum are necessarily balanced by equal forces in the opposite direction required to reinstate the former momentum.

It will be useful to consider more in detail the action of all the forces operating on a fluid in a bend of the pipe; and I will return to the case of a single right-angled bend, as shown in Fig. 29. I before spoke merely of the forces acting parallel to the line AC, and said that the forward momentum of the fluid in that line had to be destroyed in its passage round the bend DEF, and that this must be effected by a force acting parallel to AC, which would throw a forward stress on the pipe, tending to force it in the direction AC. But similarly velocity has to be given to the fluid in the direction NB; and to do this a force must be administered to the fluid which will cause a reaction on the pipe in the direction BN; and as the momentum to be established in the direction NB has to be equal to that in the direction AC, which had to be destroyed, it follows that the forces of reaction upon the pipe in the directions AC and BN are equal. These forces can be met in two ways, either by securing the bent part of the pipe DEF so that it will in each part resist the stresses that come on it, or by letting the forces be resisted by the tensional strength of the straight parts of the pipe AD and BF operating in the direction of their length; and in this case we see that the tension on AD must be equal to the force acting along AC, and the tension on BF must be equal to the force acting along BN, so that in fact the forces brought into play by the right-angled bend produce a longitudinal tension on the pipe at either end of the bend equal to the force required to destroy the forward momentum of the fluid.

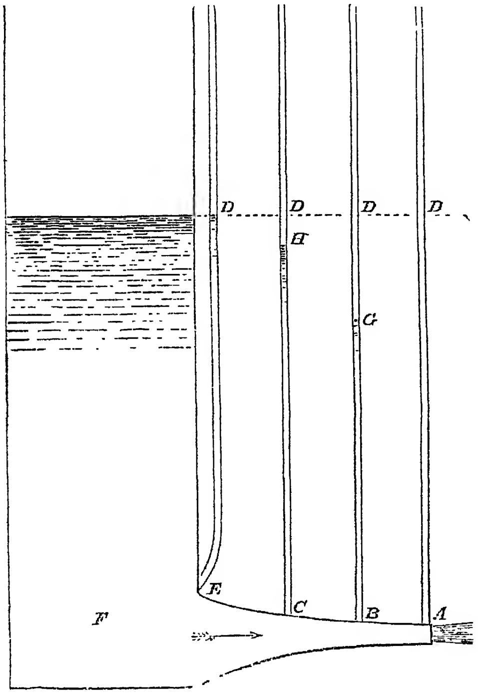

FIG. 34.

Proceeding to the case of the non-right-angled bend, as shown in Fig. 31: in this case, as we have seen, a portion only of the forward momentum of the fluid in the line AC has to be destroyed, also a certain amount of sideways momentum has to be created in a direction which we may consider parallel to the line QP; and the composition of the remaining forward momentum in the line AC with the created sideways momentum in the line QP, results in the progress of the fluid along the path FB; this partial destruction of forward momentum and establishment of some sideways momentum are essential to the onward progress of the fluid along FB. The bend DEF will be subject to the reaction of the forces necessary to produce these changes; and either the bend may be locally secured, or the stress upon it may be met, as in the case of the right-angled bend we have just been considering, by a tensional drag on the pipe at either end of the bend. There is, however, this difference between the cases, that the force required to establish sideways momentum parallel to QP cannot be directly met by the reaction of tension along the line BF of the second part of the pipe; but this force may be met by the obliquely acting tension of the pipe BF combined with the induced tension along the pipe AD. It is well known that in the case of a given force, such as that we are supposing parallel to PQ, resisted by two obliquely placed forces such as the tension along the lines DA and FB, the nearer the lines DA and FB are to one straight line, the greater must be the tension along those lines to balance a given force acting on the line PQ. Now the less the line FB diverges from the line AC, the less will be the sideways momentum parallel to QP that has to be imparted to the fluid; but at the same time and to precisely the same extent will the proportionate tension put upon the limbs DA and FB of the pipe be aggravated by the greater obliquity of their action. The sideways pull is greatest when the bend is a right angle; and then it amounts to a force that will take up or give out the entire momentum of the fluid, and it is supplied directly by the tension of the limb of the pipe at FB. If the bend is made less than a right angle, the less the bend is made, the less is the sideways pull, but the greater by the same degree is the disadvantage of the angle at which the tension on the pipe resists the pull; and it results from this that in the case of a bend other than a right angle, the tension on the pipe is the same as in the case of a right-angled bend. A geometrical proof of this is given in Fig. 33. It is evident that the radius of curvature of the bend does not enter into this consideration, and that the forces acting are not affected by the rate of curvature of the pipe, the simple measure of the forces being the increase or decrease in the momentum of the fluid in each direction. It results from this that if a fluid be flowing along a pipe with a bend in it, no matter what may be the angle of the bend, or the radius of its curvature, the reactions necessary to deflect the path of the fluid will be met by a tensional resistance along the pipe; and this tension is equal to the force that would be required to entirely destroy the momentum of the fluid.

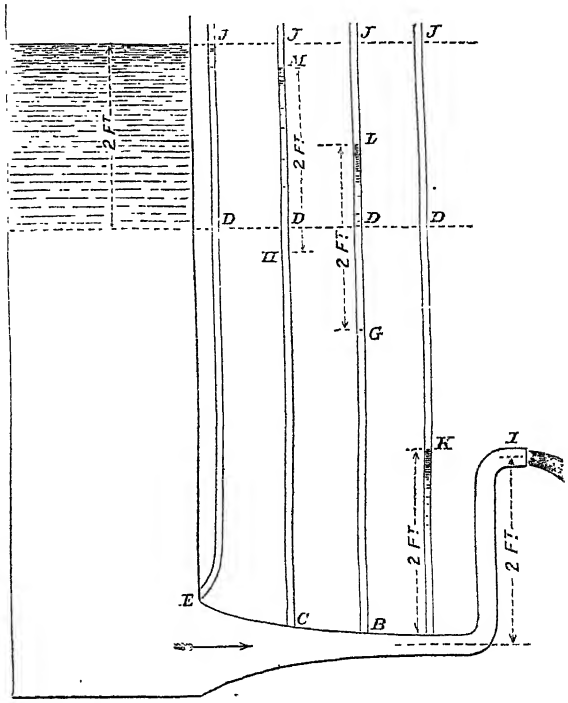

FIG. 35.

If we now assume any number of bends, of any angle or curvature, to be connected together (see Fig. 3), the equilibrium of each bend is satisfied by a longitudinal tension which is in every case the same; and this tension is therefore uniform throughout the pipe; for the tension at any intermediate point in a bend is clearly the same as at the ends of the bend, as we may suppose

the bend divided at that point into two bends, and there joined together by an infinitely short piece of straight pipe.

If, then, the tortuous pipe I have above referred to has its ends at A and B parallel to one another, as shown in Fig. 4, it is clear that the tensional forces at its ends balance one another, and the pipe, as a whole, does not tend to move endways.

NOTE B.

The law regulating these changes of pressure due to changes of velocity can be best understood by considering the case of a stream of perfect fluid flowing from a very gradually tapered pipe or nozzle placed horizontally and connected with the bottom of a cistern, as shown in Fig. 34. Let us suppose that at the points B and C the sectional areas of the pipe are severally twice and four times that at the point of exit A.

At the point of exit A the fluid is under no pressure whatever, since there is no reacting force to maintain any pressure; each particle of fluid in the issuing jet is rushing forward on its own account, neither giving nor receiving pressure from its neighbours. We know, however, what force it has taken to give the velocity which the fluid has at the point of issue A, and we measure this force by the pressure or head of fluid, lost. In the case we are considering, this head is represented by the height of the fluid in the cistern, or by the height AD.

Within the cistern, at the point E, on the same level as A, the point of issue—at this point E within the cistern, we have in effect the whole pressure due to the head of fluid equal to AD, but we have no velocity, at any rate the velocity is so small as to be inappreciable; and at the point of issue A we have no pressure at all, but we have what is termed the "velocity due to the head."

Let us suppose that at the points A, B, C, and E, gauge-glasses or stand pipes are attached so that the fluid in each may rise to a height corresponding with the pressure within the pipe or nozzle at the point of attachment.

The gauge-glass attached at A will show no pressure, thus indicating that the entire head AD has been expended in producing the velocity at the point A.

At the point B, as the sectional area is twice, the velocity is one-half that at A. Now the head required to produce velocity varies as the square of the velocity to be produced; in other words, to produce half the velocity requires one quarter of the head; thus of the whole head AD available, one quarter only, or GD, has been absorbed in developing the velocity at B, and the remainder of the pressure, which will be represented by the head BG, will be sensible at the point B, and will be exhibited in the gauge-glass attached at that point.

Again, as the pipe at C is four times the area that it is at A, it follows that, of the whole head AD, one-sixteenth part only, or HD, has been absorbed in developing the velocity at C, and the remainder of the pressure, which will be represented by the head CH, will be sensible at the point C, and will be exhibited in the gauge-glass attached at that point.

In the case I have chosen for illustration, the small end, A, of the nozzle, is open and discharging freely, and the pressure at that point is therefore *nil*. But the absolute differences of pressure at each point of the pipe or nozzle will be precisely the same (as long as the same quantity of fluid is flowing through it per second), however great be the absolute pressures throughout.

Thus, suppose that from the end of the nozzle at A a pipe of the same diameter, and of uniform diameter throughout its length, is curved upwards, so that the end of it, I, is two feet higher than A, as shown in Fig. 35, if the level of the cistern is also raised two feet, namely to the level marked J, instead of D, we shall have the same delivery of fluid as before; and the differences between the pressures at each point will be the same as before.

If we add 50 feet instead of 2 feet to the head in the cistern, and raise I to 50 feet, instead of 2 feet above the nozzle, the differences of head or pressure will still be the same, the head at A being 50 feet, that at B being BG + 50 feet, that at C, CH + 50 feet, and that at E (the cistern-level) ED + 50 feet.

To put the case into actual figures, suppose the sectional area at A to be 1 square inch, that at B 2 square inches, and that at C 4 square inches, and suppose that the fluid is passing through the nozzle at the rate of one-ninth of a cubic foot per second, we shall have a velocity at A of 16 feet per second, to generate which would require a difference of pressure between E and A, equivalent to 4 feet of vertical head. The velocity at B will be 8 feet per second, which would require a difference between E and B equivalent to 1 foot of head. That at C will be 4 feet per second, and will require a difference of pressure equivalent to 3 inches of head. If the pressure at A be zero, the pressures at B, C, and E will be 3 feet, 3 feet 9 inches, and 4 feet respectively. If the pressure at A be 1 foot, the pressures at B, C, and E will be 4 feet, 4 feet 9 inches, and 5 feet respectively; and if the pressure at A be 1,000 feet, the pressures at B, C, and E will be 1,003 feet, 1,003 feet 9 inches, and 1,004 feet respectively, always supposing the quantity of fluid passing per second to be the same. If the quantity be different, the absolute differences of pressure will be different, but will be relatively the same. If, for instance, the quantity flowing per second be doubled, the velocity at each point will be doubled, and the differences of pressure quadrupled; so that if the pressure at A were again 1,000 feet, those at B, C, and E would be 1,012, 1,015, and 1,016 feet respectively.

To sum up—the differences of hydrostatic pressure at different points vary as *the differences of the squares of the velocities* at those points.

NOTE C.

Here again the argument given in the text suggests certain other lines of argument which some persons may feel interested in following out

Suppose each and every one of the streams into which we have subdivided the ocean, to be inclosed in an imaginary rigid pipe made exactly to fit it, throughout, the skin of each pipe having no thickness whatever. The innermost skin of the innermost layer of pipes (I mean that layer which is in contact with the side of the body), the innermost skin, I say, of this layer is practically neither more nor less than the skin or surface of the body. The other parts of the skins of this layer, and all the skins of all the other pipes, simply separate fluid from fluid, which fluid, *ex hypothesi*, would be flowing exactly as it does flow if the skins of the pipes were not there; so that, in fact, if the skins were perforated, the fluid would nowhere tend to flow through the holes. Under these circumstances there clearly cannot be any force brought to bear in any direction by the flow of the fluid, on any of the skins of any of the pipes except the innermost skin of the innermost layer. Now, remembering that we are dealing with a perfect fluid which causes no surface-friction, we know that the fluid flowing through this system of pipes administers no total endways force to it. But it produces, as we have just seen, no force whatever upon any of the skins which separate fluid from fluid; consequently, if these are removed altogether, the force administered to the remainder of the system will be the same as is administered to the whole system, namely, no total endways force whatever. But what is the remainder of the system? Simply the surface of the body, which is formed, as I have already said, by the innermost skins of the innermost layer of pipes. Therefore no total endways force is administered to the surface of the body by the flow of the fluid.

Lastly, let us recur for an instant to the case of fluid flowing through the single flexible pipe. Here it was proved that the flow of the fluid through it, if it was anchored at the two ends, did not tend to displace any part of it, because the centrifugal forces produced by the flow of the fluid, and which must act exactly at right angles, or normally, as it is called, to the line of pipe at each point, are exactly counterbalanced by a uniform tension throughout the length of the pipe. If the flexible pipe has variations in its diameter, the differences of quasi-hydrostatic head appropriate to those variations are also normal to the surfaces of the pipe, being simply bursting-pressures. If, however, these normal forces were directly counterbalanced by equal and opposite and normal external forces or supports, it is obvious that this tension would be entirely relieved. Now, if we suppose the system of pipes which we have several times already imagined to surround the submerged body, to be flexible pipes (instead of rigid pipes, as we have before imagined them), the counterbalancing, or normal, external forces which exactly relieve the tension are supplied to each pipe by its neighbour, except in the case of the innermost skin of the innermost layer of pipes, since this innermost skin has no neighbour. In this instance the counterbalancing, normal, external forces are supplied by the rigidity of the surface of the body. Now we know that, since the tensional forces produced by the flow of fluid through a flexible pipe, whether of uniform or varying sectional area, have no sum total of endways force, the counterbalancing forces which exactly relieve this tension must also have no total endways force; and since the counterbalancing forces acting throughout the whole system have thus no sum total of endways force, it can be proved, as before in the case of the similar system of rigid

pipes, that if we remove the whole of the skins or sides of pipes, which separate fluid from fluid and which are all therefore necessarily in perfect equilibrium, the forces acting on the remainder, namely, on those skins which are in contact with the surface of the body, forces which therefore may be considered as acting simply upon the body, must also have no endways sum total.

THE MELBOURNE OBSERVATORY

THE Board of Visitors to this Observatory made its annual visitation on June 2, 1875. Mr. Ellery, the Government Astronomer, having obtained leave of absence, the Board found the staff of officers and all the instruments in charge of Mr. White, in whose management it unhesitatingly expresses its fullest confidence.

The buildings and instruments are in good condition, and several new and important instruments have been added to the establishment during the period under notice. These include a photo-heliograph from Dallmeyer, of London, who constructed it under the advice of Dr. Warren de la Rue; an equatorial refractor of eight inches aperture, made by Troughton and Sims, under the advice of Sir George Airy; a portable equatorial, of 4½ inches aperture, by Messrs. Cook and Son, of York; and a double-image micrometer by Mr. Browning.

The various publications of the Observatory are in a forward condition. The First Melbourne General Catalogue of 1,227 Stars, for the epoch 1870, was published early in October, in time to be distributed among the different parties charged with the observation of the transit of Venus, by whom its great utility was acknowledged.

The observatory staff had much work to do in connection with the observation of the transit of Venus, not only having to make the necessary preparations for observing the transit at their own stations, but also to assist with the requisite observations for finding the positions of the stations occupied by the different nations in that part of the world. The arrangements made by the Observatory were all that could be desired.

With regard to the ordinary work of the Observatory, Mr. White reports as follows:—

"The work with the transit circle has consisted of the usual standard stars for finding the time, and the position of the instrument; close circumpolar stars, low stars for refraction, stars with which bodies had been compared off the meridian, stars culminating with the moon, the moon itself, and stars whose places were required by outside observers for any special purpose.

"The numbers of the recorded observations are as follows:— R.A. observations, 2,064; P.D. observations, 1,150; Observations of error of collimation, 111; observations of error of level and nadir, 180; observations of error of runs of microscopes, 47; observations of error of flexure, 35.

"The state of the reductions is as follows:—

"R.A. observations up to date.

"P.D. observations.—The stars observed in 1873 are reduced with the exception of 212, which require the corrections to reduce them from their apparent to their mean places. Of the stars observed in 1874, 865 are wholly unreduced, 267 have the reductions applied as far as the refraction, 45 are reduced to their apparent places, and the remaining 45 are fully reduced. Of the stars observed during the present year, 184 are fully reduced, 46 are reduced to their apparent places, and 122 are wholly unreduced. . . .

"The magnetical and meteorological instruments are under the special charge of Mr. Moerlin. Absolute values of the magnetic elements have been made as usual once a month, and they are all reduced up to date. The photographic curves from the magnetographs, barograph, and thermographs, are developed on every alternate day, but as yet no general tabulation of them has been made; only occasional measures are taken from them for special purposes. The ordinary meteorological observations made at Melbourne and the different stations in the colony are reduced to date; the Monthly Records in Meteorology and Magnetism are prepared to the end of April, and are in the printer's hands; owing to press of work, however, in the Government Printing Office, the Records to the end of December 1874 only have as yet been received. The Yearly Report for 1873 is in hand, and that for 1874 will be prepared as soon as possible.

"The great telescope, under the especial charge of Mr. Turner, has been diligently worked during the last twelve months, except during the time that we were engaged in the special observations connected with the transit of Venus, when Mr. Turner took turns with Mr. Moerlin in observing the occultation of stars by the moon. In accordance with the strongly expressed opinion of the Board in the last Report, the work done has consisted principally of drawing the nebulæ, and mapping the neighbouring stars; ten of the nebulæ and clusters figured by Sir John Herschel have been carefully drawn, and the positions of the stars have been laid down from micrometric measurements. One nebula has been observed which is not to be found in any catalogue in our possession. Coggia's comet was examined on eighteen nights, and fifteen drawings of it obtained. A drawing of the nebula surrounding η Argus, with the stars accurately plotted in, made this year, shows no appreciable change when compared with the one made last year.

"Besides the occultation of stars by the moon, referred to before, and of which ninety-six were looked out for, and only fifteen observed, owing to the unfavourable weather of the time, a fine series of observations for positions of Coggia's comet was obtained by Mr. Ellery and myself; an observation of Encke's comet was also obtained during the present month; all of which, including the occultations, have been sent for publication to the *Astronomische Nachrichten*."

The Report concludes with a brief account of the results obtained at the four Government stations during observations of the transit of Venus.

PROF. PARKER ON THE WOODPECKERS AND WRYNECKS

ANOTHER admirable paper by Prof. Parker, exhibiting the same industry, successful elucidation of detail, and mastery of morphological principle that have characterised all his publications, appears in the recently-issued volume of "Transactions of the Linnean Society." It is chiefly devoted to an exposition of the palatal structures of the Picidæ and Yungidæ, made intelligible by the study of nestlings and young birds. The conclusions of Prof. Huxley in his paper in the "Proceedings of the Zoological Society" for 1867 are substantiated and placed on a broader basis; and thereby another chapter has been permanently added to the history of the connection between Reptiles and Birds. The assistance which scientific naturalists all over the world may render to necessarily sedentary students like Mr. Parker, by the preservation and transmission of young specimens of various ages, is nowhere more clearly manifested than in the paper now spoken of. Mr. Parker's study of Woodpeckers, both of hard and soft parts, dates from the year 1843; and the unpublished results of that labour, in the form of minutely-careful drawings, are still of considerable value for reference. Again and again the study was resumed, with somewhat unsatisfactory results, until the opportunity of dissecting young birds and of comparing them with southern species threw sufficient illumination on the difficult problem of their palatal structure.

An introduction to the paper serves to point out the proper relations between the zoologist and the embryologist. "Each kind of labourer," says Prof. Parker, "has the greatest need of the results brought out by the other: the patient dissector waits for the treasures supplied to him by the more mercurial taxonomist; whilst he, in turn, profits by the work of one to whom a single type may serve for the labour of a year or more. Yet both are learning to look beneath the surface of things, a growing knowledge of the types showing both that close kinship is often marked by great difference in outward form, and that it is easy to be beguiled by the external likeness of forms—*isomorphic*, indeed, but far apart zoologically."

A defence is made against those who would accuse the author, as well as Prof. Huxley, "of taking a narrow view of the bird-types, touching with the point of a needle some little tract, but unacquainted with and not able to appreciate the Bird as a whole." Such an accusation charges the broadest-minded men with possessing a cast of mind which would utterly disqualify them for the distinguished positions they hold. In the present case the exclusive description of the palatal structures is easily defended: for "that territory contains parts that have undergone the greatest amount of metamorphosis of any in the whole body of a high and noble vertebrate; and moreover, being in the bird the skeletal framework of the whole upper face, these parts are, as it were, an index of the amount of specialisation undergone by any particular type—the ruling determining structures that lead to all, and really demand all, the changes that take place in the rest of the organism."

Breadth of view is indeed essential, if anywhere, in such an investigation as the present. A restricted insight and experience would fail to detect and to demonstrate the substantial unity of structure existing in the palate of Lizards and of Woodpeckers, still more to establish the more minute relationships between the Rhynchosaurian Hatteria and various members of the Woodpecker group. This is what has been done. The well-defined group of the Woodpeckers, including the sub-family of Wrynecks, is so connected by its embryonic and adult palatal structures with the Lizards, that the name "Saurognathæ" is to be substituted for the morphologically-unexpressive term "Celeomorphæ," applied to them by Prof. Huxley. Their palatal region is arrested at a most simple and Lacertian stage, whilst in other respects they are metamorphosed and specialised beyond any other kind of birds.

The characteristics of the Saurognathous type of palate may be summarised as follows:—Retention and ossification of trabecular cornua; great number and bilateral independence of the vomerine series of bones, some of which are azygous (vomers, septo-maxillaries, median septo-maxillary); absence of a distinct mesopterygoid, represented, however, by a long process; a dagger-shaped basipalatine between the right and left bones; absence of a distinct transpalatine; abortive development of maxillo-palatine plates, and presence of a distinct palato-maxillary on the left side only.

One of the most instructive specimens figured is *Picumnus minutus*, a woodpecker from Bahia, Brazil, of about the size of the Golden-crested Wren. In it the vomers retain in the adult the condition manifested in the young of the Green Woodpecker, and much resembling the vomers of Hatteria. In other respects it presents resemblances to various Passerines of its own zoological area; and from it the author's imagination is led down to extinct types in which the characters of the Hemipod, the low Passerine, and the Woodpecker were existent in one generalised form—a form and a type only a step or two above the Ostrich tribe.

Numerous hints are given in this paper which lead us to look with great interest for Prof. Parker's forthcoming paper on the Ægithognathæ (Passerines) in the Zoological Transactions; and we may fitly close this notice with a pregnant passage referring to the Ægithognathous palate, showing to what problems of surpassing import these researches are supplying an answer. "I have long been familiar with its more marked peculiarities; but its morphological importance dawned upon me when I saw that the parts of that complex face, so conjugated and so metamorphosed, were really built up of elements which had their true counterparts or "symmorphs" in the Snake. But the Snake does but repeat these parts from the Amphibia; and the Amphibia borrow them from the Cartilaginous Fishes, amongst the lowest of which, namely the Lamprey, may be found the fullest development, both morphologically and functionally, of cartilages that form the substratum of the most peculiar part of a sparrow's face."

NOTES

AT the meeting of the Zoological Society, on Tuesday next, Prof. Huxley will read an important paper on the Anatomy of *Ceratodus* and *Chimæra*, and on the Classification of Fishes.

AT the recent anniversary meeting of the French Geographical Society M. Maunoir, the General Secretary, gave a highly satisfactory report. The receipts of the Society exceed 70,000 francs; ten years ago they were only 28,000. The number of members admitted from the beginning of the year is about 350, and about 1,400 are now registered. The receipts from money taken at the doors of the Geographical Congress and from donations, amounted to 175,000 francs, and the expenses to 155,000; a sum of 20,000 francs remaining in the hands of the Society will be devoted to the publication of the congressional papers. The place of meeting of the next congress has not yet been decided upon; it will probably be St. Petersburg.

THE *Daily Telegraph* publishes further details concerning Lieut. Cameron's expedition obtained from the Madeira correspondent of the paper. Cameron, it seems, intended to remain at Loando until an opportunity arrived for sending his men home round by the Cape to the East Coast. It is understood that the traveller has accumulated some very valuable geographical materials, besides a large amount of general scientific information. It appears that he followed a large river flowing out of Lake Tanganyika in a south-westerly direction, tracing its whole course till he came upon a new lake, which he named "Livingstone." From this body of water a second large river runs westward, which Cameron, having traced it for a considerable part of its length, believes to be the Congo. It would seem that he was unable to continue along the river on account of meeting with a tribe of hostile natives. He had to choose between fighting his way through these unfriendly natives, with the risk of losing all his journals and papers, or of taking a different direction. The latter alternative seemed preferable, and though it prevented the absolute verification of his important discovery he has personally no doubt that the stream flowing out of the Livingstone Lake and the Congo are one and the same.

THE *Birmingham Gazette* understands that Sir Josiah Mason is about to make another very substantial gift to the new scientific college which he is now building at Birmingham. When the foundation-stone was laid in February last it was understood that the mere building of the college would cost 100,000*l*., and Sir Josiah also transferred to trustees, as an endowment for the college, the piles of buildings in which his monster pen manufacture had so long been conducted. Now Sir Josiah is also about to hand over to the trustees the business itself, or rather the whole amount which he is about to receive for the concern, and which is expected to be about 100,000*l*. The whole of this sum, it is said, Sir Josiah intends to give to the college. The money will probably be invested in the names of the local gentlemen who have already been appointed trustees, and will form a permanent endowment for the institution.

A PRIVATE gentleman, being about to make a voyage to the West Indies in pursuit of objects of interest in natural science, has arranged to avail himself of the companionship and scientific services of the Rev. H. H. Higgins, of Liverpool. He will probably be away about four months cruising about the islands, and he will take with him two gentlemen—one a draftsman, and the other a collector, from the William Brown Street Museum, Liverpool. The expedition is made expressly for observations and collections in zoology and botany, and Mr. Higgins will have an opportunity of carrying on dredging operations. Very advantageous terms have, we believe, been arranged as to the division of the treasures which will be the result of the voyage. Mr. Higgins will be glad to receive suggestions with regard to the work he is about to undertake.

THE scientific public will be glad to learn that a movement has been set on foot to enlarge the existing Wigan Mining and Mechanical School, inaugurated eighteen years ago by Dr. Lyon Playfair, and now numbering nearly 200 evening students. At a public meeting held at Wigan on the 24th inst., attended by nearly all the colliery proprietors of the district, resolutions were passed, resolving to establish a permanent building with museum, laboratory, and all the appliances for giving a thorough technical education in Mining, Mechanics, Geology, Machine Construction, Steam, and Chemistry. Large subscriptions have already been promised, including 1,000*l*. from Lord Crawford and Balcarres, 500*l*. from Mr. Hewlett, the Managing Director of the Wigan Coal and Iron Company, who promise 125*l*. a year.

ON Monday the Prince of Wales opened the new Zoological Garden at Calcutta, recently formed under the auspices of the Lieutenant-Governor of Bengal.

THE Municipal Council of Paris has voted a handsome sum of money in support of the State Academies of Paris. The vote was carried by twenty-three against nineteen. The minority was composed of clericals who are opposed to the instruction given by Government, and ultra-republicans, who are opposed to the grant of any money for superior instruction.

CAPT. MOUCHEZ leaves Paris shortly to command the war vessel which is to complete the Hydrographical Survey of the Algerian coast. The expedition is expected to be away for a full year.

MR. HENRY WILLETT, the hon. secretary of the Sub-Wealden Exploration, has issued his 14th quarterly report. He states that the contractors are laudably endeavouring, at their own cost, to enlarge the bore-hole, so as to enable them to reach 2,000 feet and to produce cores undeniably satisfactory to the promoters. Mr. T. Warner, of Brighton, is willing to contribute 400*l.* in all for the next 500 feet after 2,000 feet. The ultimate decision as to the continuance of the work will rest with the central committee in London, who will, of course, be guided mainly by the question of finance.

INTELLIGENCE received at Madrid on the 28th from the Philippines announces that a terrible hurricane swept over the provinces of Albay and Camarines, in the southern part of the Island of Manilla, on the 30th of November. Two hundred and fifty persons are stated to have been killed, and 3,800 inhabited houses, the crops, and a considerable number of animals were destroyed. General consternation prevailed in Manilla.

THE French Society of Ethnography has granted its great medal to the memory of Doudard de Lagrée, the organiser of a scientific exploration on the banks of the Mekong in Indo-China.

THE official paper of the Governor-General of Algeria announces that the Algerine Meteorological Board has completed its organisation and will be very shortly placed in communication with the international service presided over by M. Leverrier. Weather telegrams from various places will be sent daily.

THE Academy of Sciences held its anniversary meeting on Monday. M. Bertrand delivered an *éloge* on General Poncelet, the great geometer and mathematician, who died twelve years ago, leaving a number of most valuable books, of which a general edition has been published recently. Amongst the prizes distributed was one to M. Denayrouze for his apparatus for working in mines and for submarine explorations.

THE cultivation of coffee in India is steadily progressing, and although the introduction of the plant into the eastern portions of the country is of ancient date, it is only within the last twenty years that much attention has been given to its production. The principal plantations are situated in Mysore and the Neilgherry Hills, at an elevation of 3,000 to 4,000 feet above the level of the sea. The climate of these districts, besides being well adapted to the cultivation of the coffee-plant, is not so injurious to the health of Europeans as many other parts of the country, and it is probable that the industry will be largely developed. In 1842 the value of coffee exported from British India was 74,957*l.* Ten years later it had advanced to 84,306*l.*; in 1862 to 462,380*l.*, till in 1872 it had increased to 1,380,410*l.*

AT the same time the cultivation of tea is advancing even more rapidly, though its introduction is much more recent. The Assam tree is celebrated for its fine quality. The existence of this tea-producing country was only recognised in 1834, when Lord Bentinck introduced some Chinese growers, and the trade became firmly established. In 1842 the value of tea exported was 17,244*l.*; in 1852, 59,220*l.*; in 1862, 192,242*l.*; and in 1872, 1,482,186*l.*

THE *Journal of the Asiatic Society of Bengal*, vol. xliv. part 2, contains a paper by Capt. J. Waterhouse, Assistant Surveyor-General of India, on "Photography in connection with the Observation of the Transit of Venus at Roorkee."

THE Report of the Dundee Free Library Committee is drawn up with great care and considerable elaboration, and contains some very useful statistics as to the numbers of books issued in various departments, and the classes to which the readers belong. As might be expected the books taken out in light and miscellaneous literature are in an overwhelming majority, though those belonging to the various sciences have a creditable amount of patronage which we hope to see gradually increase. We think a more satisfactory classification of the sciences might be adopted than that contained in the Report. The Natural History Museum connected with the Library is evidently being enriched with valuable specimens, and we are glad to see the Naturalists' Society is prospering. There is also a University Club housed in the building, which numbers 140 members, and "seeks in the first instance to foster Culture and the Higher Education, with the ulterior object of cultivating public opinion in the direction of University extension in Dundee."

THE ravages of the Phylloxera among the vines have caused many attempts to be made to discover a new kind of beverage which might take the place of the juice of the grape. The Marquis de Villeneuve reports that in China a *pseudo* wine called *Tsien-ia* is much used, which is concocted from a preparation of four plants, common in that country, and mixed together in certain proportions. The plants are dried and powdered, and made into a paste, which is sold in the form of balls or squares at the rate of about 3*d.* a pound. One square or ball will make several pints of a fermented liquor, pleasant to the taste and much resembling wine, which is much sought after by Europeans and others living in China. A factitious brandy is also prepared in the same way, and the manufacture is so simple that with a capital of 5*l.* or 10*l.* to purchase the apparatus, a man may make twenty-five gallons of "brandy" a day. The Marquis de Villeneuve affirms that the "wine" thus produced is of good quality and possesses no injurious ingredients.

PART 2 vol. i. of the "Transactions of the Watford Natural History Society" is to hand, containing the four papers read on May 13 last, besides a number of miscellaneous notes and observations.

MR. G. H. KINAHAN has published a paper read by him at the Royal Historical and Archæological Association of Ireland, on some prehistoric antiquities in the neighbourhood of Drumdarragh, Co. Antrim.

ABOUT a year ago we noticed the publication by the New England Society of Orange of the "Babbit Portfolio," containing some beautiful photographs of remarkable trees in the neighbourhood of Orange. The same Society has recently issued the "Haskell Portfolio" (after a well-known citizen of Orange), containing photographs of other fine trees, even finer in execution, we think, than the previous ones. The trees represented are the Condit Chestnut (*Castanea vesca*), the Sugar Maple (*Pyrus malus*), the Park Tulips (*Liriodendron tulipifera*), and the Essex Maple (*Acer rubrum*).

WE have received the Report of the first Annual Conference and Exhibition of the Cryptogamic Society of Scotland, held at Perth on Sept. 29, 30, and Oct. 1; both conference and exhibition seem to have been a complete success.

STATISTICIANS calculate that there are now in work some 200,000 steam-engines, with a total power of 12,000,000 horses, corresponding to the muscular strength of 100,000,000 men.

ALMOST all the Carthaginian antiquities which had been sunk with the *Magenta* have been recovered by Denayrouze's diving apparatus and submarine lamp.

THE additions to the Zoological Society's Gardens during the past week include a Black Lemur (*Lemur macaco*) from Madagascar, presented by Captain Burke; a White-fronted Lemur (*Lemur albifrons*) from Madagascar, a Night Parrot (*Stringops*

habroptilus) from New Zealand, a Grey Ichneumon (*Herpestes griseus*) from India, deposited; a Yellow Baboon (*Cynocephalus babouin*) from W. Africa, purchased; a Gavial (*Gavialis gangeticus*) from India, presented by Capt. Barnet: a Common Fox (*Canis vulpes*) European, presented by Mr. W. Saville.

SCIENTIFIC SERIALS

THE *Journal of the Royal Agricultural Society of England*, Second Series, No. xxii.—The contents of this number are most attractive. To science is assigned the leading place in the arrangement. The first paper is devoted to the Colorado potato-beetle, and is from the pen of Mr. Bates, F.L.S., who does not profess to impart any original information, and who is unable to come to any definite conclusion as to the probability of its appearing in these countries. The paper is calculated to confuse rather than to enlighten us on this point. For while in one place the author goes to show that the possibility of living specimens arriving here cannot be doubted, he observes elsewhere that the analogies of the case supply ground for confidently believing that there is exceedingly little probability of their propagating and spreading in this country. We are also told that "the creature has developed extraordinary flexibility of constitution and habits since it left its quiet home in the Rocky Mountains, and that we cannot be quite sure what it will eventually do." In another passage Mr. Bates says:—"The potato-beetle is no insidious enemy, like the majority of insect plagues, but meets the farmer in open fair fight." What does he mean by a fair fight between an insect which destroys whole fields and districts, and the helpless farmer?—Mr. Carruthers, F.R.S., consulting botanist to the Society, contributes a paper and a note on the potato disease. In the "paper" he reports on what he calls the results of the competition for the prizes offered through the Society in 1874 for potatoes which would resist the disease for three years in succession. The "note" gives a brief account of Mr. Worthington Smith's discovery of the resting spore of the potato fungus. The paper must have been written before the discovery. The truth is the discovery throws a curious shadow not only on the paper but on the course pursued by the society in connection with the whole subject. We were not quite prepared to find that the consulting botanist of this great society would be permitted to announce, as he has done in this paper, that in investigating this disease we must summarily dismiss the soil from our consideration. "Neither soil, nor methods of cultivation," we are told, "exercise any influence on the prevalence of the disease." For the present we can only say these statements are as unsound as they are astounding. The *Journal* contains a long paper on laying down land to permanent pasture, which is a joint production. The bulk of the information is given second-hand; that is to say, on information furnished by several agriculturists, a long paper is based by the joint authors. The number contains too much matter of this character. The views of an American naturalist on the Colorado potato-beetle are given in a paper by Mr. Bates. Mr. Carruthers seeks to enlighten us on the potato disease by information collected from various sources; and a number of scattered facts on one of the most important of agricultural subjects—the profitableness of pasture as compared with arable land—are grouped and reviewed in a great variety of ways, some of which are calculated rather to mislead than to enlighten the reader. There are several passages in the paper which will produce the impression that the gentleman to whom has been assigned the chief part of the joint authorship is not intimately acquainted with agriculture as at present practised. We take one passage as an illustration: "There are many persons so enamoured of a special rotation—say the four-course—that to extend the period of artificial grass to two years appears to them a violation of all the true principles of scientific farming. The four-course is their ideal of modern farming. A course of cropping which has been proved highly beneficial on some of our most famous corn-growing districts is supposed to be the only legitimate system to be pursued by intelligent farmers elsewhere." Who are the persons referred to? It may be well to remind the gentleman who wrote this paper that English farmers are calling out for more freedom of action in the cropping of their land, and that for several years past vast numbers of them have been doing that which he would appear to have discovered in 1875. We cannot at present make room for further criticism on this paper; and we are glad to be able to state that the number contains several meritorious articles.

THE *Journal of the Chemical Society* for November contains Dr. Hofmann's Faraday lecture, entitled "The Life-work of Liebig in Experimental and Philosophic Chemistry; with allusions to his influence on the development of the collateral sciences and of the useful arts." The lecture is illustrated by a portrait of Liebig, and an autotype copy of a letter from Liebig to Faraday.—Prof. J. W. Mallet contributes a paper on achrematite, a new molybdo-arsenate of lead, and Mr. W. J. Lewis a note on the crystallography of Leucaurin, being an appendix to a former paper by Messrs. Dale and Schorlemmer.—The journal contains its usual number of valuable abstracts from foreign periodicals.

Morphologisches Jahrbuch.—In the second part of this journal Dr. B. Solger discusses the homology of the cervical vertebræ and nerves in the Sloths, and concludes that the vertebræ up to the 22nd are homologous in Cholœpus and Bradypus, but that the homologies of the first twelve nerves cannot be determined; the nerves from the 13th to the 23rd are homologous.—Another paper by Dr. Solger describes two cartilaginous pieces in the visceral skeleton of *Chimæra monstrosa*, which appear to have been hitherto unnoticed.—Dr. Hermann Fol gives an account of the so-called endostyle of Huxley in various genera of Tunicata, and appears to establish it satisfactorily as a slime-gland. Excellent figures of its ciliated and glandular epithelia are given.—Prof. Gegenbaur devotes twenty-two pages to a consideration of the omohyoid muscle, which he believes to be a remnant of a continuous muscle whose origin extended from the sternum along the clavicle to the scapula. He also gives an account, with microscopic sections, of the nipples in *Didelphys* and in *Mus decumanus*.—Dr. Carl Hasse's paper on *Amphioxus lanceolatus* is devoted to a demonstration of the structure of the eyespots, in which he finds cells which may be designated optic cells, as distinguished from the pigment-cells.—Prof. Gegenbaur occupies forty-seven pages with a detailed and very hostile criticism of Götte's recently-published work on the Development of the Toad as a basis for the Comparative Anatomy of the Vertebrata. He censures it in very many respects as empirical and unscientific.

Jahrbuch der kais.-kön. geologischen Reichsanstalt, band xxv. No. 2.—In this number of the Jahrbuch, Dr. E. Tietze, who has been some time in Persia, describes the springs and spring-formations that occur in Demavend mountain and its neighbourhood; most of the springs are thermal, and deposit large quantities of calcareous tufa.—The next paper gives details of the work done in the chemical laboratory of the Geological Survey, and includes upwards of 200 analyses.—Dr. C. Doelter describes the geological structure, the rocks, and minerals of the Monzoni Alps in the Tyrol. This paper is illustrated with a geological sketch-map and two plates of minerals.—Among the "Mineralogical communications" the most generally interesting paper is one by Professor Fuchs on the earthquakes and volcanic eruptions of 1874. He enumerates 123 earthquakes, distributed as follows:—Winter 37; (Jan. 12, Feb. 15, Dec. 10); Spring 32; (March 12, April 11, May 9); Summer 25; (June 7, July 5, Aug. 13); Autumn 29; (Sep. 9, Oct. 9, Nov. 11).—The remaining papers are these:—"On Sahlite as a rock-constituent," by E. Kallowsky; "On the chemical composition of meionite," by E. F. Neminar; "On Lievrite," by L. Sipócz; "On the minerals occurring in the metalliferous veins of the Pribram region," by F. Babanek; "On rocks from the island of Samothracia," by J. Niedzwiedzki.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Dec. 9.—"On some Electro-magnetic Rotations of Bar-magnets and Conducting-wires on their Axes," by G. Gore, F.R.S.

In all the published forms of Ampère's experiment of the electro-magnetic rotation of a vertical bar-magnet or conducting-wire upon its axis by Ampère, Faraday, Sturgeon and others, the magnet or wire has either been immersed a large portion of its depth in mercury, or its middle part has been connected by a wire with a surrounding annular channel filled with mercury, and the electric current passed into or out of the magnet or wire by means of that liquid, and the mercury has formed an essential part of the arrangement.

In all published cases of rotation of bar-magnets on their axes by the influence of electric currents, the two ends of the magnet

has had *dissimilar* poles. By meditating upon certain facts connected with this subject, I concluded that, by passing a current from one end to the other of a magnetized rod or wire having *similar* poles at its two ends, the magnet would probably rotate, and experiment has demonstrated that conclusion.

Upon a thin wooden tube 15 centims. long and 7 millims. bore, I wound a cotton-covered copper wire 1·7 millim. diameter, from one end of the tube to the middle, then reversed the direction of winding, and continued to the other end and back to the middle, again reversed, and coiled to the first end of the tube; by which arrangement the passage of a current through the coils produced two similar poles at the ends of the tube, and two others of the opposite kind at the middle.

The tube being now fixed in a vertical position, a straight iron wire 15 centims. long, and 1·8 millim. diameter, pointed at its lower end, and surmounted by a brass mercury cup 5 millims. diameter, containing a drop of mercury, was supported entirely within the tube and free to rotate, by a similar cup (surmounting a fixed vertical brass rod), at the lower end of the tube; the upper end of the axial wire being kept in position by a vertical brass rod fixed above the coil and terminated at its lower end by a sharp point of platinum in the mercury cup.

A current from 6 one-pint Grove's elements, arranged as 3, being now passed through the coil, brass rods, and axial wire, the latter rotated rapidly.

A copper wire substituted for the iron one would not rotate, probably because copper is so little capable of acquiring longitudinal magnetism.

To ascertain if the coil-current simply performed the function of longitudinally magnetizing the axial wire, I took an iron wire 23 centimes. long and 2·7 millims. diameter, sharp-pointed at its lower end; soldered to its upper end a double wire of cotton-covered copper, each wire being 1·7 millim. diameter, coiled the double wire upon the axial rod in two layers, and so as to enable two *similar* poles to be formed at the extremities of the axis, and terminated the copper wires by a little brass mercury-cup just above the top end of the vertical iron axis. By supporting this apparatus as the axial wire in the previous experiment, and passing the current, rotation occurred.

Reversing the direction of the current did not reverse the direction of rotation.

These experiments, produce a striking effect in a lecture, because the rotation appears to be produced without reaction of the moving part of the apparatus upon any external or fixed body.

In each of these cases of rotation, an upward vertical current entering a lower south pole or leaving an upper one, caused the upper end of the rod to rotate in the direction of the hands of a watch, and a downward current entering or leaving a north pole also produced that direction of motion, and reversing the poles in either case reversed the effect.

In each of these instances of rotation, without the aid of a current near the middle of the magnet, the coil being so constructed that the current in it could not be reversed without reversing that in the fixed conductors near it, reversing the direction of the current did not reverse that of the rotation, because the two acting influences were reversed together, and therefore each apparatus had its own direction of rotation, either right handed (↻) or left handed,* according to the direction in which its coils were wound. It follows from this that a current, the direction of which is alternately reversed, will drive the apparatus quite as well as one in one uniform direction.

I now endeavour to increase the effect. For this purpose I substituted for the upper brass rod a fixed coil consisting of one layer of copper wire upon an iron wire axis, but having dissimilar poles at its ends and no poles at its middle part, and placed between it and the lower brass rod a right-handed one free to rotate. The opposed poles of the fixed and movable coils were of opposite kinds, *i.e.* north and south. On passing a current from a Noe's thermo-pile of 96 elements,† connected as 24, rapid rotation in a right-handed direction occurred. I now substituted for the lower brass rod another fixed coil, similar to the upper one, but of an opposite direction of polarity, and passed the current again; still more rapid rotation in the same direction took place, and the effect was very striking. In this latter instance, two south poles free to move were opposed to two fixed north poles, and in each instance the current was passed upwards.

I now substituted for the movable coil a vertical wire of iron 13 centims. long and 1·7 millim. diameter, surmounted by a small brass mercury cup; passed the current from the thermo-pile, and obtained rotation, but less rapid than before; but by inclosing this wire in the axis of a fixed coil which produced appropriate and similar poles at its two ends, as in paragraph 3, and repeating the experiment, very great velocity of rotation was obtained. Rotation of a somewhat thicker wire of nickel was also obtained, both with and without the aid of the current in the middle fixed coil. I also tried, without the aid of the middle fixed coil, and with it, a copper wire of similar dimensions to the iron one, and obtained rotation freely. Each of these rotations agreed in direction with those of the movable coil.

The apparatus represented in the annexed sketch was employed for nearly all the various modifications of the experiment, by substituting for one or more of the coils metallic wires, &c., as desired. The upper part of the brass pillar A was capable of sliding in the lower part B, and could be fixed by a screw C, which encircled the split end of the tube B. The fine adjustment was effected by means of the screw D, the lower end of which rested upon the top of a tall brass rod inside the brass pillar. The upper and lower fixed coils or rods E and F were insulated from the brass clips G and H, and the battery was attached to the binding-screws I and J. K is a binding-screw for connecting with the upper coil or rod.

I also obtained rotation of the iron wire whilst the wire was in a horizontal position, its ends resting in hollows in the ends of the iron axes of the two fixed coils, and the ends of those axes and of the movable wire lying upon the surface of pools of mercury in small watch-glasses. The movable iron wire was inclosed in the axis of a thin iron tube within a fixed coil, having appropriate and similar poles at its ends. The current from the thermo-pile produced very rapid rotation. This result proves that the rotations are not due to terrestrial magnetic influence.

As the directions of magnetic polarity, electric current, and rotation agree with those in the different forms of Ampère's experiment, and as in most, if not all, of the previously known cases of rotation of a bar-magnet or conducting-wire on its axis an electric current passes through the end of the bar or wire, it is evident that those rotations were due, not only to the portions of current in the mercury, and fixed conductors connected with it, near the middle of the magnet or wire, but also to the influence of the currents in the fixed conductors near the ends of the magnet or wire.

[*Note added September*, 1875.—It having been suggested by Professors Maxwell and Stokes that the rotation in the foregoing experiments was due to the influence either of the magnetism of the fixed magnets or of the current in the fixed conductors, near the ends of the movable wire or magnet, upon the portions of current in the cups of mercury, I diminished the internal diameter, both of the upper and lower cups, from 4 millims. to 1·75 millim., and arranged the following apparatus and experiment.

The fixed upper wire was of brass 2·5 millims. diameter and 60 millims. long; it had no coil upon it, and was used as a conductor only; its lower end terminated in a fine point of a steel needle protecting 6 millims. The lower fixed wire, also used as a conductor only, was of platinum to resist the action of the mercury; it was 2·3 millims. diameter and 75 millims. long, with a cavity in its upper end 3·5 millims. deep and 1.75 millim. diameter, and containing a thin plate of ruby in its lower part, with a minute hole in the centre for the needle point to rotate in. The movable wire was 2·5 millims. diameter and 125 millims. long, its upper half being composed of soft iron and its lower half of brass; its lower end terminated in a needle-point like that of the upper fixed wire, and its upper end had a cavity and perforated ruby plate like that in the lower fixed wire. A voltaic coil 60 millims. long and 7 millims. internal diameter, composed of four layers of cotton covered with stout copper wire, was used to magnetize the iron half of the movable wire, and fixed by means of a separate support in a proper vertical position beforehand, so as to inclose in its axis the iron wire portion only. The little cups were also each half filled with a minute globule of mercury before putting the movable wire into its place.

After adjusting the wire so as to make rotation easy, a current from 6 Grove's elements of one-pint capacity, arranged as a series of 6, also as a double series of 3, was passed through the coil and vertical wires; and the direction of the portion of the current in the coil alone, also in the vertical wires alone, was varied; but notwithstanding that plenty of current passed, no signs of rotation could be detected. These results, therefore,

* By a "right-handed" coil, I mean one the upper end of which rotates in the same direction as the hands of a watch.

† I have found this apparatus very convenient for such experiments.

strongly support the opinion that the rotation in the experiments was due to the action of the portions of the current in the cups of mercury.]

Linnean Society, Dec. 16.—Dr. G. J. Allman, F.R.S., president, in the chair.—The following papers were read:—On the structure and development of the bird's skull (part II.), by W. K. Parker, F.R.S. This and the former paper are parts of a large piece of work done by the writer in this particular field. A similar paper on the skull of Passerine birds appears in the present number of the Transactions of the Zoological Society; to be followed by another on the same subject. The writer's wish to work out a large series of well illustrated papers on the bird's face arose from the new interest given to this special research by Prof. Huxley's masterly memoir "On the Classification of Birds" (Proc. Zool. Soc., April 11, 1867), and his paper "On the Classification and Distribution of the Alectoromorphæ" (Ibid, May 14, 1868). The writer has worked out this subject in two ways, viz., by exhaustive work at one type of skull, making research in every part, and also by taking a part of the skull, the fore-face, and comparing this part in many types. The present paper is a piece of the latter kind of work, but begins with some new embryological details to serve as a supplement to his memoir on the fowl's skull (Phil. Trans., 1869); and this especially with regard to the development of that most interesting but puzzling bone, the "columella auris." This is shown to be developed in the house-martin (*Chelidon urbica*) in the same manner as in the reptilia. As Prof. Huxley sought, in his memoir, to give a morphological classification of birds based on the cheeks and palate, it has been the wish of the writer to carry on his friend's work, and to test it as well as extend and give it form and body. In the present paper the meaning of the peculiar structure of the face in crows, sparrows, warblers, &c. (Prof. Huxley's Coracomorphæ), is sought to be made plain by reference to the development and metamorphosis of the parts. In these the single vomer of the adult is shown to be constructed out of four bones and two cartilages; and all this composite structure is seen in them to be fused with the nasal capsule. This form of face, the most specialised of any of the class is called the "Œgithognathous" face or palate; and the huge army of birds possessing it are called "Œgithognathæ." Thus we have two terms for the group; first, a zoological "Coracomorphæ;" and second, a morphological "Œgithognathæ;" and these two groups are almost superimposable. In other birds, however, with open palates, the "Schizognathæ;" or with strongly closed and united palates, the "Desmognathæ," the zoological and morphological groups are not capable, in many instances, of being laid fairly the one on the other. Prof. Huxley put the Goatsuckers and Humming-birds amongst his "Œgithognathæ;" in the present paper they are shown to be as truly schizognathous as the Fowl or the Plover. In this paper the skull of these two types is largely illustrated. Many kinds of the desmognathous type of palate are described and figured, and their varieties explained. This is largely done with the birds of prey, amongst which the writer puts the Cariama (*Dicholophus*). Lastly, the schizognathous face is illustrated in the skull of the Sea-mew. Birds of the Gull tribe are shown to arise from the specialisation of the Plover type; they are a high kind of Charadrian bird. An interesting discussion followed, in which Dr. P. L. Sclater and Dr. Murie took part.—Notes on the plants collected and observed at the Admiralty Islands March 3-10, 1875, by Mr. H. N. Moseley.—On a sporl of *Paritium tricuspe*, by Dr. C. King.—Supplement to the enumeration of the fungi of Ceylon, by the Rev. M. J. Berkeley and Mr. C. E. Broome. Two interesting new genera are here described, *Endocalyx* and *Actiniceps*, possibly intermediate between Myxogastres and Trichogastres.

CAMBRIDGE

Philosophical Society, Nov. 29.—The following communication was made to the Society on the temperatures observed in a deep boring at Speremberg near Berlin, as given in a report of a paper by Professor Mohr, of Bonn, by Mr. O. Fisher (NATURE, vol. xii. p. 545). The greatest depth recorded is 3390 feet. The temperatures are given in Reaumur's scale. The author showed that the equation

$$v_{,} = -\frac{251}{10^8}x^2 + 0\cdot012982x + 7\cdot1817,$$

in which v is the temperature, and x the depth, exactly represents the temperature curve. This curve will give a maximum temperature of

$$40^0{\cdot}7532 \text{ R., or } 123^0{\cdot}6947 \text{ Fah.,}$$

at a depth of 5171 feet. If there was no cause to disturb the temperature, it ought to conform to a straight line, given by the above equation altered by omitting the term in x^2. Consequently a cause was sought which would change such a straight line to the parabolic form. The first cause examined was a change in the conductivity of the strata depending on the depth, and it was found that a law, which would make the conductivity vary inversely as the distance of any point above the level of greatest temperature, would account for the observed facts. But it was argued that such a law was entirely improbable. The next cause examined was the effect of the percolation of meteoric water through the strata, and the result was found to be that this circumstance would account for the observed temperatures, provided the quantity of water which passed through the rock in a unit of time bore a certain ratio to the quantity of rock passed through. The quantity of water requisite to produce the effect had not been determined. It was remarked that the results of this investigation make it appear that the true law of underground temperature would be better obtained from borings of moderate than of very great depth, because the disturbance of the temperature curve from the rectilinear form is greater the further we descend.

MANCHESTER

Literary and Philosophical Society, Nov. 8.—Alfred Brothers, F.R.A.S., in the chair.—The fauna of Cymmeran Bay, Anglesea, by John Plant, F.G.S. (part 2).

Nov. 30.—Edward Schunck, F.R.S., president, in the chair. —On the estimation of very small quantities of lead and copper, by M. M. Pattison Muir, F.R.S.E., Assistant Lecturer on Chemistry, Owens College.—On certain circumstances which affect the purity of water supplied for domestic purposes, by M. M. Pattison Muir, F.R.S.E., Assistant Lecturer on Chemistry, Owens College.

BERLIN

German Chemical Society, Dec. 13.—A. W. Hofmann, president, in the chair.—Lothar Meyer described an experiment to show that iodine does not fuse in a vacuum-tube but only in tubes filled with air; pressure being a condition of its fusion.—E. Schunck and H. Roemer have found a new isomeride of alizarine in the residues of the manufacture of the latter body. It is soluble in cold baryta-water with a dark red colour, likewise in lime-water. Its power of crystallisation is very great; but for dyeing purposes it is useless.—L. Friedburg compared various methods for purifying sulphuret of carbon. For manufacturing purposes he recommends distillation over palm-oil; but to obtain it chemically pure he prefers the action of fuming nitric acid, which attacks the impurities only, but not the sulphuret of carbon. At the same time a violet substance is formed. Sulphuret of carbon dissolves nitrous, hyponitrous, and sulphurous acid gas. —A. Flückiger has studied the explosive decomposition of white precipitate mixed with iodine.—E. de Souga heated the amalgams of silver and of gold to the temperature of boiling sulphur and found that at this temperature they retained a considerable proportion of mercury.—V. Merz and K. Schellenberger proved cyanogen to be able to produce substitution in aromatic hydrocarbons.—F. Beilstein and A. Kurbalow described the preparation of dichloraniline and of trichloraniline by passing chlorine into a solution of aniline in acetic acid.—W. Michler has succeeded in forming a urea with four ethyl groups, replacing its four atoms of hydrogen, by passing oxychloride of carbon into diethylamine. This compound, tetra-ethylated urea is a liquid, and this fact explains that it has been overlooked by former investigators.—Aug. Laubenheimer described metachloronitrobenzol and its derivatives, viz. a chlor-azobenzol, chlor-hydrazobenzol, and chlor-oxazobenzol; compounds distinguished by their power of crystallisation.—H. Scheiding has transformed bromonitro-napthylamine (alpha) by oxidation into phthalic acid, and draws conclusions from this fact to explain its constitution.—L. Jackson has prepared a brominated bromobenzol and a brominated soluidine.—C. Liebermann and Gissel have investigated the relationship between two compounds, viz., chrysophanic acid, $C_{14}H_6(OH)_2O_2$, contained in rhubarb and other plants (isomeric with alizarine); and of chrysaminic acid, $C_{14}H_2(NO_2)_4(OH)_2O_2$, a product of the action of nitric acid on aloes. It has generally been supposed that the latter substance is a nitro-substitution compound of the former. This, however, is now proved to be erroneous. Hydrochrysammine, the reduction-product of chrysaminic acid is now proved to be

$$C_{14}H_2(NH_2)_4OH_2O_2 (= C_{14}H_{12}N_4O_3),$$

and not $C_{14}H_{12}N_2O_6$, as formerly stated by Dr. Schunck. The

sulphate of this body, treated with nitrous acid, yields *a new isomeride* of alizarine, called chrysazine, and not chrysophanic acid, as would be the case if the former view were correct. At the same meeting, therefore, two new isomerides of alizarine have been announced, and thus of eight isomerides considered possible according to present views, seven have actually been discovered.

VIENNA

Imperial Academy of Sciences, Oct. 14.—The following papers, &c., were communicated:—Description of a new air-ship, by M. Codron.—The crania of the Novara collection, by M. Zuckerhandl.—Notes from the chemical laboratory of Innsbruck University, by M. Barth and others (treating of the action of fuming sulphuric acid on benzo-sulpho-acid and benzo-disulpho-acid, some derivatives from ellagic acid, nitro derivatives of anthraflavone, new naphthaline derivatives, and ferrocyanide of tetramethylammonium).—The independent formation-law of continued fractions, by M. Günther.—The development of the Euler Algorithmus, by M. Klug.—Researches on the separation of aqueous vapour in plants, by M. Eder. He first examines the external surfaces of plants as regards permeability for aqueous vapour; then the evaporation through leafless branches; and thirdly, the behaviour, as regards evaporation, of those parts of plants that are richer in water. He then describes experiments on transpiration of leafy branches and rooted plants under various conditions of moisture, light, motion of air, &c.—On the action of glycerine on starch at high temperatures, by M. Zulkowsky.—On the heat phenomena which occur on solution of ammonia in water, and their utilisation in employment of this salt for cold mixtures, by M. Tollinger.—On hypertrophic thickening in the interior of the aorta, by M. Schnopfhagen.—On Malfatti's problem, and the construction and generalisation by Steiner, by M. Mertens.—On Cinchonin, by M. Weidel.—On the heat-equilibrium of gases acted on by external forces; on the heat-conduction of gases; and on integration of partial differential equations of the first order, by M. Boltzmann.—Observations (meteorological and magnetic) at Vienna Observatory, in July to September.

Oct. 21.—An experiment towards explaining terrestrial magnetism, by M. Benedict.—Involutions of the chords in cissoids, by M. Jahradnik.—Researches on the colouring matters of bile, part v., On the action of bromine on bilirubin, by M. Maly. He shows that the molecule of bilirubin is twice as large as has hitherto been supposed.—On the double tangents of curves of the fourth order with three double points, by M. Durège.—Researches on the nature of the salmon (*Salmo Schiffermülleri*, Bloch) found in the lakes of Salzkammergut, Salzburg, and Berchtesgaden, by M. Fitzinger.—On occurrence and biology of Laboulbeniaceæ, by M. Peyritsch.

Oct. 28.—On development of the elements of Crustacea, by M. Hoeber.—Report on a journey in the western part of the Balkan and neighbouring regions, by M. Toula.—On a new condensation-product of gallic acid, by M Oser.—On the green colouring matter of *Bonellia viridis*, by M. Schenk.

Geological Society, Nov. 16.—The discovery of lake dwellings in the peat-bogs near Laibach, by Ch. Deschmann These were discovered accidentally on the occasion of a road ditch being opened, and were afterwards systematically explored for the Laibach Museum. The extent of the lake-dwellings hitherto uncovered amounts to about 600 square fathoms. They cover an area of about 13 fathoms in breadth, extending parallel to the border of the ancient lake. The piles, some thousands in number, are rammed into the clay which forms the bottom of the peat-bog, their broken ends projecting 1 or 2 feet above the clay. Above the latter lies a deposit 5–6 inches thick, containing chiefly the remains of human industry, together with bones of various animals. This again is covered by the peat to a thickness of 5–6 feet. The lake-dwellings near Laibach are of special interest on account of the great abundance of bones and hartshorn, most of them showing signs of workmanship. The remains of stag alone that were found are supposed to belong to 200 different individuals; and besides various remains of ox, buffalo, hog, wild boar, goat, sheep, bear, badger, beaver, more rarely of wolf and lynx, &c., were discovered.—On the volcanoes of the Isle of Réunion (Bourbon), by Dr. R. Drasche. The author proved that the eruptive action since the first outbursts has proceeded continually from west to east. The oldest lava streams have an acid (strachytic) character; the later, up to the present day, are basaltic.—A fossil land-turtle from the Vienna basin, by G. Haberlandt. It was found in the later Tertiary, in a quarry near Kalksburg, and is the first land-turtle ever discovered in Austrian Niogene deposits, whilst sea and river turtles occur frequently therein. The fossil was named *Trionix precedens*.—M. Zugmaier showed an *Inoceramus* found in the Vienna sandstone near Klosterneuburg, a very important discovery in reference to the geology of the Alps, regarded as forming another proof of the justness of the views always maintained by the Austrian geologists that the sandstone-strata bordering the northern part of the Alps belong chiefly to the Cretaceous period.—M. Paul gave a report of the results obtained by him in the course of last summer concerning the Karpathian Sandstone in Silesia, Hungary, and the Bukovina, that forms a direct continuation of the Alpine Vienna Sandstone just mentioned. He is convinced that the so-called Ropianka group of these sandstones, which contains the petroleum, belongs also to the Cretaceous formation.—M. Vacek exhibited an interesting fragment of a jaw-bone from a very small and probably young *Mastodon longirostris*, found in the Belvedere strata near Vienna. It had been presented to the Geological Institution by Lieut. Tihu.

WELLINGTON, N.Z.

Philosophical Society, Aug. 7.—Address by the President.—Dr. W. Z. Buller, C.M.G., gives a narrative of the progress of the scientific societies in New Zealand, and the various works which have been written on the natural history of the colony, and reviews the work done by the Society during the past year, as published in vol. vii. of the "Transactions" of the New Zealand Institute:—"From year to year the scientific work of the New Zealand Institute has kept pace with the rapid progress of the colony, and the last volume of 'Transactions' (No. vii.) is in every way worthy of its predecessors, both as to bulk and quality. On a cursory perusal it is evident that our Society has done its fair share of work during the year, no less than twenty-four of the papers selected by the governors as worthy of publication having emanated from our members. As most of you are aware, our vice-president, Mr. Travers, is one of the most industrious of our working members, and the present volume contains a lengthy contribution from him, entitled 'Notes on Dr. Haast's supposed Pleistocene Glaciation of New Zealand.' The author dissents entirely from the learned doctor's views, as propounded in his report to the Provincial Government of Canterbury in 1864, and since repeated; and following up his former article on 'The Extinct Glaciers of the South Island,' he has now placed before us an able exposition of his own views on this subject. Another important paper read before the Society during the past year is that by Dr. Hector, on Whales; and the excellent plates which accompany it, from photographs by Mr. Travers, add much to the interest of the article. It contains a full description of *Neobalæna marginata*, founded on a specimen which was captured among a large school of black-fish at Stewart's Island, and forwarded to the Colonial Museum by Mr. Charles Traill; also of the 'sulphur-bottom' (*Physalus australis*), the skeleton of which is now in the Wellington Botanic Gardens; and of that interesting form of zyphoid whale known as *Berardius hectori* from a specimen cast ashore in Lyall Bay in January last. It is to be hoped that Dr. Hector will be able to carry out his intention of publishing while in England a monograph of the Cetacea inhabiting the Southern seas, for which, as he informs me, he has collected and taken home ample material. There is probably no other section of Zoology in which a contribution of this sort would be more acceptable to the *savans* of Europe, owing to the present neglected state of its literature and the confusion of nomenclature in which many of the species are involved. There is another article from the same pen, on New Zealand Ichthyology, which contains descriptions of no less than sixteen new species of fishes, all taken recently on our coast, thus proving that this field of investigation is far from being exhausted. In the section Botany, the first article is a paper read by Mr. Buchanan in November last, on the flowering plants and ferns of the Chatham Islands, the materials being drawn from the collection in the herbarium of the Colonial Museum, nearly the whole of which was made by Mr. Henry Travers during his two expeditions to those islands in 1866 and 1871. The article throughout bears testimony to Mr. Buchanan's usual care and accuracy, and the illustrations, five in number, are very beautifully executed. That of the so-called Chatham Island Lily (*Myosotidium nobile*), a handsome plant, with large glossy leaves and clusters of blue flowers, which I was fortunate enough to discover during a visit to the Chathams just twenty years ago, is especially noticeable. Our late president, Dr. Knight, resuming a subject in which he has already

made several important contributions to science, presents us with a valuable paper on New Zealand lichens, and with another containing descriptions of some new species of Gymnostomum, all the carefully drawn illustrations being from the author's own pencil. The papers on chemistry have emanated, as usual, from Mr. Skey, the analyst to the Geological Survey, the value of whose work in this department of science has already been brought prominently before you by a former occupant of this chair. I will not detain you longer, as there are several papers to be read; but I would just point out that the eminently practical treatise by Mr. Lemon, on duplex telegraphy, and the suggestive paper by Mr. Mackay, on the hot winds of Canterbury, show that other subjects have been discussed, and that the attention of our Society has not been confined to any particular branch of scientific inquiry; that, on the contrary, it has during the past year kept in view the avowed object of its existence, viz. 'the development of the physical character of the New Zealand group: its natural history, resources, and capabilities.'"—A paper was read from the Ven. Archdeacon Stock, containing remarks upon a large bat that had been seen by him in 1854, which he believed to be a new variety. Mr. Kirk stated that he had seen a large bat at the Clarence River, but he had been unable to distinguish it from *Scotophilus tuberculatus*.—The President read a paper entitled "Notes on *Gerygone flaviventris*." The paper contained extracts from "The Birds of New Zealand," and observations in reply to a paper from Mr. Justice Gillies, in last year's volume of "Transactions."—A paper entitled "Remarks on Dr. Finsch's Paper on Ornithology in vol. vii. of 'Transactions of the New Zealand Institute,'" was also read by the President. The paper contained criticisms on Dr. Finsch's views respecting classification, as propounded in a paper read before the Otago Institute. A discussion ensued, in which the author of the paper and Messrs. Kirk and Graham took part, on the question, "What constitutes a species?" The President contended for the specific value of *Apteryx mantelli* of the North Island, on the ground that it was readily distinguishable from the other bird, and that the variation was *constant;* while Prof. Kirk agreed with Dr. Finsch, who proposes to call it *Apteryx australis* var. *mantelli*, considering that the bird discovered in the North Island is merely a variety of the species in the South—*Apteryx australis*—the slight difference between them being insufficient to warrant their separation.

Aug. 21.—J. Carruthers, C.E., Engineer-in-chief for the Colony, On volcanic action regarded as due to the retardation of the earth's rotation.—Mr. J. C. Crawford, F.G.S., On the igneous rocks of Wellington. The paper pointed out in a lucid manner the course that past explorations had taken in regard to the igneous rocks of this province, and indicated the direction that future explorations should take.

CALIFORNIA

Academy of Sciences, Sept. 20.—Dr. Blake made some remarks on the old Sierra glacier in the neighbourhood of Johnson's Pass, at the head of the south fork of the American river. The pass forms a low gap in the mountains about 7,500 feet above the sea, and extends about a mile and a half from north to south, the summit of the mountain being nearly level for that distance. To the east of the pass and 1,000 feet below is Lake Valley, fifty miles long from north to south, and twenty miles broad in some parts; this valley contains the basin of Lake Tahoe, which has a depth of 1,600 feet. The topography of the pass is such that no moraine matter would reach the head of it until the basin of Lake Valley was filled by ice above the level of the pass, or by a glacier 1,000 feet thick, nor during the decline of the cold would any extensive glacier form there after the level of the ice in Lake Valley had fallen below the level of the pass. Such being the case, we have at the head of the American valley the results of glacial action during the middle of the glacial epoch, or at least during the time the glacier in Lake Valley was increasing from a thickness of 1,000 feet to a thickness of 1,600 or 1,700, and also whilst it was diminishing from its maximum depth down to the level of the pass. The indications are that during this period a very high summer temperature must have prevailed, alternating with the greater cold of winter. The considerations on which this conclusion is founded are, first, the fact that no permanent ice-covering could have existed at the head of the pass at the time the Lake Valley glacier had already reached a thickness of 1,000 feet, otherwise moraine matter could not have been deposited in the vast moraines now found at the head of the pass. Notwithstanding the great winter cold and the increased snowfall, at least far on in the glacial epoch, the heat of the summers must have been more than sufficient to thaw the annual snowfall at this elevation when its thickness was not increased by inflowing glaciers. Another fact indicating the existence of a high summer temperature is the comparatively small extension of the glacier down the valley of the American river. During the height of the glacial epoch the thickness of the glacier at the head of the valley must have been 600 or 700 feet above the level of the pass, and yet the bulk of the moraine matter it transported has been deposited as terminal and lateral moraines within eight miles of the summit. As the valley in this distance has only fallen about 800 feet the melting of the ice must have been much more rapid than it would be with our present summer temperature.—Mr. Lowry, of the U.S. Coast Survey, read a paper on a modification of what is known as the three-point problem in hydrographical surveying, by which a position would be determined by means of two points the distance of which was known, and a point on the shore of undetermined distance.

LASLETT'S "TIMBER AND TIMBER TREES"

Timber and Timber Trees, Native and Foreign. By Thomas Laslett, Timber Inspector to the Admiralty. Crown 8vo, pp. 352. (London: Macmillan and Co. 1875.)

IN all parts of the world where the vegetation partakes of an arboreous character, the wood is applied by the natives either for building their huts or houses, for their canoes or war-vessels, or for various domestic purposes, according to the extent of civilisation under which they live. This universal application of timber dates back to the earliest ages, and though the world's consumption of wood has been increasing ever since, and more especially in modern times, the supplies have never yet absolutely failed. Though the trade in timber, properly so called, that is for building purposes as distinguished from ornamental woods, is one of immense proportions and great value, the more general application of iron at the present day for constructive purposes has to some extent, no doubt, prevented a dearth in the timber market. Notwithstanding this substitution of iron both in shipbuilding and in general mechanical work, no absolute diminution in the quantities of timber imported into this country has been effected. On the contrary, the official returns show a gradual increase both in rough and in planed or *dressed* timber, large quantities of which now come regularly from Sweden and Norway, from Russia, British North America, and other countries.

There are but few, if any, of our commercial articles, whether they be of home or foreign produce, that have a wider range of interest or more numerous ramifications than the wood and timber supplies. Primarily the subject may be divided into two divisions, the first dealing with timber as used for constructive purposes, and the second with woods as used by the cabinetmaker or for ornamental work; and still another important division is that of dye woods.

When we consider that the value of timber chiefly for building purposes imported into this country during the year 1874 amounted to over twenty millions sterling, it is surprising that so little is generally known or so few books have been written on a subject of such great commercial and general importance. Besides the produce of our own forests, composed for the most part of oak, larch, fir, ash, beech, &c., the bulk of the wood imported from Sweden, Norway, Russia, &c., is the produce of coniferous trees, the botanical origin of which are for the most part known; but over and above these are numerous woods which, though they are and have been articles of commerce for many years past, are still quite unknown as to their botanical sources. And it is not a little remarkable that most of these unknown woods are the produce of some part of the South American continent. From Brazil and Paraguay, for instance, we are constantly receiving samples of finely-marked hard and apparently durable woods, but no information ever reaches us of the nature of the trees furnishing these woods. If collectors would only bear in mind that samples of wood with native names only are next to valueless, and would use every endeavour to secure and bring home a flowering specimen of the tree producing any particular wood, they would be helping to develop the resources of the forests, besides contributing to the knowledge of the flora of the country. But this is a matter which does not concern the importer so long as the necessary supplies are forthcoming and remunerative prices can be realised; and it is by the agents or exporters alone at the port of shipment that this information can be obtained, consequently our knowledge of the sources of the ornamental hard woods of commerce remains pretty much as it did ten or even twenty years ago. It is true that at the several International Exhibitions, notably those of 1851 and 1862, some remarkably fine collections of woods were exhibited, but only in comparatively few cases were really trustworthy catalogues prepared. Even the British Guiana collections, which were remarkable for the size of the specimens and the care exercised in their selection, were wofully deficient in scientific nomenclature, and remain so to the present time, simply on account of the absence of flowering specimens, which should have been collected at the time of cutting the timber.

It is no doubt in consequence of these obstacles and the scant material at command that no one has hitherto been tempted to take up our timber and wood supplies as a special subject. Many are the collections that have been formed of British and foreign woods, but they have never found a champion in the same way that drugs did in the late Daniel Hanbury, who grudged neither time, trouble, nor expense in seeking authentic information in his favourite pursuit. The most complete lists of woods perhaps ever published are those contained in the Jury Reports of the Great Exhibition of 1851, where, besides notes on the qualities of the woods and their uses, their weights per cubic foot and their specific gravities are in some cases given. In 1852 a useful "Descriptive Catalogue of the Woods commonly employed in this country for the Mechanical and Ornamental Arts" was published by Charles Holtzapffel, but this book is of course now out of date, and nothing of any importance has since appeared beyond a few occasional lists and papers scattered about in different journals.

It was therefore with some satisfaction that we took up the book whose title stands at the head of this notice, with the hope that we should find it a trustworthy handbook of woods in general. It required, however, but a slight glance to show us that it was devoted almost exclusively to the consideration of timber for building or carpentry work, to the exclusion of ornamental woods. This we regret the more as the timber and hard wood trades, though distinct in themselves, are nevertheless closely allied subjects, and treated together with proper care and attention, would form a most valuable work.

Taking the book as it is, we find that a large portion of the early part is devoted to the question of the formation and structure of wood, matters which we think unnecessary in a work of this description, occupying space which might be much more advantageously used. A chapter is also given on the computation of the ages of trees and their rate of growth. After referring to the computed ages of well-known large trees, by which it has been estimated amongst others that the oak attains to an age of

810 to 1,500 years, the yew from 1,214 to 2,820, and the Baobab (*Adansonia digitata*) to 5,000 years, the author points out that these figures have been based upon the general assumption of each concentric ring of wood being the growth of one year. Speaking of his own experience, he says:—"I have carefully examined and counted the annual layers of a great many specimens—taking generally the average of the trees—with the view to show the common and comparative rates of growth, and have tabulated them to afford an opportunity of noticing any variations there may have been in the time required to form the wood in each of the several given diameters of 6, 12, 18 inches," &c. In these tables it is shown that in fifteen specimens of oak, the diameter of whose stems were in all cases 6 inches, the number of rings ranged from 12 to 49; in the same number of sections measuring 12 inches diameter they ranged from 19 to 105, and in those of 18 inches diameter from 24 to 160. In sections of Greenheart (*Nectandra Rodiæi*) of 6, 12, and 18 inches diameter, the concentric rings were respectively 37, 60, and 83, while in Mexican mahogany of the same dimensions the result showed the number of rings at 17, 30, and 44. In most cases from six to ten sections were examined, and the average so obtained.

In the matter of ordinary timber the information given is varied and tolerably complete, and the opinions of the author as regards strength, durability, and value for practical purposes may, of course, be taken as the opinion of one having experience and authority to speak on such matters. Moreover, the tables showing the breaking weights of the different woods and their specific gravities are the results of actual experiments. It is much to be regretted that in a work of this kind, which has not been produced without some care, more attention has not been given to scientific accuracy, not only in tracing out the sources of the woods mentioned, but also in bringing what botanical nomenclature has been attempted down to modern times. Thus, for instance, the "Maçaran duba" of Brazil (p. 182) might have been accredited as being a species of *Mimusops*, the "Cedro," on the following page, not as a species of "Cedar" but of *Cedrela* (*Cedrela odorata* probably), and the "Vinhatico" (p. 186) probably *Persea indica*. Again, with regard to African oak or teak, it is stated to be "probably the *Swietenia senegalensis* or *S. Khaya*," but it is well known that the durable timber commonly known under the above names is produced by *Oldfieldia africana*, a Euphorbiaceous tree. The Cuban Sabicu wood, likewise, of which the stairs of the great Exhibition building in Hyde Park in 1851 were constructed, and which, we believe, are still in use at Sydenham—such is the durability of the wood—is described as being produced by *Acacia formosa*, but it is under *Lysiloma sabicu* that any description of this wood is to be found in works of a botanical character.

It is not with the view of depreciating the value of the book that we point out these errors. In a new edition, with the aid of a botanist and a determination to extend the scope of the work so as to include all woods known in commerce, the value of the book might be considerably enhanced. As it is, however, besides the technical details there are numerous interesting facts distributed through its pages, many of which are new to us.

JOHN R. JACKSON

RECENT FRENCH EXPERIMENTAL PHYSIOLOGY*

Physiologie Expérimentale. Travaux du Laboratoire de M. Marey. (Paris: G. Masson, 1876.)

THE second of the memoirs in the work before us, by M. Marey, contains the description of a new *schema*, or dynamical model of the circulatory system, which from the ingenuity of its construction calls for special notice.

M. Marey, not satisfied with the original attempt of Weber to reproduce the phenomena of the circulation in a system of elastic tubes, nor with his own earlier efforts in the same direction, was led to the construction of the one to be noticed immediately. He tells us that all previous models were correct enough in imitating certain special points in the vascular circulation, but these were at the expense of, and to the total neglect of, others. The perfect reproduction of each phase is the end he has had in view in the construction of the new apparatus.

It can be proved without doubt that the heart takes a longer time to relax than to contract; the systolic curve, when represented graphically, is therefore more abrupt than the diastolic. To represent this on paper mechanically, the easiest method is by the employment of a cam or eccentric, which, as it turns, lifts a lever resting upon it and following the variation in its eccentricity.

In Fig. 1 the winch handle turns an axle on which two cams are fixed, the whole being connected with the two steady-arms and the immovable upright board on the left-hand side. A flywheel tends to render the rotation of the axle uniform. The irregularly-shaped eccentrics (C.V. and C.O.), the form of which will be explained further on, each move one of the smaller boards to the right of the figure, because these are pressed towards the left by the elastic spring F, and the dilatation of the cavities of the artificial heart (V and O), whilst they are being refilled. They transmit their movements through the intervention of the fixed pulleys attached to the boards, which latter again act on the artificial heart by the strain they exercise upon the cords S.O. and S.V. The action of the auricle being intermittent, the machine is so arranged that the cord S.O. is lax (as in the figure) during the time that it is at perfect rest. The ventricle never being in a state of true repose, but always in a state of contraction or expansion, it does not require the extra apparatus.

The artificial heart is constructed with caoutchouc cavities, supplied with valves to represent those in the human circulation. The *auricle* is covered with netting, to which four parallel cords, running through holes in the big board, are attached. The cords are fixed on a square piece of wood, which is kept in position by a spiral spring, and in connection with the moving board by the thread S.O. The *ventricle* has over it a case (white in the figure) to the edges of which cords are fixed, which are attached at their other ends to a board, which is put into communication with the moving board by means of the hooks and elastic rings (F), and the cord S.V. It is evident that any strain on the cords S.V. or S.O. will compress the auricle (O) and the ventricle (V) against the main board to which they are attached, and so produce a systole of

* Continued from p. 146.

these viscera. A magnified view of this artificial heart, into the cavities of which recording "ampoules" have been introduced, is given in Fig. 2.

As to the construction of the cams, M. Marey draws a curve to represent the systole and diastole of the ventricle of the actual heart, figuring it as a simple rise followed by a less abrupt fall. He divides the linear horizontal projection of this by twenty equidistant points, from which he projects the same number of parallel vertical lines, or ordinates. Taking a small board he draws on it a circle, from the centre of which radiate twenty equidistant lines, of which, when one has been measured off so as to equal in length the first ordinate of the cardiac horizontal curve, the others are made to correspond with the second, third, &c. On uniting by a line the extremities of these rays, a closed curve is the result, which must form the edge of the cam C.V. The cam C.O. is constructed in a similar manner from the auricular trace.

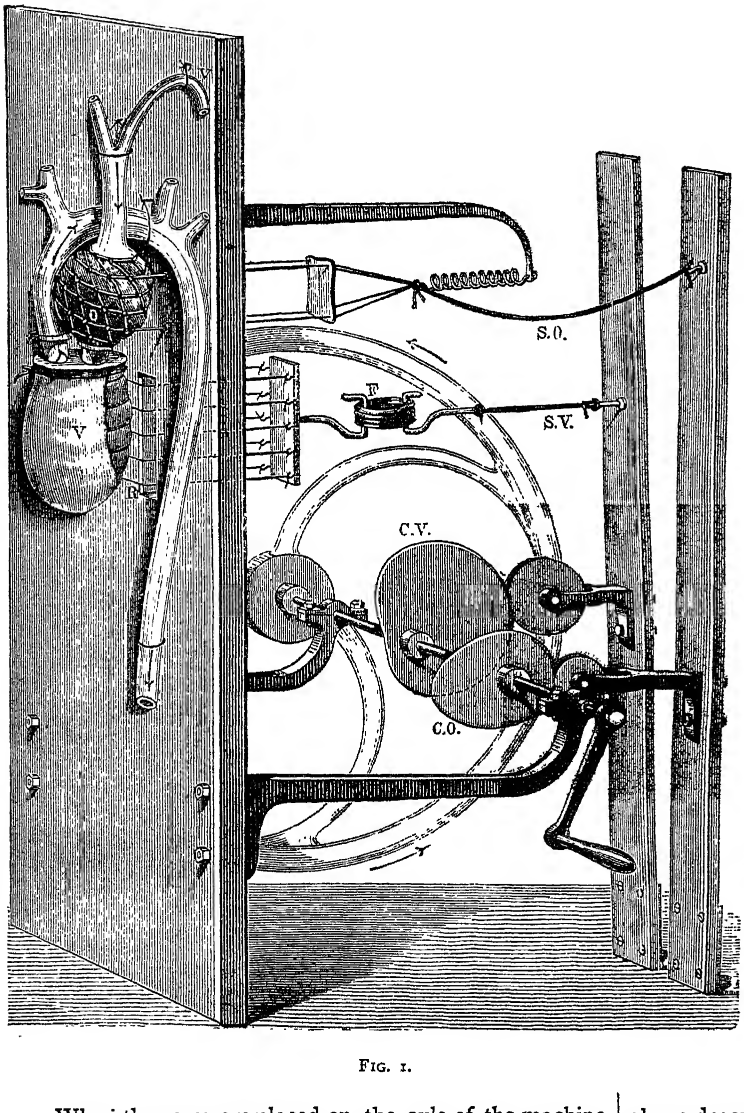

FIG. 1.

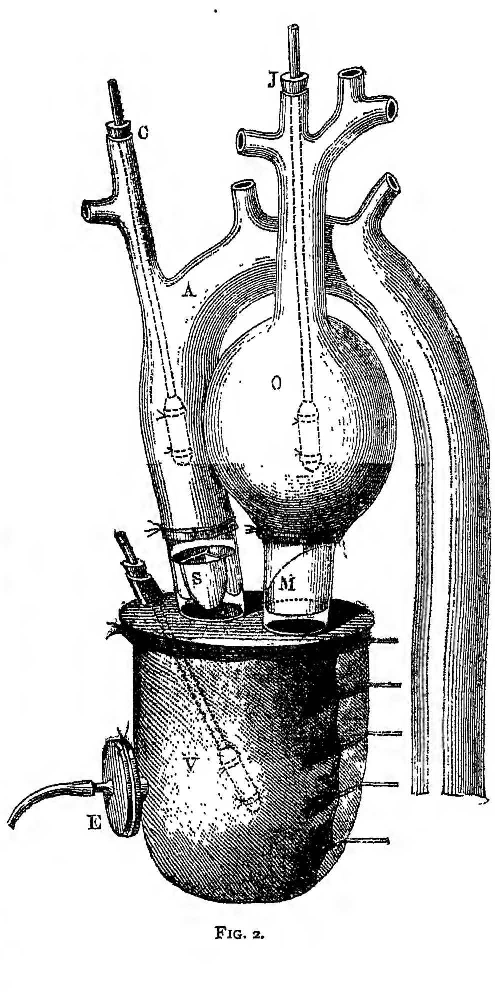

FIG. 2.

When the cams are placed on the axle of the machine in such a position that its rotation in one direction at a certain speed produces a compression (or systolic movement) by the auricular one at the interval of time before that of the ventricular which elapses between the systoles of the living auricles and ventricles, then the actual cardiac revolution is correctly imitated both in this particular and in the relative duration of the systoles themselves.

To verify the accuracy of the arrangements in the above-described *schema*, traces have been taken from it similar to those from the auricles, ventricles, and arteries of the horse. Fig. 2 illustrates the actual position, in the artificial heart, in which the elastic ampoules (sacs filled with air) which transmit its movements to recording levers (Fig. 3) were placed; and Fig. 4 is a simultaneous tracing from the four, the fourth being that of the motion of the heart-wall at E. The top curve is that from the auricle; the next is from the ventricle; and the third from the aorta.

In Figs. 1 and 2 the proximal vessels alone are represented to save confusion.

M. Marey claims for this his new *schema* that with it he can reproduce all the phenomena of the cardiac circulation; at the same time that with it he can master all the theories with reference to the significance of the most important elements of the pulsation of the heart. In this we think he is too sanguine; for there are fundamental elements of the cardiac circulation which it is quite unable to indicate even the existence of by means of it. One of the most important of these is the fact that the relative length of the systole and diastole varies with the rapidity of the pulse, a most important point not at present sufficiently laid stress on. Another is the active diastole of the ventricle, which immediately follows the closure of the aortic valve. These and other minor considerations all go to prove that, though the new *schema* of the circulation is a great improvement upon all others yet introduced, nevertheless the exact representation of acts so complicated as the systole of muscular cavities cannot yet be imitated by the employment of the unaided mechanical powers.

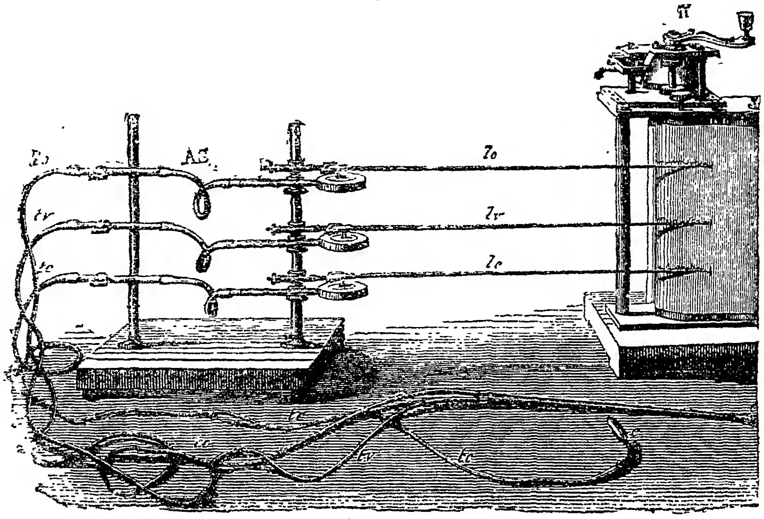

FIG. 3.

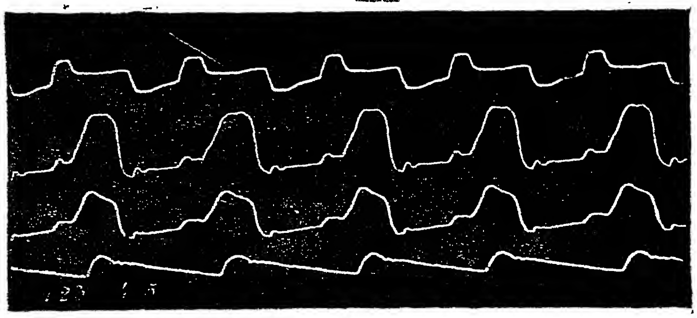

FIG. 4

DAMMANN'S RACE-PHOTOGRAPHS

Ethnological Photographic Gallery of the Various Races of Man. By C. and F. W. Dammann. (London: Trübner and Co.)

THE science of anthropology owes not a little to the art of photography. It is true that in previous times some few artists took the trouble to draw careful race-portraits. Catlin's American Indians (particularly the large copies) and Burchell's Hottentots and Bushmen, were among those of real value. But most engravings of race-types to be found in books were worthless, either wanting the special characters of the race, or absurdly caricaturing them. Now-a-days, little ethnological value is attached to any but photographic portraits, and the skill of the collector lies in choosing the right individuals as representatives of their nations. Thus the great *Anthropologisch-Ethnologisches Album* of Carl Dammann of Hamburg, completed some months go, is one of the most important contributions ever made to the science of man. Consisting of fifty plates, portfolio size, with ten to twenty photographs on each plate, it goes far toward an adequate representation of man in all his varieties. A copy may be seen at the Anthropological Institute, but its cumbrousness and cost (18*l.*) are beyond the limits of most private libraries. It is therefore satisfactory that the publishers have now brought out a smaller educational atlas, price 3*l.* 3*s.*, containing from 150 to 200 portraits, in a binding suitable for a drawing-room book. We wish it all success, for it will make new anthropologists wherever it goes.

The plan on which the portraits are arranged is mainly geographical, exact race-division being from the nature of the case impracticable. Indeed one of the effects of both the large and small albums will be in a negative direction. They will do more than any quantity of written criticism to check the rash generalisation as to race so common in ethnological systems, and they will do this by impressing on the minds of students the real intricate blending of mankind from variety to variety. It is not impossible that some day the time may come for scientifically calculating the constitution of a race, on Quetelet's principle of a central type with gradually decreasing variants. But that time has not come yet, and the most

that can at present be done to define a race-type is vaguely to make out some of its dominant features. A good example may here be seen in Plate I., which is headed "Germanic Types," though not consisting entirely of them. The last portrait is of a Welsh market girl, and just above her is Livingstone, who as we know was from the Gaelic Island of Ulva. If there is such a thing as a Keltic type, these two portraits show it; they might very well have been father and daughter. The contrast of the dark, near-eyed, compact-featured Welsh girl with the fair North German peasant woman next her is excellent, and the Bavarian lady next again shows the difference as well as possible between South and North German.

It is needless to enumerate the peoples of each district of the globe who have contributed their cartes-de-visite to this album, but a few remarks on incidental points occur as one turns over the plates. A young newly-married couple from China suggest an answer to the question, At what age may ethnological portraits best be taken? No doubt it should be somewhere about twenty years old, more or less, when the physical type has become developed, but the influence of thought, occupation, and circumstances have not yet masked the lines of race. In these plates, the elderly Chinese broker and the Japanese gentleman aged sixty-four, are in expression curiously like what Europeans of the same age and occupations might be. Yet when they were young, the faces of these Orientals probably bore no such apparent European likeness. What an ethnologist wants is not the cast of education and experience, but the mere national face, and this must be taken young. Again, for contrast between purity and mixture of nations, it is interesting to compare Plate XII., containing Siberian tribes of comparatively uniform type, with the heterogeneous figures in the next plate from Morocco and Algeria. The gradual blending of races, of which mention has been already made, may be well studied in Plates VIII. to XI., which bring into view better than it ever has been shown before, how the Malay peculiarities are to be traced into the Chinese and Japanese types. Lastly it may be remarked that the often-repeated ethnological theory deriving the natives of America from Eastern Asia, will receive but little support from a comparison of the portraits here given from Siberia, Japan, and China on the one hand, and North America on the other.

By way of fault-finding, it may be added that the short letterpress at the foot of the plates wants revision.

EDWARD B. TYLOR

OUR BOOK SHELF

The Eastern Seas: being a Narrative of the Voyage of H.M.S. "Dwarf" in China, Japan, and Formosa. With a Description of the Coast of Russian Tartary and Eastern Siberia, from the Corea to the River Amur. By Capt. B. W. Bax, R.N. With map and illustrations. (London: John Murray, 1875.)

CAPT. BAX spent three years, 1871-4, cruising about in the waters on the east of Asia, and has written a pleasant gossipy account of what he saw. He went over ground that has been often traversed, and has not much that is new to tell. Many details, especially historical, are confessedly borrowed from well-known authorities, so that the work is to some extent a compilation. An unnecessarily large amount of space is devoted to accounts of various wrecks that occurred on the coasts near where the *Dwarf* happened to be cruising, and many incidents of trifling importance are narrated, adding considerably to the size but not to the value of the book. Probably the most valuable part of the work is that wherein the author's visits to Formosa and to the Russian coasts are described. Capt. Bax had some favourable opportunities of becoming acquainted with the Formosans, both civilised and wild, and gives some interesting details as to their appearance, manner of life, and customs; his second chapter is a history of the island from its discovery by the Chinese. There is a good map of the island, and it would have added to the value of the work had there been a map of the whole region with which the book is concerned. In his narrative of the voyage of the *Dwarf* along the coast of Asiatic Russia, some interesting facts are given as to the present condition of the Russian possessions in that quarter as far north as Nikolevsk. Capt. Bax also made an ascent of Fusiyama, in Japan, of which he gives a pleasant account. Altogether, although the work adds very little to our knowledge of either China, Japan, or Asiatic Russia, it contains a good deal of interesting reading.

Commodore J. G. Goodenough. A Brief Memoir. By Clements R. Markham, C.B. (London and Portsmouth: Griffin and Co.)

THIS is a modest and well-written narrative of the life of a man whose premature death is a distinct loss to the British navy and to geographical science. Every naval officer should read it, and indeed all who wish to be inspired by the record of a noble life. The unfortunate circumstances connected with the death of Goodenough must be fresh in the memory of our readers. He undoubtedly was a martyr to what he conceived to be his duty; he fell in the attempt to conciliate the savages of Santa Cruz Island, and to assure them of the good intentions of England towards them. Had he been spared he would no doubt have done much good in this direction, as well as added to our knowledge of the Pacific Islands. Commodore Goodenough had high ideas of the scientific and other qualifications which are necessary to make an efficient naval officer, and took every opportunity to advocate these ideas. He himself was a man of varied attainments, and was a student up to the last. He took a warm interest in geographical science, and was for long an earnest advocate for a new Arctic expedition. Commander Markham and several other officers on board the *Alert* and *Discovery* had the advantage of serving under Goodenough; while Mr. C. R. Markham was himself his shipmate at an early part of his career. A good portrait is prefixed to the narrative.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Sir Thomas Millington and the Sexuality of Plants

I THOUGHT it was sufficiently obvious that Sir Thomas Millington's claims to be regarded as the discoverer of the function of the stamens in what are called hermaphrodite flowers was based upon what is stated by Grew. That I confess has always appeared to me conclusive upon the matter. I am not aware that Sir Thomas Millington ever published anything in his own name upon the subject.

With regard to Grew's book, I think Mr. Bennett is still under some misapprehension, which I trust he will allow me to point out to him. In NATURE (vol. xiii. p. 86) he speaks of a first edition of 1671, and also of an edition of 1681. In NATURE (vol. xiii. p. 166), he appears to identify the first of these with Grew's Treatise, "The Anatomy of Vegetables Begun, with a general account of vegetation founded thereupon," published in

1672. In 1682, he says that Grew published an enlarged edition of this smaller work under the *same* title. But this is not really the state of the case. The title of the large book is "The Anatomy of Plants, with an Idea of a Philosophical History of Plants." The volume has Sir Christopher Wren's *imprimatur*, which runs as follows:—

"At a meeting of the Royal Society, Feb. 22, 168½, Dr. Grew having read several *Lectures* of the *Anatomy* of *Plants*, some whereof have been already printed at divers times, and some are not printed; with several other *Lectures* of their *Colours*, *Odours*, *Tasts*; as also of the *Solution* of *Salts* in *Water*; and of *Mixture*; all of them to the satisfaction of the said *Society*: It is therefore Ordered, That He be desired, to cause them to printed (*sic*) together in one Volume.

"CHR. WREN, P.R.S."

The "Anatomy of Plants Begun" is simply reprinted in this volume. "The Anatomy of Leaves, Flowers, Fruits, and Seeds" is, however, printed for the first time. In the second part of this, called "The Anatomy of Flowers prosecuted with the bare eye and with the microscope," which was read before the Royal Society, Nov. 9, 1676, is contained Grew's discussion of the function of the parts of the flower in which the statement about Millington occurs..

Grew's "Anatomy of Plants" can no more be described as a second edition of the "Anatomy of Plants Begun" than Prof. Huxley's "Lay Sermons" can *collectively* be described as a second edition of any *one* essay republished in that volume.

The object of the quotation from Sprengel was to show what was his opinion of the claims of Camerarius to be considered the discoverer of sexuality in plants. As Mr. Bennett (vol. xiii. p. 166) makes a point of nothing being cited from Sprengel as regards Millington; here is what Sprengel says on that head. Speaking of Grew:—

"Summam vero meruit et seræ posteritatis gratitudinem, quod primus sexuum differentiam in partibus vel fœcundantibus vel fœcundandis *non invenerit*, *sed tamen defenderit* ac evulgaverit. Ipse verecunde satis et candide Thomam Millingtonium, Savilianum professorem Oxonii nominat, qui sibi dixerit, apparatum eum seminiformem (the anthers) vices partium mascularum probabiliter gerere" ("Hist. rei Herb.," ii. 14).

Next as to Camerarius and Ray, Mr. Bennett says that the observations of the first antedated those of the second by two years. On Mr. Bennett's own showing the date of Camerarius's tract is 1694 (NATURE, vol. xiii. p. 86). The date of the first volume of Ray's "Historia," in which he alludes to the subject, is 1686.

As to Theophrastus it is well known that classical writers on natural history were aware that the unisexual flowers of the date required the "pulvis maris," or pollen, to enable them to set their fruit. But I am not aware that till the time of Grew and Millington the fact that the vast majority of plants contain stamens and ovaries, *i.e.*, both male and female organs, had ever been ascertained. What these persons did for the first time was to point out the function of the essential organs of the flower.

Mr. Bennett, instead of taking his facts secondhand from Prof. Sachs's no doubt excellent "Geschichte," ought to have looked into the authorities himself. He would then avoid the error of quoting non-existent editions and of drawing conclusions which would be inexpugnable if they were not based on erroneous dates.

Article "Birds" in "Encyclopædia Britannica"

IN that portion of the article "Birds," which I have lately written for the "Encyclopædia Britannica," I said (page 729, column 2) that *Odontopteryx* had "jaws armed with true teeth," and in this respect resembled *Ichthyornis*. The mistake has just been pointed out to me, and I shall be greatly obliged by being allowed to correct it, as far as is possible, in NATURE. The sentence should run thus: "jaws armed with tooth-like processes, and in this respect differing from Professor Marsh's *Ichthyornis*."

Fertilisation in the Basidiomycetes

IN your review of Dr. Pringsheim's "Jahrbücher" (NATURE, vol. xiii. p. 156) you refer to Dr. Max Reess' paper on the Fertilisation of the Basidiomycetes; this paper you compare with the results recently obtained by Van Tieghem, Dr. Eidam, and myself, and you say that the observations of the three former all tend in one direction, which fact should lead botanists to look with very great caution on my results, which are somewhat different.

As I am tolerably well acquainted with the three papers first mentioned, perhaps you will kindly allow me to point out that Dr. Reess' carpogonium, and the carpogonium of Dr. Eidam, are very different bodies, and that the latter author, in the "Botanische Zeitung," even puts a note of interrogation before his own interpretation of the body he figures as a possible carpogonium.

The spermatozoids as described and illustrated by me in the *Gardeners' Chronicle* for Oct. 16 and 23 last, are not essentially different from Dr. Eidam's spermatia; they agree in size, but I maintain that the threads which bear these male bodies come direct from the cystidia, and not from the basidia, and that they are at first spherical. In Dr. Eidam's excellent plate there are sixteen germinating spores shown which do *not produce spermatia*, and in each instance the spores are shown *as ruptured*. Three other spores are shown as *producing spermatia*; now these latter spores are engraved to twice the size of the former, and all three are *unruptured*. The explanation simply is that the latter threads have not come from the spores at all, but from a cystidium—the spores engraved have not germinated, and have merely been *washed against* the spermatia-bearing threads.

As for the species experimented upon abroad (except Van Tieghem's plant), one is rare, and the other not British; the plants I have been working upon are common everywhere.

In the January number of the *Popular Science Review* will be found an illustrated paper of mine on the "Reproduction of *Agaricus lacrymabundus*." In this essay will be found not only some new facts as to the reproduction process in the Basidiomycetes, but a *résumé* of the views now generally held on this subject.

WORTHINGTON G. SMITH

The Late Eclipse

I FIND in NATURE, vol. xiii. p. 86, a letter from Dr. Schuster, commenting on some remarks made by me last April respecting the photographic results of the late eclipse. He appears to consider that these remarks related to him personally, which certainly was not my intention. He speaks further of a mathematical solution promised by me, for which he has "had to wait already a considerable time." I remember nothing of such a promise, nor can I conceive how I could have promised, instead of giving at once, the solution of so simple a matter. Dr. Schuster proves very readily that the spectrum of the corona can be photographed in one minute; but I am not aware that anyone has questioned the fact. What I questioned myself was whether the spectral images of the corona can be so photographed that the true extension of the corresponding coronal envelopes can be shown. To quote my own words ("Science Byways," p. 168): "The whole light" [of the corona] "acting at once to form a photograph does not show *the full extension* of the corona, the outskirts simply losing themselves through excessive faintness. . . . How, then, can a minute portion of that light produce any photographic trace" [of the *outskirts*]? "How much less can this minute portion show *the whole extension* of the green solar envelope?" It was the hope that this might be effected which I described as mathematically unsound.

I am so busy that I cannot enter further into this matter. But in any case the only justification of controversy respecting it would be the hope that some purpose useful to science might be subserved. This seems unlikely.

New York, Dec. 16, 1875

Blowpipe Analysis

THANKING you sincerely for the very well written and not altogether uncandid (if rather severe) review of my lately published work on this subject (NATURE, vol. xiii. p. 164), against any part of which I would not at present presume to appeal, I would ask for a corner of your valuable space to explain, with regard to "the production of a precipitate" of sodium sulphide by the addition of a drop of water to a fused mass of soda with a sulphide on aluminium plate, that the term "precipitate" undoubtedly used by me (as the reviewer says so) is obviously a "slip of the pen," for there can be no room to *precipitate* anything in a drop of water from a fused mass on aluminium plate.

What I must have meant to say is, that the sodium sulphide appears like a precipitate, *i.e.* as a powder, in the partly dissolved mass. The reason of its appearing to be black on aluminium, and not, as it ought orthodoxically to be, brown, I cannot tell, as the metal is not attacked. Perhaps my reviewer can? I only say that it is so.

May I take this opportunity of soliciting you to afford, if possible, a little more space in your valuable journal, to the admittedly neglected subject (in England) of blowpipe analysis? It is, I can assure any of our chemists who have not much employed it, *a most fascinating* study, which will amply repay any leisure time expended upon it.

W. A. Ross

Meteor in the Daytime

Dec. 22, about 2 P.M., as our servants were sitting at dinner by the kitchen window, two of them were startled by the sudden appearance of a brilliant meteor descending in the E. with a little inclination to the N. It was not as large as the moon, but much larger than Mars or Saturn, white, and like lightning, with a very quick course, leaving a train as broad as itself, and preserving its full size till it was lost behind the top of an oak tree at a little distance, whose branches, though leafless, seem to have concealed it from view. The next day I found by means of a compass and a joined ruler, that its azimuth was E. by N., its inclination towards N. about 10°, the upper window frame, where it probably came into sight, 48°, and the top of the tree 21° above the horizon. I have not, as yet, heard of any other observation of this remarkable meteor. The position of Hardwick Vicarage, where it was seen, according to the Ordnance Map, is Long. W. 3° 4′ 23″, Lat. N. 52° 5′ 20″.

Protective Resemblance in the Sloths

As "mimicry" and "protective resemblance" have chiefly been noticed among insects and the lowest of vertebrated animals, the following observation regarding the three-toed sloth, made at the beginning of this century, and therefore much in advance of the period at which attention had been directed to this subject, is, in these days, not without interest. It is taken from a work not frequently met with, namely, Baron Albert von Sack's "Narrative of a Voyage to Surinam" (London, 1810). In chap. xvi. at p. 170, he says:—"The colour and even the shape of the hair are much in appearance like withered moss, and serve to hide the animal in the trees, but particularly when it gets that orange-coloured spot between the shoulders, and lies close to the tree; it looks then exactly like a piece of branch where the rest has been broken off, by which the hunters are often deceived." The colour of the hair of the body is thus distributed in *Arctopithecus castaneiceps*, *A. griseus*, and *A. flaccidus* ("Notes on the Species of Bradypodidæ in the British Museum," by the late Dr. J. E. Gray. Proc. Zool. Soc., 1871, p. 428, Plates xxxv.–xxxvii.).

Brants, in his "Dissertatio Zoologica Inauguralis de Tardigradis" (Lugdun. Batav., 1828), p. 28, says of the sloths:—"At provida natura, cum animanti negaverit arma et tela, velleri cum colorem tribuit, quo subducatur oculis ferarum et adversariorum fere eadem ratione, ac Pallas retulit de *Pteromye volante*." The passage to which reference is made is in the "Novæ species quadrupedum e glirium ordine," p. 357:—"Dum vero in Betuletis præsertim vitam agunt, sapienter a natura perspectum est, ut omni tempore anni exalbido canescentem colorem velleris servent, quo cortici betularum ita fiunt similes, ut scandentes vix, imo sub diluculum, quo tempore præsertim excurrunt, plane non conspici eminus possint, coque ab avibus rapacibus nocturnis securiores sunt." Reference is also made to Prince Maximilian of Nieuwied's "Beiträge zur Naturgeschichte von Brasilien," tome ii. s. 480.

Coffee in Dominica

In Nature (vol. xiii. p. 38, and under the head of "Coffee in Dominica"), it is stated that the "falling off in the cultivation of the coffee plant, in a soil and climate which experience showed was eminently suited to it in every respect, was due to the extensive destruction of the plants by what was there known as the coffee blight." The foregoing statement requires this qualification, that after the appearance of the coffee blight, and when the coffee crop was gradually decreasing in quantity, the old coffee planters made no attempts to check the ravages of the destroying insect, but, in many instances, cut down the valuable trees, planted the sugar-cane, and converted their coffee-works into sugar-works. I could mention the names of several estates where what I have described was done. I think it right also to add that in some portions of Dominica, where the coffee-trees were simply abandoned, they now stand, and, considering their age and the neglect to which they have been exposed, they bear fairly well. During the last two years, and since the disastrous fall in the price of cane sugar, I have been endeavouring to reintroduce here the coffee cultivation, and, on the Tabery estate, 12,000 young trees of my own planting are doing well. You will confer a great and lasting benefit upon this beautiful but neglected and almost unknown island by calling attention to its capabilities as a coffee-producing country.

Edmund Watt

South Chiltern, Dominica, Dec. 11, 1875

The Law of Storms

I have to thank you for publishing, in Nature of Dec. 2, 1875, my letter in reply to M. Faye's theory of cyclones, and I have now to submit some remarks on his theory of waterspouts.

I understand him to maintain that the dark part of the waterspout, which we see, contains a core of transparent air, which is descending at the centre of a vortex, and that the dark visible external part is a cloud formed by an ascending counter-current.

All this is unproved, and I think baseless. No dynamical reason can be assigned why there should be a downward current at the centre of the vortex. If the waterspout is formed in a vortex, which I think probable, though I am not certain of it, the vortical motion will produce not a downward but an upward current at its centre, in consequence of the diminution of barometric pressure, due to the air being thrown to the circumference by the centrifugal force. We see such upward currents formed in the little dust-whirlwinds that form themselves over streets and roads in windy weather.

Further, if M. Faye's theory were true, and if the waterspout were transparent at the centre, it could not be so well defined and solid as it usually is, nor could it be formed so rapidly.

The true theory of waterspouts is expounded in Espy's "Philosophy of Storms," a work which, notwithstanding its great error of denying the rotation of cyclones, made an era in meteorology, and, so far as I am aware, is not yet superseded.

When vapour is condensed into water, forming cloud, the latent heat of the vapour is liberated and expands the air. A simple calculation shows that, after deducting the destroyed volume of the condensed vapour, the increased volume of the air due to this expansion is between four and five times as great as the volume of the vapour before condensation. If, then, the air is nearly saturated with moisture, and the temperature in a state of convective equilibrium for dry air (that is to say, when the difference between the temperatures of any two strata is that due to the difference of their pressures), and condensation begins in any column of air, the effect of liberating this heat will be to make the air of that column warmer and lighter than the air at corresponding heights in the surrounding columns. What follows is from Espy's work, page 44:—

"It begins, by its diminished specific gravity, to rise, and then, if all circumstances are favourable, the cloud will increase as it ascends, and finally become of so great perpendicular depth, that by its less specific gravity the air below it, in consequence of diminished pressure, will so expand and cool by expansion, as to condense the vapour in it; and this process may go on so rapidly that the visible cone may appear to descend to the surface of the sea or earth from the place where it first appears, in about one or two seconds. The terms here employed must not be understood to mean that the cloud actually descends; it appears to the spectator to descend, but this is an optical deception, arising from new portions of invisible vapour constantly becoming condensed, while all the time the individual particles are in rapid motion upwards."

To this I will add as very probable, if not quite certain, that the rarefaction thus caused at the waterspout will produce an inflow of air from all sides, and this will produce a vortex at the centre; this again, by its centrifugal force, will increase the rarefaction, and thus will intensify the effect. But the commencement of the waterspout is in the way described by Espy in the above extract.

Old Forge, Dunmurry, Co. Antrim, Dec. 12, 1875

The Glow-worm

ALTHOUGH in several Natural History Encyclopædias Scotland is excluded from the list of countries containing the glow-worm, I can aver that in Nithsdale and in the parish of Tynron, Dumfriesshire, they are quite plentiful. Yestreen, in Tynron, I observed one, to my surprise, shining by the wayside. It is a proof of the mildness of the season, no doubt, as I never saw them in December before, but have seen them several times as late as October.

When carrying one home one evening in my open hand it contracted itself and leaped out of my hand. This is a power they possess which I have seldom seen mentioned. The light in winter is much feebler than in summer, but the time was ten o'clock, or more than six hours after sunset that I saw it, whereas I never witnessed the glow of one in summer so long after dusk. Some that died with me forcibly reminded me of the poet's remark that between the rose's shadow and the very rose there was not a greater contrast than that between "the dead glow-worm and the worm that glows." J. SHAW

Tynron Schoolhouse, Dec. 26, 1875

OUR ASTRONOMICAL COLUMN

ENCKE'S COMET.—By the calculations of Encke and others who have continued them, we are in possession of the dates of perihelion passage of the comet which bears his name, from 1786 to 1875. If these be arranged and the intervals taken between the successive dates, it will be found that in the course of these ninety years the effect of perturbation has not changed the period of two successive revolutions by a hundredth part. The revolution 1819-1822 was 10·1 days longer than that between 1815 and 1819, and the revolution 1845-1848 was 11·1 days shorter than the preceding one, and these are the largest variations exhibited. In the same period, the longest interval between two successive arrivals at perihelion is 1215·6 days, 1842-1845, and the shortest 1200·2 days, 1868-1871.

In aphelion the distance of the comet from the orbit of the planet Jupiter by the elements of 1875 is 0·915, too great to allow of any violent perturbation. In about 123½° heliocentric longitude, and 6°·50′ north of the plane of the ecliptic the comet approaches the orbit of Mercury within 0·038; to bring the bodies into closest possible proximity it is necessary that the planet shall arrive at perihelion 12½ days before the comet, and we know that a very close approach to this condition took place in November 1848, whereby, on the 22nd of that month, the comet was brought within 0·0378 from the planet, a distance of about fifteen times that which separates the moon from the earth. A close encounter with Mercury appears hardly possible before the year 1904.

If the orbit of Encke's comet was fixed within its present comparatively restricted limits by planetary attraction, it seems quite as likely that this may have been occasioned by an extremely close approach to Mercury as that Jupiter at some distant period should have been the disturbing agent.

OCCULTATIONS OF THE PLANET SATURN.—We are not very fortunate in this country as regards the circumstances of the batch of eleven occultations of Saturn by the moon, which take place in successive lunations, commencing on the 22nd of March next; the only one visible in England being that on the morning of the 7th of August, and this will be a daylight phenomenon, the sun rising, at Greenwich, more than half an hour before the immersion. Of the ten occultations of the planet in 1870, three were visible here, and the occultations of that year possessed greater interest from the circumstance of the wider opening of the rings, than those of 1876 are likely to be attended with, wherever witnessed. The near approach of Saturn to the moon's limb between 1 and 2 A.M. on July 11, as viewed at Greenwich, does not appear to be converted into an occultation in any part of these islands.

While writing upon occultations, a word may be said of the close approach of the planet Jupiter to the star β^1 Scorpii, on the morning of February 28, which is entered as a possible occultation in the American Ephemeris. β Scorpii is a double star, the components being of 2 and 6½ magnitudes, distance about 13″, or according to the "Melbourne General Catalogue" of 1870, the smaller star follows in R.A. 0·40s., and is 11″·95 north of the brighter one. The apparent position of β^1 Scorpii on Feb. 27 is in R.A. 15h. 58m. 14·41s., and N.P.D. 109° 28′ 2·1″. The *Nautical Almanac* place of Jupiter, which is from Bouvard's Tables, will probably require a correction of about + 0·90s. in R.A., in which case the conjunction of planet and star would take place a few minutes after meridian passage at Greenwich on the morning of the 28th or about 5h. 40m. A.M., and the north limb of Jupiter is brought close upon the star, but there still seems likely to be a difference of some three or four seconds in N.P.D., by which small quantity the star may escape occultation. The companion is too far north to be occulted. This judgment is formed by a comparison of the latest published corrections of Bouvard, given by the Greenwich observations, and the differences between Le Verrier and Bouvard at the end of 1877.

A close approach of Jupiter to this star is recorded by the Chinese as early as the year A.D. 73; on the 12th of February the planet was very near the star, four days afterwards the star was seen having been previously hidden by the superior brightness of Jupiter; and the Chinese also report that the planet which had been very near to β Scorpii A.D. 512, January 12, occulted it on the 17th of April following.

PROF. STOKES ON THE EARLY HISTORY OF SPECTRUM ANALYSIS

THE following extract from a letter, relating to the early history of spectrum analysis, from our highest English authority on physical optics, cannot fail to interest, apart from its intrinsic importance, a wide circle of readers. I have therefore obtained permission from Prof. Stokes to forward it to NATURE.

C. T. L. WHITMELL

"CAMBRIDGE, *Dec.* 23, 1875

. . . . "I felt that the coincidence between the dark D of the solar spectrum and the bright D of a spirit-lamp with salted wick could not be a matter of chance; and knowing as I did that the latter was specially produced by salts of soda, and believing as I did that even when such were not ostensibly present, they were present in a trace (thus alcohol burnt on a watch-glass and a candle snuffed close, so that the wick does not project into the incandescent envelope, do not show bright D), I concluded in my own mind that dark D was due to absorption by sodium in some shape. In what shape? I knew that such narrow absorption-bands were only observed in vapours; I knew that as a rule vapours agree in a general way with their liquids or solutions as to absorption, save that in lieu of the capricious absorption of the vapour, we have a general absorption attacking those regions of the spectrum in which the vapour-bands are chiefly found. Hence as the sodium *compounds*, chloride, oxide, &c., are transparent, I concluded that the absorbing vapour was that of sodium itself. Knowing the powerful affinities of sodium, I did not dream of its being present in a *free* state in the flame of a spirit-lamp; and so I supposed that the emitting body in the case of a spirit-lamp with salted wick was volatilised chloride of sodium, capable of vibrating in a specific time, or rather two specific and nearly equal periods, by virtue of its sodium constituent; but that to produce absorption the sodium must be free. I never thought of the extension of Prevost's law of exchanges from radiation as a whole to radiation of each particular refrangi-

bility by itself, afterwards made by B. Stewart; and so I failed to perceive that a soda flame which emits bright D must *on that very account* absorb light of the same refrangibility.

"When Foucault, whom I met at dinner at Dr. Neil Arnott's, when he came to receive the Copley Medal in 1855, told me of his discovery of the absorption and emission of D by a voltaic arc, I was greatly struck with it. But though I had pictured to my mind the possibility of emitting and absorbing light of the same refrangibility by the mechanism of a system of piano strings tuned to the same pitch, which would, if struck, give out a particular note, or would take it up from the air at the expense of the aërial vibrations, I did not think of the extension of Prevost's theory, afterwards discovered by Stewart, nor perceive that the emission of light of definite refrangibility *necessitated* (and not merely *permitted*) absorption of light of the same refrangibility.

"Reviewing my then thoughts by the light of our present knowledge, I see that my error lay in the erroneous chemical assumption that sodium could not be free in the flame of a spirit-lamp; I failed to perceive the extension of Prevost's theory, which would have come in conflict with that error.—Yours sincerely,

(Signed) "G. G. STOKES

"To Chas. Whitmell, Esq."

"P.S., Dec. 31.—As Sir Wm. Thomson has referred in print to a conversation I had long ago with him on the subject, I take the opportunity of describing my recollection of the matter.

"I mentioned to him the perfect coincidence of bright and dark D, and a part at least of the reasons I had for attributing the latter to the vapour of sodium, using I think the dynamical illustration of the piano strings. I mentioned also, on the authority of Sir David Brewster, another case of coincidence (as was then supposed, though it has since been shown to be only a casual near agreement) of a series of bright lines in an artificial source of light with dark lines in the solar spectrum, from which it appeared to follow that potassium was present in the sun's atmosphere. On hearing this Thomson said something to this effect: 'Oh then, the way to find what substances are present in the sun and stars is to find what substances give bright lines coincident with the dark lines of those bodies.' I thought he was generalising too fast; for though *some* dark lines might thus be accounted for, I was disposed to think that the greater part of the non-terrestrial lines of the solar spectrum were due to the vapours of *compound* bodies existing in the higher and comparatively cool regions of the sun's atmosphere, and having (as we know is the case with peroxide of nitrogen and other coloured gases) the power of selective absorption changing rapidly and apparently capriciously with the refrangibility of the light.

"If (as I take for granted) Sir William Thomson is right as to the date [1852] when he began to introduce the subject into his lectures at Glasgow (Address at the Edinburgh Meeting of the British Association [1871], page xcv.), he must be mistaken as to the time when I talked with him about Foucault's discovery, for I feel sure I did not know it till 1855. Besides, when I heard it from Foucault's mouth, it fell in completely with my previous thoughts.

"I have never attempted to claim for myself any part of Kirchhoff's admirable discovery, and cannot help thinking that some of my friends have been over zealous in my cause. As, however, my name has frequently appeared in print in connection with it, I have been induced to put on paper a statement of the views I entertained and talked about, though without publishing.

"In ascribing to Stewart the discovery of the extension of Prevost's law of exchanges, I do not forget that it was re-discovered by Kirchhoff, who, indeed, was the first to *publish* it in relation to light, though the transition from radiant heat to light is so obvious that it could hardly fail to have been made, as in fact it was made, by Stewart himself (see 'Proceedings of the Royal Society,' vol. x. p. 385). Nor do I forget that it is to Kirchhoff that we owe the admirable application of this extended law to the lines of the solar spectrum."

SCIENCE IN THE ARGENTINE REPUBLIC *

THE fourth part of the Bulletin of the National Academy of Sciences recently founded at Cordova, in the Argentine Republic, completes the first volume of this remarkable work, of which we have previously given some account to our readers.† The present part is mainly occupied by the conclusion of a long article upon the vegetation of the little known province of Tucuman, in the interior of the Republic, by Dr. Hieronymus, commenced in a former number. This is based upon the observations made by the author during a long and extensive scientific journey in that province, and upon the collections amassed by Dr. Lorentz in the same districts in 1871 and 1872, which have been mainly determined by Prof. Grisebach, of Göttingen. A second important article is by Dr. D. A. Döring, and treats of the land and freshwater Molluscs of the Argentine Republic, amongst which are a considerable number of new species, and several interesting novel forms discovered by the author. A third memoir, from the pen of Dr. Burmeister, treats of the abnormal Hymenopterous insects of the Linnean genus *Mutilla*, and forms a complete monograph of the native species of this group, which will be very acceptable to entomologists. By the chronicle appended to the number, we learn that the strife which has prevailed between the Director of the Academy and the six German professors originally imported for its constitution has terminated in the signal defeat of the latter. After the expulsion of about half the number, the remainder resigned, and their places have been filled by other professors from the same country, whom we trust Dr. Burmeister will find more tractable. That they are full of work is evident by the contributions to science already published in the present volume, upon the successful completion of which we heartily congratulate the energetic and illustrious Director of the Academy of Natural Sciences of the Argentine Republic.

SOME UNSOLVED PROBLEMS IN THE MANAGEMENT OF THE MARINE AQUARIUM

IT would be fatal to further progress in that direction in which so much has been achieved during the last ten years, if the zoological conditions of even the most successful of existing marine aquaria were to be blindly accepted as incapable of improvement, and especially if further experiment in reference to the vexed question of aëration were to be barred by the assumption that any one of those rival systems which are typified in the practice of Brighton, Sydenham, or any other similar establishment, is necessarily the best which can be attained.

More discussion than it has yet received is due to the broad question whether the total or almost total exclusion of vegetation from public aquaria is based on necessity or philosophy; whether artificial may not be advantageously supplemented by this most natural and automatic mode of aëration; and the further question remains, to what extent must the conditions of the aquarium be modified, as regards circulation and introduction of air, in order to render practicable the establishment and maintenance of a healthy vegetation, if the propriety of its introduction

* "Boletin de la Academia Nacional de Ciencias exactas existente en la Universidad de Cordova." Entrega iv. (Buenos Ayres, 1875.)

† See NATURE, vol. xi. p. 253.

be once conceded as a result of theoretical considerations?

Before briefly discussing these questions, let us refer for a moment to one or two other minor points which deserve a passing consideration as bearing upon the state of the marine aquarium as a miniature sea, the health of whose inhabitants is ensured in proportion as its actual conditions approach to those of its natural prototype.

It has been suggested that the proportion of carbonic acid held in solution in the water is a matter of more importance than has been recognised, and that the effect of the constant influx of a copious and finely comminuted stream of air passing night and day through the tanks is, after pretty completely oxidising the organic matter with which their contents are charged, to displace the resulting carbonic acid, and so reduce its percentage below the normal amount present in the ocean; and a parallel has been drawn between the condition of the inhabitants under these circumstances and that of human beings breathing an atmosphere containing an abnormal proportion of oxygen.

In confirmation of this opinion, it has been pointed out that one of the prominent results of the *Challenger* researches is that animal life is abundant at the bottom of the sea, while the amount of carbonic acid held in solution in its lowest strata exceeds that of the surface layer by six or seven per cent.

Now, it is certain that, supposing all sources of further or continuous supply of carbonic acid to be excluded, the exposure to the air of any given bulk of water containing the maximum quantity of that gas which it is capable of holding in solution (or any less quantity) will finally result in its total elimination; for Dalton long ago established laws from which it follows that when water saturated with a gas, *e.g.* carbonic acid, is placed in contact with the open air, the whole of such gas is set free, while the water absorbs the constituents of the air.

Hence the small quantity of carbonic acid always present in sea-water is not due to absorption from the air, but to the incessantly renewed supply afforded by the oxidation of organic matter in the sea itself.

If this supply were not constantly maintained, this constituent would vanish from the ocean. Its higher percentage in the lower strata of the sea is doubtless due to three causes: 1, to the comparative stillness of the water, whereby the diffusion of the solution is retarded; 2, to the absence of direct contact with the air and exposure to the wind; 3, and chiefly, to the increased pressure, whereby solution of the gas is greatly facilitated; for under pressure of 1 atmosphere and at ordinary temperatures, 1 cubic centimetre of water dissolves in round numbers 1 cubic centimetre, or 1·529 milligrammes, of carbonic acid, while under double that pressure the absorption is double, and so forth, varying directly as the pressure, *approximately*.

It can hardly be doubted that this presence of a larger proportion of carbonic acid in the lowest depths of the ocean has a distinct correlation to the character of their special inhabitants.

Prof. Wyville Thomson writes: "In the 'warm area,' and wherever the bottom is covered with ooze, calcareous forms predominate, and large sandy cristellarians, with their sand-grains bound together by calcareous cement, so that the sand-grains show out, dark and conspicuous, scattered on the surface of the white shell." And again: "The dredging at 2,435 fathoms at the mouth of the Bay of Biscay gave a very fair idea of the condition of the bottom of the sea over an enormous area. . . . The surface layer was found to consist chiefly of entire shells of Globigerina bulloides, large and small, and fragments of such shells mixed with a quantity of amorphous calcareous matter in fine particles;" and he proceeds to trace how the gradual subsidence of this ooze is forming, under the pressure of superincumbent water, vast geological strata, just as they have been formed for countless ages in the past.

Now, carbonate of lime is much more freely soluble in water containing carbonic acid than in pure water. Hence the abundant supply of this substance in the bed of the ocean is doubtless freely taken up into solution, to be in turn abstracted and secreted by fresh generations of living animals; and thus the carbonic acid forms, as it were, a carrier or circulating medium, if not essential to, at any rate vastly facilitating the ever-alternating processes of life and death, by which the surface of the submarine globe is being constantly and profoundly modified.

But, on the other hand, the animals kept in aquaria are essentially surface-dwellers; the tubicolous Annelids, Actiniadæ, Echinoderms, Crustacea, Nudibranchs, Mollusca, and fishes, which can be successfully kept in confinement all belong to this category, and are captured either between tide-marks or within a few fathoms of the surface. Coral-building Anthozoa perish as the subsidence of the areas in which they dwell plunges them into depths exceeding fifteen or twenty fathoms, a fact which is the basis of Mr. Darwin's simple and elegant theory of the formation of circular reefs and "atolls."

It appears that the amount of carbonic acid present in the tanks of a marine aquarium must represent the balance between the quantity evolved from decaying animal matter, exuviæ, excreta, remnants of food, and the like, and that eliminated from the water by the absorption of air. It has probably never been determined, and its accurate estimation would be a problem both easy and interesting.

But in comparing or contrasting the conditions under which animals live in the confinement of the tanks with those which prevail in the open sea, it must not be forgotten that there is present in an artificial collection of animals an element wholly different from those which exist in the ocean.

In the upper layers of the sea, at any rate, the bulk of water passing over any given animal is tens of thousands of times greater than if the whole contents of the largest aquarium were circulated over it daily. In comparison, the animals are far more sparsely distributed, and dead organisms, together with rejectamenta of all sorts, are swept away by the first tide, and practically got rid of once and for all, so far as their effect on the living individual is concerned.

In the aquarium, animals are disposed in groups artificially brought into comparatively close juxtaposition, and direct oxidation is the only means of removing the various organic impurities of which they are the source.

The observations of the *Challenger* naturalists show that the amount of organic matter in surface and bottom waters is about the same, being about $2\frac{1}{3}$ times as great as in intermediate strata. It corresponds, therefore, to the more abundant distribution of animal life; yet no one can doubt that the percentage of organic matter present in the aquarium vastly exceeds that in the sea, owing to the non-dilution of decomposing animal matter by any such enormous influx of pure water as is supplied by the tides and currents of the ocean.

Hence there is an evident necessity for much more direct aëration in order to prevent the accumulation of organic matter either dissolved or suspended.

Pari passu with aëration, the formation of carbonic acid increases, but as this substance is in turn eliminated by excess of air, experiment alone can determine whether the amount present in the aquarium, as now worked, is greater or less than that contained in either the upper or lower strata of the ocean.

We may, at any rate, safely conclude that it is of the utmost importance to have command at all times of a superabundant *power* of aëration.

The possibility of increasing it to meet the emergency of some sudden temporary pollution arising from the death of some of the inhabitants, the careless introduction

of excess of food, or some other casualty coming into the category of possible accidents, may be invaluable. The influx of air can always be regulated, or even stopped, while an insufficient supply might be fatal, at least to the more delicate animals.

Let us now consider briefly the larger question, whether vegetation ought to be admitted at all, and if so, under what limitations and with what precautions.

It is a proposition requiring no proof that the more nearly the actual conditions of nature can be approached in our tanks, the more likely is success to ensue, and the more varied will be both the classes and species of animals which it will be possible to domesticate and maintain in health.

An aquarium without seaweeds does indeed seem a wide departure from this standard, and inasmuch as vegetation fulfils the double function of naturally aërating the water by absorbing carbonic acid and evolving oxygen, and of affording wholesome and palatable food to fishes and molluscs, its introduction would appear highly desirable if not attended with dangers more than sufficient to counterbalance its advantages. On this point my friend Mr. Hughes writes to me as follows in a recent letter :—"I can no more see how fishes and molluscs can do without vegetation than the higher primates without cabbages. I feel certain that the mortality of fishes is due to its absence in public aquaria. In my own tanks I have seen a Blenny tugging at a mere rag of Ulva, black almost with age, for half an hour, to get a mouthful of 'green meat.'

"Our most beautiful family of British fishes, the Wrasses, haunt the banks of Zostera and Fucus ; and they do this for more than mere play ! "

The lovely tribe of Nudibranchs is practically excluded at present by reason of the absence of their natural food, the one or two species now admitted being animal feeders, and by no means the most beautiful of their class.

Why, then, are not seaweeds seen in the aquaria at Brighton, Sydenham, or Paris?

I believe the answer to be this. For some reason they do not appear spontaneously in the tanks of public aquaria ; possibly because the water is deprived of all germs of vegetation by the process of filtration or purification to which it is subjected before use ; more probably because, in order to secure purity, it is generally taken from deep water, where such germs are likely to be absent.

Certain it is that in water taken from near shore and not filtered, vegetation very speedily makes its appearance ; and it is impossible to suppose that the gentle flow of water in the aquarium could present any obstacle to the development of germs which are not prevented from finding a resting-place and reproducing their species in every rock-pool on shores washed by the tides and lashed by the storms of the open Atlantic.

As vegetation does not spring up spontaneously in the tanks, and as the possibility of doing without it has been practically demonstrated, its introduction has been avoided because the growth of Algæ is so rapid that they are apt to become uncontrollable, to overgrow and hide the animals from view, and at certain seasons by their rapid decay to introduce into the tanks a large amount of decomposing matter of the most objectionable kind—difficult to remove by oxidation, and likely to be fatal to many of their delicate inmates.

It cannot be doubted that the careless or indiscriminate admission of vegetation into the marine aquarium is open to all these objections ; but, on the other hand, it seems probable that its careful and judicious introduction would be productive of excellent results to the health of the animals, while there cannot be two opinions as to its adding vastly to the charm of the whole scene. To clothe, or partly to clothe, the bare and monotonous grey and yellow surfaces of rock which now form the regulation background of our tanks with tufts of green and red seaweeds waving their delicate tresses in the gently-flowing water, would add the one thing now wanting to make the aquarium in practice what it is in theory, a miniature reproduction of rock-pools and sea-caves.

Now, the larger part of our British seaweeds are annual, and perish rapidly in autumn and winter, after producing countless zoospores from which a fresh generation of plants is to be born in due time.

These annual Algæ would be dangerous inmates of an aquarium, but in all three sections of the class (Rhodospermeæ, Melanospermeæ, and Chlorospermeæ) there are perennial as well as annual species, and in the first division the plants are usually of a more delicate nature than in the two latter, of slower growth, and therefore more manageable.

We should therefore choose from among the Chlorospermeæ the one or two species which alone are perennial or biennial, such as *Cladophora arcta* and *Codium tomentosum.*

Unfortunately all the other species of Cladophora are annual, as also are those of Enteromorpha and the lovely *Bryopsis plumosa*, which, however, might be tentatively admitted by reason of its small size, slow growth, and singular beauty.

Ulva latissima, lactusa and *linza* are also all annual, and should certainly be introduced very sparingly, if at all, and with precautions designed to control and curtail their growth, to which reference will presently be made.

Among the Melanosperms scarcely any would be available. It is among the Rhodosperms that the ornaments of the aquarium might be chiefly sought ; and although experience would doubtless prove that some species of this charming group would not flourish in confinement, probably a sufficient number would be found, whose graceful forms and attractive colouring would add immensely to the beauty of the tanks, and which would yet be sufficiently slow in growth to be under the necessary control.

What could exceed in elegance the waving fronds of *Ptilota plumosa* or the plaited tresses of *Plocamium coccineum ?*

What more delightful contrast could be imagined than that of the white and pink somewhat rigid tufts of *Corallina officinalis* mingling with the bronze-coloured leaves of *Chondrus crispus ?*

What more charming juxtaposition than that of *Gelidium cornutum*, with its purple-black branches, the regularity of whose sub-division almost suggests a metallic crystallisation, with the crimson ribbons of *Delesseria sanguinea*, filmy almost to transparency ?

Unfortunately the elegant Ceramiums are all annual, but among such species as *Rhodomela subfusca, Polyides rotundus, Polysiphonia fastigiata, Dasya coccinea*, and a score of others, all perennial and of moderate growth, there is an abundant choice of variety in form, habit, and colour, which would certainly justify the experiment of setting apart one or two tanks in some public aquarium for their trial.

Were such an experiment to be tried, it would be desirable to use every precaution first of all to ensure a clear field by the elimination, as far as possible, of all pre-existing germs of other species than those which it is proposed to cultivate ; a precaution, however, the *necessity* of which the appearance of existing aquaria scarcely suggests.

Freshly gathered plants might then be introduced, in all cases attached to pieces of rock or other base, which would make it easy to remove them immediately if they proved unsuitable for the purpose in question.

If a large number of young plants made their appearance on the sides or front of the tank, it would not be a serious matter to run out the contents, scrub the surfaces clean, refill it, and replace the original plants.

By using the perennial species exclusively or mainly, it would be possible to depend solely or essentially upon specimens thus attached, and having these always in reserve, ruthlessly to exterminate any young individuals which might spring up at inconvenient times and places or in superabundant numbers, although it is more probable that our marine friends would in most cases save all trouble upon this point by anticipating the process.

Whoever among the managers of our public institutions will have the enterprise to try this experiment will probably set at rest one of the unsolved problems of aquarian management, and open up a new field of public interest and of scientific research by largely extending the list of animals which it is possible to keep in a state of health in the marine aquarium.

A. W. WILLS

THE NEW OBSERVATORY AT VIENNA

IN the *Monthly Notices* for November is an interesting paper by Dr. De la Rue on the preparations which are being made on the Continent for promoting physico-astronomical observations. The paper refers mainly to the new observatory which is being erected at Vienna, and the illustrations which we are able to give will enable our readers to form some idea of the plan of the building.

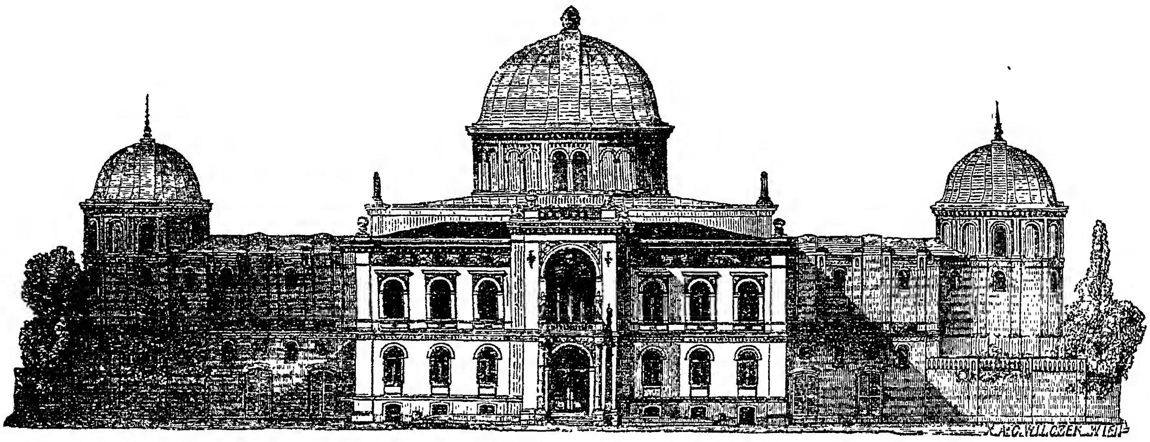

FIG. 1 represents the south front of the observatory, the central entrance opening into the dwelling of the director, which is to the south of the large dome.

"It is scarcely necessary for me to tell the Fellows of the Royal Astronomical Society," Dr. De la Rue says, "that their favourite branch of our science, namely, the physics of astronomy, is now engaging the earnest attention of foreign professional astronomers to a greater extent than obtained only a few years ago, and that grand preparations are now being made at several Continental State-observatories to grapple with the important truths which can only be revealed by adequate instrumental appliances such, indeed, as are far beyond the reach of most private fortunes. It was a matter of satisfaction to me to learn that photographic observatories are to be included in at least two of those observatories, namely, in Paris and Vienna."

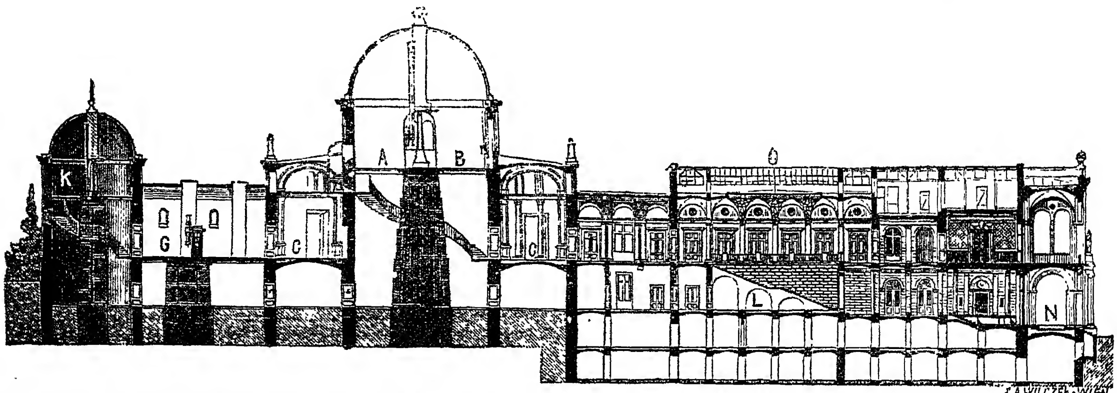

FIG 2, drawn on a smaller scale than Fig. 1, shows the general arrangement of the establishment in plan. A B is the great dome, 42 feet in diameter; this dome is surrounded at its lower portion by the central hall C C, which will contain all the portable instruments. From this central hall access is obtained to the terraces D, adapted for observations with portable instruments or the naked eye. The rooms E and F will receive the meridian instruments, and in G is to be placed the prime vertical. The smaller domes, H, I, and K are each 25 feet in diameter; besides the instruments spoken of in the text, one of these domes will most probably be equipped with an altazimuth or a heliometer.

Dr. De la Rue refers to the old Vienna Observatory, which was founded in the year 1753, and rebuilt in 1826-27, but has been long so crowded round by other buildings as seriously to interfere with the satisfactory performance of astronomical work. After repeated representations to the Austrian Government, the present Director, M. C. von Littrow, obtained in 1873 the sanction of the Minister of Public Instruction, K. von Stremayer, for the erection of the building which is now approaching completion. The new observatory is about three miles to the north of the centre of the city, and was not commenced before Prof. Weiss, First Assistant at the Obser-

vatory, had visited the principal observatories in England and America, and the workshops of the first instrument makers in these and Continental countries. The site of the observatory, of which the foundation-stone was laid in June 1874, is a plateau of between 14 and 15 acres at an elevation of about 200 feet above the mean level of Vienna. The observatory is 330 feet long in the direction of north-south, and 240 feet in that of east-west. It is hoped that the building will be completed in 1877, and Dr. De la Rue, judging from the progress which had

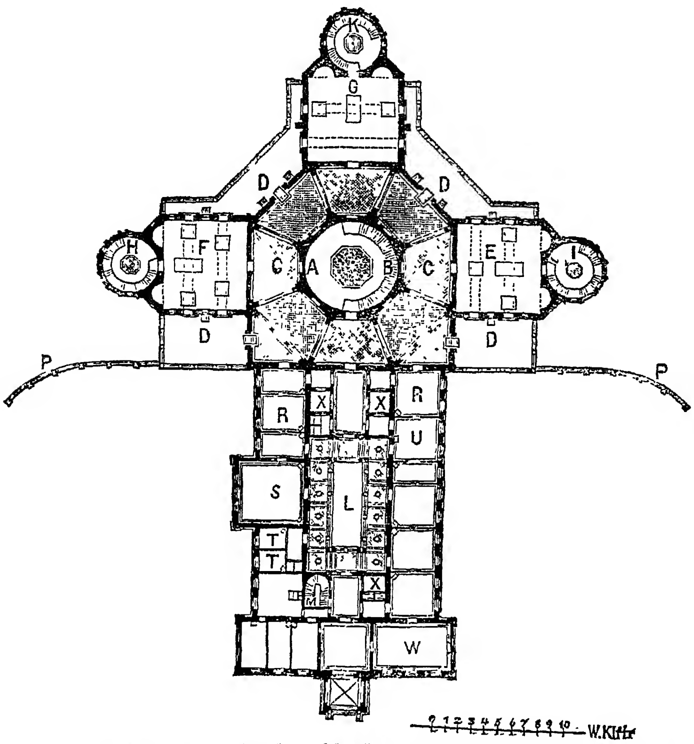

FIG. 3.—It will be seen that the first floor of the director's house is on the same level as the ground floor of the observatory ; the apartments of the assistant astronomers are on the ground floor. C C show the section of the gallery surrounding the ground-floor of the great dome ; L, the section of the staircase. Referring again to Fig. 2, W is the director's house in plan ; S and T T, the library ; U, the lecture theatre ; and lastly, R, the offices.

been made when he visited it in October last, believes it will be ready to receive the instruments at that time.

The principal instrument of the observatory will be a refractor of about 26 inches aperture, to occupy the central dome of 42 feet internal diameter, both of which, as well as three smaller domes, two of which are shown in Fig. 1, are being constructed by Mr. Howard Grubb of Dublin. One of these smaller domes will contain an equatorial refractor of 12 inches aperture, by Mr. Alvan Clark, of Cambridgeport, Mass. "These two instruments, together with a meridian circle having a telescope of 8 inches aperture, and augmented by the instruments in the old observatory, will constitute the first equipment of the new establishment. Later on it is intended to place in the third dome an equatorial reflector specially adapted for photography, and also a prime vertical instrument in the room near the fourth dome, to the north of the central dome."

One arrangement, which Dr. De la Rue, with some justice, considers a drawback to an otherwise admirably arranged establishment, is that the buildings comprise the dwellings of the director, and apartments for the assistant astronomers. Although this arrangement will no doubt add to the comfort of the astronomers, "it would have been," Dr. De la Rue says, "in my opinion, preferable for the dwellings to have been detached, as the heated air emanating from them will be liable to disturb the definition of the instruments." We hope, however, that practically no real inconvenience will arise from this arrangement.

"From the preceding description it will be seen," Dr. De la Rue concludes, "that Austria will not be left behind in the steps which are being taken to promote physico-astronomical observations ; and I sincerely hope that our own Government will ere long adopt measures to ensure to England a fair chance of honourably competing in the advancement of that branch of astronomical science which the Fellows of this Society have done so much to promote mainly from their own individual resources."

THE ROYAL SOCIETY COMMITTEES

FEW outsiders are aware of the amount of administrative work done by the Royal Society by means of its numerous committees. The work in this direction done during the past year is so well set forth in the recent anniversary address (just published) of the president, Dr. Hooker, that an abstract of it will no doubt be interesting to our readers. The principal committees are the Eclipse Committee, the Transit Naturalists' Committee, the Arctic Committee, and the *Challenger* Committee.

The first enterprise referred to by Dr. Hooker was the Arctic Expedition, in the scientific equipment and instructions of which the Royal Society took an important part. Referring to the cruise of the *Valorous*, Dr. Hooker stated that it was through the representations of the Royal Society that Mr. Gwyn Jeffreys and an assistant were appointed to carry on temperature soundings and deep-sea dredging.

"Capt. Loftus Jones and Mr. Jeffreys dredged on the Greenland coast from 70° 30′ N. lat. to the entrance of Davis's Straits, and in the Atlantic as far as 25° 58′ W. long., in depths of which the greatest was 1,785 fathoms; and temperature-soundings were taken at eleven out of the twenty stations indicated in the Admiralty Instructions.

"Among the valuable results obtained are the fact that the fauna of the Greenland seas agrees with its land flora in being mainly Norwegian, there being (with the exception of the Echinoderms) an absence of many North-American forms, which, as it appears, have not been found eastward of the meridian of Cape Chidley in Labrador. A remarkable mollusk, previously dredged at a depth of about 1,000 fathoms off the coast of Portugal by the *Porcupine*, and which, when first found in a fossil state in the newer tertiaries of Sicily was supposed to be an extinct type, reappears in the deep waters of Davis' Straits ; and a *Campanularia* was found, specifically identical with one discovered this year in the opposite hemisphere, viz. in Kerguelen's Land, by Mr. Eaton, the naturalist of the Transit of Venus Expedition to that island. A most singular sponge-like diatom, named by Dr. Dickie *Synedra Jeffreysi*, with living *Globigerinæ* entangled in the colloid collecting-matter of its frustules, was taken in the towing-net.

"The existence of a remarkable elevation of the floor of the ocean was ascertained in lat. 56°N., long. 34°42′ W., where soundings of 690 fathoms were obtained between depths of 1,450 fathoms on one side and 1,230 fathoms on the other—an interesting fact when taken in connection with H.M.S. *Bull-dog* having found a similar elevation in lat. 59° 40′ N. and long. 29° 30′ W. It makes known the probable existence of a sub-oceanic ridge running N.E. and S.W. between Great Britain and Greenland."

With regard to the Transit of Venus Expedition, Dr. Hooker referred to the results obtained by the naturalists, who, on the recommendation of the Council, were appointed to accompany the expeditions to Rodriguez and Kerguelen's Land ; in the former case Messrs. Balfour, Gulliver, and Slater, and in the latter the Rev. A. E. Eaton. With many of the results obtained by these naturalists our readers have already been made acquainted.

Rodriguez, Mr. Balfour has shown, is, after all, a volcanic island, possessing neither granite nor sandstone, but composed wholly of igneous rocks, with patches of coralline limestone along the coast. It belongs, therefore, geologically and geographically, to the Mascarene group. The general characters of its fauna and flora approximate very closely to those of the Mauritian group, upwards of 300 miles westward. Dr. Hooker then referred to the remains of extinct birds, including those of the Solitaire, and of extinct tortoises, which have been found in Rodriguez. Mr. Slater is of opinion that both classes of remains were entombed subsequently to the visits of Europeans. With regard to Mr. Balfour's Report on the Flora of Rodriguez, Dr. Hooker stated it as a very remarkable fact that one of the two new genera of flowering plants which have been found belonging to the natural order Turneraceæ, is most closely allied to a peculiar Panama genus; and that one of the new species has only a single congener, which is a Pacific Island plant.

Mr. Eaton's Report on the Natural History of Kerguelen's Land we have already given at length in vol. xi. pp. 35, 75. Full information as to the results obtained by all the naturalists will be published, and, after a complete set has been reserved for the National Collections, the remaining specimens will be distributed. The total expenditure incurred was 1,512*l.*, of which 1,396*l.* has been contributed by Her Majesty's Government, and the rest has been defrayed out of the Donation Fund.

With respect to the Total Eclipse Expedition of April, 1875, Dr. Hooker speaks as follows:—

"Towards the close of last year (1874) the desirability of observing the total eclipse of the sun, which was to take place in India, engaged the attention of your Council; and the subject was under its consideration when a letter was received by me from His Majesty the King of Siam, offering hospitality and assistance should the Royal Society deem it expedient to appoint scientific men to observe it from His Majesty's dominions.

"Your Council being of opinion that both the importance of the occasion (totality during this eclipse being of longer duration than during any other that would be observed in the present century) and the liberal offer of His Majesty required careful consideration, appointed a committee of five astronomers and the Society's officers to report upon the feasibility of undertaking such an expedition with a reasonable prospect of success. The Committee was advised that no time was to be lost in arriving at a conclusion, as only four months would elapse before the occurrence of the eclipse.

"The first step taken was to communicate with the First Lord of the Treasury and the Secretary of State for India, and ascertain whether, should the attempt be made, Her Majesty's Government would be disposed to co-operate with the Society.

"The answers were most favourable; but still grave doubts were entertained by several of the Committee as to whether it were possible to make the necessary preparations and arrangements with sufficient completeness to secure adequate results.

"After much deliberation it was decided in the affirmative, the Committee's decision being based on the following favouring circumstances:—That confidence in its feasibility was expressed by those members of the Committee who had themselves conducted or accompanied eclipse expeditions in foreign countries; that two eminent observers, Messrs. Janssen and Tacchini, were already in India and their services available; that Her Majesty's Government would co-operate by proposing to Parliament a grant in aid of 1,000*l.*, which would be augmented by another of 300*l.* from the Donation Fund of the Society; that the Secretary of State for India and the Governor-General of India had promised active co-operation by sending an expedition to the Nicobar Islands, where, as well as in Siam, totality would be visible; that both the Indian Government and the Admiralty had granted passages in their vessels, and that the Peninsular and Oriental Company had offered to give passages to the observers and their assistants at greatly reduced rates; that His Majesty the King of Siam would defray all expenses of the party sent to his territories; and lastly, which perhaps weighed most with the Committee, was Mr. Lockyer's disinterested offer to superintend all the arrangements of observers and instruments, to prepare the instructions for their guidance abroad, and to make all the necessary telegraphic and other communications with India and the Straits Settlements previous to, and during the progress of the expedition.

"As in the case of former eclipse expeditions, invitations to take part in the observations were addressed to foreign men of science distinguished for their researches in solar physics; but Prof. Tacchini was the only one who could accept. At the same time Dr. Vogel, of Berlin, a well-known photographer, was asked to assist, and he accompanied the expedition.

"A communication was received from M. Dumas, the perpetual Secretary of the Paris Academy of Sciences, with reference to Mr. Janssen's proposed observation of the eclipse; and instructions were sent to Singapore that every assistance should be afforded to that distinguished physicist.

"As a final result of these preliminary arrangements, there were two strong parties in position on the morning of the 6th of April, of whose members no less than six were sent out from England. One party, a combination of Italian, Indian, and English, went to Camorta in the Nicobar Islands; the other, French and English, made their way to Chulai Point in Siam. In the first party were Prof. Tacchini, Capt. Waterhouse, Prof. Pedler, Dr. Vogel, and Messrs. Meldola and Reynolds; in the second were Dr. Janssen, Dr. Schuster, Messrs. Lott and Beasley, each amply provided with assistants.

"The Committee decided that at both stations the observations should be mainly photographic; and the instruments furnished had for their object the registration of the violet spectrum of the corona and chromosphere as a whole, and that of the spectrum of an isolated portion of the image.

"Ordinary photographs of the corona and of the polariscopic effects of its light were also provided for.

"In spite of the most hopeful anticipations, the weather at Camorta proved bad on the morning of the eclipse, and, as has been observed on former occasions, the reduction of the temperature, due to the withdrawal of the sun's heat, produced a mass of cumulus cloud which prevented a most thoroughly equipped party from making any observations whatever during totality.

"The success of the Siam party has been also far less than was anticipated. An unfortunate break-down in the Suez Canal, and some misunderstanding, in consequence of which the promised Government steamer was not forthcoming, caused delays which left so little time for the final adjustment of the instruments when the observers at last reached their station, that some records are altogether wanting; and the attempt to photograph the spectrum of an isolated portion of the chromosphere proved a failure.

"The most important results obtained are (1) a series of photographs of the corona, taken with a prism of small angle in front of the object-glass, which show several rings and part of the form of the outer corona; and (2) a series of views of the corona, ceiefly taken at different times of exposure. The discussion of the observations has not yet been taken in hand; but it is not too early to state that several results of great interest and value have been secured.

"The King of Siam himself made a sketch of the corona and forwarded it to the Society. In common with others which accompany the reports, it does not differ very greatly from the figure photographed on the plate.

"I cannot conclude this short reference to one branch of our activity during the past session without congratulating English Science upon the fact that the eclipse was not suffered to pass unobserved, and without expressing our obligations to all those whose names will be mentioned at length in the report, who both here and abroad at each stage of the arrangements afforded us valuable assistance, not forgetting the observers themselves, who in the service of science volunteered for a duty not without risk, and from the performance of which, indeed, some have suffered in health."

Dr. Hooker next referred to the *Challenger* expedition, and to the interesting discoveries "which seem literally to have crowded along the course of the vessel." He referred to the light thrown by the *Challenger* researches on the formation of azoic clays and schists, on submarine geography, and on the distribution of pelagic life.

"In the depths of the sea, as on the surface of the land, are contiguous areas peopled by very different assemblages of living things. As on the land we ascend to meet a colder temperature, accompanied by forms of life of wider distribution than at lower elevations, so in the seas of warm and temperate regions we descend to meet with analogous conditions. The ocean thus mirrors one of the most striking features of the distribution of terrestrial life, and, mirror-like, it turns the picture upside down. Furthermore, this analogy is confined to the warm and temperate zones of the sea; in the cold zones this order of things is reversed; there, as on land, we descend to warmer temperatures, and the deepest sea is peopled by animals proper to a much lower latitude. The total result is a uniformity in the general

distribution of oceanic life that has no parallel on land; and facts in the migration of marine animals and plants that were formerly accounted for by assuming that they possessed greater powers of withstanding changes of temperature, are now accounted for by conditions more closely resembling those that obtain on the land."

Dr. Hooker then referred to the lamented death of Dr. von Willemoës-Suhm, and to the arrangement whereby Prof. Huxley has been able to act as Prof. Thomson's substitute at Edinburgh.

Speaking of the Meteorological Committeee, Dr. Hooker stated that "the anomalous connection between the Royal Society and the Meteorological Office on the one hand, and between that office and the Government on the other, is likely soon to be terminated, the Lords Commissioners of the Treasury having appointed a Committee to inquire into the working of the present office, and the value of the results hitherto obtained. According to the instructions of the Treasury, the inquiry is to be directed to two principal points of scientific interest, viz. (1) How far the statistics hitherto collected have led to the discovery or confirmation of meteorological laws. (2) How far the principles upon which storm-warnings are given have been justified by results."

While pointing out that America was in some respects more advantageously situated than England for meteorological investigation, Dr. Hooker showed that, on the other hand, England has advantages for promoting the study of terrestrial meteorology that no other country has—namely, her foreign possessions and colonies, and the command of the telegraphs with which the ocean is in process of being crossed in every direction. "We have known," he says, "what it is to read at our breakfast-tables telegrams from all parts of the world of the prices of stocks and of political incidents of the previous day; why should we not, then, obtain daily statistics of the climatic conditions of these and other remote regions, and inaugurate in England a system of meteorological registration which, if its elements were obtained from but a few well-selected spots, would instruct and interest every intelligent person in the climate of the globe, and in the end lead to scientific results of great value."

Dr. Hooker cannot but think that the Committee of the Treasury will have the opportunity of recommending to Her Majesty's Government the adoption of measures that would greatly increase the scientific efficiency and public interest of the Meteorological Office.

Dr. Hooker referred in terms of disappointment to the unexpected interpretation which has been put by the Law Lords on the terms of the Gilchrist bequest, whereby no part of it can be allotted to "the advancement of learning" *i.e.* of research, but all to the propagation of knowledge. Dr. Hooker hopes that a future and more enlightened generation "will introduce into the theory and practice of the law an interpretation of the 'advancement of learning' more in harmony with scientific ideas and the requirements of the age."

The president concluded his address by alluding to the Government Loan Collection of Scientific Instruments, which is being formed at South Kensington.

"In the proposed exhibition not only are modern scientific methods and instruments, and the various methods of practical instruction in science to be fully dealt with, but it is also proposed that the history of science shall be illustrated by the actual instruments which have been employed from the time of Galileo downwards, in those critical experiments and discoveries which mark the principal stages along the road of progress."

THE FRENCH ACADEMY AWARD OF PRIZES

AT the anniversary meeting of the Paris Academy of Sciences on Dec. 23 the following prizes were awarded as the result of the competition for 1875:—

1. Grand prize in the Mathematical Sciences, not awarded, and the subject re-set for competition in 1878—"Investigation of the elasticity of crystalline bodies from the double point of view of experiment and theory."

2. Grand prize in the Physical Sciences. The subject was, "To investigate the changes which take place in the internal organs of insects during complete metamorphoses." The prize was awarded to M. Künckel, Assistant-Naturalist at the Paris Museum.

3. The Poncelet prize, to M. Darboux, for his analytical and geometrical works.

4. The Montyon prize in Mechanics, not awarded.

5. The Plumey prize of 2,500 francs was awarded to M. Madamet, French naval engineer, for an apparatus invented by him to indicate at any moment the number of turns made by a marine steam-engine by the simple inspection of a dial, and without the need of employing a watch.

6. Fourneyron prize of 1,000 francs, to M. Sagebien.

7. The Lalande prize in Astronomy, to M. Perrotin, of the Toulouse Observatory, for his astronomical work generally, but specially for his discoveries of small planets.

8. The Lacaze prize in Physics, 10,000 francs, to Prof. Mascart, for his researches on the solar spectrum, on the measure of the dispersion of gases, on the influence which the motion of the earth has on optical phenomena, and for his investigation of the rate of light.

9. Montyon prize in Statistics, to M. Borius.

10. The Jecker prize of 5,000 francs awarded to M. Edouard Grimaux for numerous researches in Chemistry, more especially in chemical synthesis.

11. The Lacaze prize in Chemistry, 10,000 francs, to M. Favre, Dean of the Faculty of Sciences of Marseilles, for his great work on the transformation and equivalence of chemical, physical, and mechanical forces. It was while pursuing his researches in thermo-chemistry, commenced thirty years ago in conjunction with Silbermann, that M. Favre was led to investigate the great question of the equivalence of work effected by forces of different origin. M. Favre, giving an experimental demonstration of the most ingenious of Joule's views, made use of his mercury calorimeter, in the form of a thermometer in whose reservoir may be placed one or more elements. He thus established that the heat developed by resistance to the passage of electricity in the conductors of a simple voltaic couple, is simply borrowed from the total heat due to the chemical action which engenders the current; if this resistance to the passage of electricity be annulled we obtain, as the work of the pile with closed circuit, the quantity of heat which will be due to chemical action alone without the transmitted electricity.

12. The Barbier prize in Medicine, to Prof. Rigaud.

13. The Desmazières prize divided between M. Eugène Fournier, author of two memoirs on the Ferns of Mexico and of New Caledonia, and M. Emile Bescherelle, author of two memoirs on the Mosses of the same countries.

Prizes 14, 15, and 16 not awarded.

17. Grand prize in Medicine and Surgery, to M. Onimus.

18. Montyon prize in Medicine and Surgery. These prizes, of 2,500 francs each, were awarded to M. Alph Guérin, M. Legouest, and M. Magitot respectively. "Encouragements" of 1,500 francs each were awarded to M. Berrier-Fontaine, to M. Pauly, and to M. Raphaël Veyssière.

19. The Bréant prize not awarded.

20. The Godard prize in Medicine, awarded to M. Alph. Hergott.

21. The Serres prize not awarded; but a reward of 3,000 francs was given (1) to M. Campana for his researches on the anatomy and physiology of the respiratory and digestive apparatus, and of the serous membranes of birds; and (2) to M. Georges Pouchet for a MS. work on the development of the skeleton, and especially the cephalic skeleton of osseous fishes compared with that of some other vertebrates.

22. The Chaussier prize in Medicine, of 10,000 francs, divided between M. Gubler, M. Le Grand du Saulle, MM. Bergem and l'Hote, and M. Manuel.

23. The Montyon prize in Experimental Physiology, 764 francs, to M. Faivre, Dean of the Faculty of Sciences of Lyon, for his researches on the functions of various parts of the nervous system of insects. M. Faivre has established that among insects the localisation of function and the division of physiological work, are carried further than is generally supposed.

24. The Lacaze prize in Physiology, 10,000 francs, awarded to M. Chauveau, Director of the Veterinary School of Lyon, for his researches on virulent and contagious diseases. M. Chauveau has proved that the virulent activity of the vaccinal, variolar, and glanderous virus is not due to the liquid, as a whole, but oftenest to corpuscles which are held in suspension. M. Chauveau has, moreover, discovered that the agents of contagion have not only as a vehicle the liquids which come from the bodies of the sick, but that they may be transmitted to healthy animals by means of air and water. He shows that the human variola is a distinct malady by itself, of which the primary source is the organism of the horse.

25. Montyon prize, in connection with unhealthy occupation, 2,500 francs, to M. Denayrouse for his invention to protect workmen while in the midst of an irrespirable medium.

26. The Tremont prize, 1,000 francs, having been awarded for three years, 1873-75, to Prof. A. Cazin, an "encouragement" of 500 francs was awarded to M. Sidot for his researches on the various conditions of carbon and on the protosulphuret of carbon.

27. The Gegner prize of 4,000 francs was awarded to M. Gaugain to assist him in pursuing his researches on electricity and magnetism.

28. The Laplace prize, consisting of a complete collection of the works of Laplace, was awarded to M. Bonnefoy, "dux" of the École Polytechnique in 1875.

NOTES

Prof. Huxley, on Tuesday last, at the Zoological Society, in his paper on *Ceratodus*, in describing the brain of that fish for the first time, showed how closely it approached that of the Lepidosiren, and how that in some points it resembled the Selachian rather than the Ganoid type. He gave cogent arguments against the theory of Gegenbauer with reference to the typical conformation of the fore limb, and laid special stress on the affinities of the animal with *Chimæra*.

The Crown Prince and Princess received the leading German scientific men on Monday at Berlin, in order to confer upon the means of securing an adequate representation of Germany in the exhibition of scientific intruments to be held in London next May. Besides Doctors Achenbach and Falck, the Ministers of Commerce and Education, there were present Herren Kirchhoff, Dubois-Reymond, Dove, and Foerster, as physicists; Herren Hoffmann and Maghellans, as chemists; and Herren Reuleaux and Siemens as representatives of mechanical science. Mr. Cundiffe Owen, the Director of the South Kensington Museum, was present at the audience. A German committee was formed to promote the objects of the meeting. This is the latest adhesion to the scheme, and we are now able to say that the arrangements are complete in the case of Germany, the United States, Belgium, Holland, and Switzerland. In all these countries, committees appointed by Government are collecting instruments either for the Research, the Historical, or the Educational department.

The following extract from the Order Paper of the Legislative Council of New Zealand, Oct. 19 last, seems to show that a supposed prehistoric man may perhaps become the subject of a judicial inquiry. The skeleton in question was exhumed in the course of excavations made for Moa bones and associated human remains by Dr. Haast, as detailed in his paper ("Trans. N.Z. Institute," vol. vii.), and as that author holds strongly to the Palæolithic age of the deposit, while others assert its comparatively recent date, it will be interesting to observe what light the coroner's inquest will throw on the subject:—"The Hon. Mr. Mantell to move, That there be laid upon the table copies of any proceedings at any inquest held upon a body found, under suspicious circumstances, in a cave known as the 'Moa Bone Point Cave,' at Sumner, in the Province of Canterbury, on Saturday, Oct. 19, 1872, whose skeleton is reported to be in the Christchurch Museum. And, in the event of no such inquest having been held, that the Government lay upon the table a statement of the reasons why no inquest was held; or assure the Council that instructions will be forthwith issued to the proper authorities to make such inquiry as may, if possible, lead to the identification of the individual whose body was so found, and set at rest any doubts as to the manner in which he came by his death."

We would draw the special attention of our readers to a paper in the current number of the *Journal of Mental Science*, by Dr. Herbert B. Major, entitled "Observations on the Brain of the Chacma Baboon." Having, in his Graduation Thesis before the University of Edinburgh, shown that in the smaller apes the size of the nerve corpuscles of the cortex of the occipital lobes was less than in the human subject, the author has analysed, layer by layer, the cortical substance of the brain of the chacma and man, his observations as yet being entirely negative. The points investigated are the number and appearance of the layers; the character of the nerve-strata; also the vessels and the white medullary substance.

The large female chimpanzee, Mafoka, at Dresden, which has recently attracted so much attention, died, we regret to say, a short time ago. Dr. Meyer promises us an account of the animal.

A paper by Prof. Reinhardt has recently been published at Copenhagen, on the Glyptodon remains of Brazil, together with the account of a new species, *Glyptodon* (?) *dubius*.

The *éloge* of General Poncelet at the anniversary of the Paris Academy was the occasion of a pathetic scene. A tribune had been set apart for the use of Poncelet's widow, who was sitting with her lady companion. When M. Bertrand referred to the attentive care which had surrounded the last days of the departed geometer, and the real worship paid to his memory by the noble woman who had been his wife, Madame Poncelet could not restrain her weeping, and her emotion was communicated to the whole audience. The house was crowded by friends and pupils of Poncelet.

The Meteorological Society of Paris has elected M. Janssen president for 1876. Mr. R. H. Scott, the director of the English Meteorological Service, has been nominated a member of the Council, and M. H. St. Clair-Deville one of the vice-presidents.

At a recent meeting of the Vienna Geological Society, the Director, M. von Hauer, welcomed Dr. E. Tietze, who, after more than two years' sojourn in Persia, had safely returned to Vienna. He made extensive geological researches, especially in Mount Elburz, and eastward as far as Asterabad and Sharood. He visited, besides, the environs of Asabeidshan, Ispahan, Chamjar, and the province of Farsistan, as also the salt desert south-east of Teheran.

The "Results for 1873 of the Meteorological and Magnetical Observations taken in Victoria, Australia," have been received. In addition to the usual averages, which appear to be carefully made, Prof. Ellery gives valuable summaries of electrical phenomena, hailstorms, frosts, snow, sleet, gales, and strong winds, together with a detailed statement of the "hot winds" which have occurred during the year in different parts of the colony, and which form so important a feature of the Australian climates. The publication is accompanied with a map, showing the positions of the meteorological stations and the telegraph and railway routes.

From Dr. King's recently-issued report on the cinchona plantations in British Sikhim, which we have previously noticed, we learnt for the first time that an efficient febrifuge was being made and sold at a cheap rate in India. On this subject Mr. Gammie, the resident manager of the Government plantation at Darjeeling, writing to Dr. Hooker, says: "We are now busy collecting cinchona bark, and propose to collect about ninety tons of dry bark this season, which we can easily do. We are manufacturing it on the spot into a cheap febrifuge, which is evidently quite as effectual as quinine. The medical department appears to be taking kindly to it, for within the last three months I have sent them over 600 lb. of it, and they are asking for more. We are now making from 40 lb. to 50 lb. a week, but are daily expecting orders to extend our factory, so as to make at least double that quantity. We have good hopes of being able to sell the febrifuge at one rupee an ounce and pay all expenses." Mr. Wood, the Government Quinclogist, has, it appears, been appointed to officiate as Professor of Chemistry at Calcutta, and since his departure for the capital, the manufacture has fallen upon Mr. Gammie.

PROF. C. HOLTEN has sent us "Tables Météorologiques de Copenhague pour l'année 1874," prepared by him, and published under the auspices of the Royal Danish Academy of Sciences and Letters. A special feature of this publication is the long averages which appear with the monthly sheets of observations. As regards rain, the averages are for fifty-five years, and as regards temperature for ninety-two years. The temperature averages are particularly valuable, seeing that they are given for this long series of years for each day, each five-days period, and each month of the year.

THE contents of the Southport Aquarium have been studied with marked interest by a large number of persons during the Christmas holidays. Amongst recent additions is a very fine specimen of *Alligator lucius*, from New Orleans, more than 8½ feet in length, a very large number of young alligators, some only a few inches, a school of herrings of all sizes, two masses of living sponge containing large colonies of brittle star-fish, young skate hatched in the aquarium, in the octagonal table tanks, which also contain a magnificent collection of sea anemones, echini, living bivalve shells, zoophytes, annelids, and seaweeds. Amongst recent improvements noticeable in this aquarium is the placing of sheets of india-rubber between the plate-glass fronts of the wall tanks and the iron mullions, which has had the effect of entirely preventing the cracking of the glass from sudden changes of temperature. The quantity of water circulating in the tanks has been increased, fresh supplies being only received to compensate for evaporation. The company have a large number of iron tanks placed at the end of the pier to receive at once rare fish brought in by the deep-sea trawlers.

WE regret to hear of the death of Mr. James Hinton, well known as a writer in practical physiology and in philosophy.

M. GERMER BAILLIÈRE, the enterprising editor of the *Revue Scientifique* and *Revue Littéraire*, has started two new periodicals, an "Historical Review," quarterly, and a "Philosophical Review," monthly.

A TRIBUTE of respect was paid by the late French National Assembly to the learned Minister of Public Instruction, M. Wallon, who was elected a life-member of the Senate, representatives of every political party having voted for him, although he had declined to stand as a candidate.

THE Catholic University of Paris opened its course of scientific lectures on Dec. 27. The lecturer in higher mathematics is M. Serret (not the well-known member of the Institute). The lecturer in physics is M. Brauly, who was the *préparateur*, or general assistant of M. Desains, the Sorbonne lecturer. No lecturer has yet been found for botany.

THE establishment of a School of Mines at Lille is in contemplation.

AN Imperial ordinance, published on Jan. 1, directs that the thanks of the Russian Government be conveyed to Prof. Nordenskjöld, for his exploration of the Polar Sea up to the Yenisei River.

THE Government has ordered that the annual cost of the Ordnance Survey of the United Kingdom shall be reduced. During the past and present week a large number of civil assistants at the head-quarters at Southampton have received their discharge.

EXPERIMENTS will be tried in France within a very few days with a new system of taking up and depositing letter-bags from a railway-train running at a great velocity. The apparatus, which was invented by a chief telegraphist, is entirely self-working, and great expectations are raised by the French Administration. A waggon of the Lyons railway has been entirely fitted up on the new principle, and a special post for collecting and delivering has been erected in the Varenne St. Maur Section.

A SPECIAL meteorological monthly paper has been published by M. H. St. Clair-Deville, who has just organised the Algerian Meteorological Service. The first number was issued a few days ago.

MOST interesting experiments are now being conducted at the Northern Railway Station, Paris, in the use of light generated by gramme magneto-electric machines. Success has been only partial, owing to the want of motive-power, but hopes are entertained of a speedy and successful result.

WE are glad to see from No. 2 of the *Iowa Weather Review*, that the scheme of meteorological observations for the State of Iowa has thus far proved a success. For the first decade of November, Dr. Hinrichs received eighty station reports from all parts of the State. A report of the results is at once prepared and forwarded to the newspapers for publication. The rest of the *Review* is taken up with minute directions as to the method of observing for the purpose of securing accuracy, uniformity, and fulness in the results of the observations embraced by the scheme.

MR. MURRAY has issued cheap editions of the narratives of Livingstone's first and second African expeditions. In the case of the former the cheap edition seems to be a reprint of that published during the author's lifetime, while the second is somewhat abridged. Both are neatly got up, contain most, if not all of the original illustrations, and will be welcomed by many who desire to possess the original narratives of the work which has made Livingstone immortal.

A REMARKABLY valuable discussion by M. Belgrand, of the inundations of the Garonne, viewed specially in connection with the heavy rains which fell over France from the 21st to the 24th of June last, has been appearing at intervals for the past fortnight in the *Bulletin International* of the Paris Observatory. It is pointed out, from the dates of their occurrence, that the inundations of the southern portion of the basin of the Garonne which slants from the Pyrénées, have nearly always occurred in spring or early summer, and at the same dates either no floods at all, or comparatively unimportant floods, were experienced in the northern portion of the basin which slopes down from the Cevennes and central plateaux of France. It is to be noted that it is just at this season that the rainfall of the southern portion of France attains its annual maximum, and the nearer to the Pyrénées the more decidedly is the May-June maximum marked, and that the melting of the snows which have accumulated on the Pyrénées during the winter months proceeds most rapidly. On the other hand, it is shown that the great inundations of the northern portion of the basin occur generally during the cold months of the year, and that at the time of their occurrence there have been no corresponding great floods at Toulouse, in the southern portion of the basin. It is during the cold season that the rainfall reaches its annual maximum on leaving the slopes of the Pyrénées and advancing northwards over the basins of the Tarn, Lot, and Dordogne. The disastrous inundation of June, 1875, was in accordance with the experience of previous floods in the south of France. As a great flood it was limited to the river courses sloping down from the Pyrénées; and the nearest approach to a great flood elsewhere was in the basin of the Argout, the most southern tributary of the Tarn, and it was the flood of this tributary which occasioned almost the whole of the flood of the Tarn. At such places as Auch, situated in a narrow valley, and, where, consequently, the drainage area is small, the inundation was much less disastrous than at Toulouse and places similarly situated

near the confluence of large affluents draining a wide extent of country. The following official statement of the numbers of the persons drowned, classed according to the departments, will indicate the line of greatest devastation :—Ariège, 73; Gironde, 1; Haute Garonne, 330; Lot-et-Garonne, 20; Tarn-et-Garonne, 116; total, 540. The discussion of these inundations with reference to the season of the year in which they have occurred in different portions of the Garonne basin, and in their relations to the physical configuration and annual maximum rainfall of each district, indicates a line of inquiry which, if further prosecuted, cannot but lead to most important practical results.

THE additions to the Zoological Society's Gardens during the past week include three Moose or Elks (*Alces machlis*) from N. America, two Arabian Gazelles (*Gazella arabica*) from Arabia, deposited; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by the Rev. W. Ewart; a Green Monkey (*Cercopithecus callitrichus*) from W. Africa, presented by the Rev. J. W. Ayre; an Earle's Weka Rail (*Ocydromus earlei*) from New Zealand, presented by Capt. H. Braddick.

SCIENTIFIC SERIALS

Bulletins de la Société d'Anthropologie de Paris, fascicules 2, 3, 1875.—The former of these numbers gives the discussion which followed the reading of a paper by M. Pommerol, on the rock-excavations, basins, rocking-stones, and holes observable in many of the rocks of Puy-le-Dôme. Contrary to the view which he had advanced in regard to their connection with prehistoric or early historic races, and their formation by man for domestic or religious purposes, the society generally concurred in the opinions maintained by MM. Leguay, Hamy, and Mortillet, that such formations are for the most part the results of natural causes, and that flint implements would have been incapable of acting upon the hard granite of which they usually consist. They admitted, however, that some of the depressions and holes may in a few instances have been enlarged in process of time through human agency, after having become the scene or object of superstitious veneration.—M. Morice laid before the Society a report of the various races which now occupy Cochin China, the most numerous and characteristic of which are the Annamites and Cambodians. Next in point of numbers stand the Chams and the Mois, or mountain-men, and beside these a hybrid race, half-castes between Annamites and the Chinese settlers, and known as Minuongs, is rapidly attaining consideration as a distinct class.—M. Hamy gave a brief summary of a memoir, which he will soon publish *in extenso*, on the craniological characters of the race that now occupies the Island of Timor, and which he considers to be not far removed from the Papuan Negritos. His examination of a number of Timorian skulls has led him to accept as proved the distinctive characteristics assigned to the race by Owen, Busk, and De Quatrefages.—M. Topinard's paper on Australian hybrids gave rise to a long discussion, but can scarcely be said to have contributed directly or indirectly to the elucidation of any of the difficulties involved in the subject.—M. Piette's communication of the result of his exploration of the Gourdan and Lortel caverns is interesting from the fact that, in addition to the ordinary reindeer-lion, aurochs and other animal remains found in such caves, he discovered parts of two human jaws. One of these—the lower maxillary bone of an adult man, to which several much-worn teeth were still attached—was found at Gourdan in close proximity to bones referred by the author to *Cervus canadensis*, or a closely allied form. The other jaw, apparently that of a child of seven, who had died during dentition, was excavated from the floor of the Lortel cavern at a depth of 6 metres.—M. Condereau laid a paper before the Society, and explained the elaborate series of tables which he has constructed to illustrate his system of the classification of articulate sounds, and which he hopes to see accepted by anthropologists as the basis of some uniform phonetico-physiological alphabet, by which writers of different nationalities may be brought on a common ground for the comparison of the different articulate sounds of which the human voice is capable.—M. Broca brought under the notice of the Society a negro skull belonging to their museum, where it forms the fifteenth in the General collection, in order to show how the normal parietal foramina may present such unusually large dimensions as to assume after death the appearance of artificially produced parietal perforations. At a previous meeting of the Society, on March 18, M. Broca had exhibited a skull taken by M. de Palmas from an ancient cemetery in the Canary Islands, which presented a double parietal opening.—A very interesting and important paper was read by M. Broca on May 20, when he laid before the Society a *résumé* of the "Craniometrical Instructions" which they had commissioned him to draw up for the guidance of anthropologists. In accordance with the directions of the Commission these instructions are preceded by a description of the anatomy of the head, in which an entirely new anatomical nomenclature has been adopted, for which M. Broca craved the approval of his *confrères* on the ground of the obscure terminology hitherto in use in craniology. Among a number of novel terms we may instance such words as endocranium and exocranium; pteron and discus for the ascending and the horizontal parts of the greater ala; inion for the external protuberance of the occipital; and basion, opisthion, staphanion, pterion for distinctive portions of the occipital, frontal, and temporal fossa. M. Broca announces that this new system of cranial terminology will be soon published *in extenso* in the "Memoires" of the Society.—M. Collineau, in connection with the subject of arrest of development in the osseous and other parts of the brain, as shown by M. Broca in his paper on parietal perforations, drew attention to the extraordinary spread of religious mania in France, of which he gave numerous instances amongst the higher as well as lower classes, and appealed to medical and other scientific men to devote themselves to the elucidation of this important subject.

Der Naturforscher, November, 1875.—This number contains an account of some interesting researches by M. Exner, on the capability of perceiving a time-difference between two impressions of sense. Suppose a stimulus to act at moment *a*, and another at moment *b*, how near may *a* and *b* come together and the impressions continue distinct? M. Exner examines the various cases of two impressions on the same, and on different elements of an organ of sense, on similar elements of a pair of organs, and on elements of different sense organs.—From experiments on decomposition of albumen in animal bodies, M. Forster concludes that the blood of one animal introduced into the vascular system of another behaves like the blood already present; that albumen solutions brought into the blood are decomposed like albuminous substances received through the stomach and intestine; and that, of the albumen present in the body, that which is firmly held in organs and cells is but little decomposed, while that entering the intestine or blood-vessels in solution is mostly decomposed.—The physical properties of a freezing mixture of sulphuric acid and ice are investigated in a paper by M. Pfaundler, and M. de Coppet discusses superfusion and supersaturation according to the mechanical theory of heat. Most of the remaining papers hardly call for notice here.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Dec. 16, 1875.—Note on the Placentation of Hyrax, by Prof. Wm. Turner, of Edinburgh. The author describes the result of his study of a spirit specimen, his object being to verify or refute the recent statements of MM. H. Milne-Edwards and George, which, contrary to the observations of Sir E. Home, Owen, Huxley, and others, are to the effect that the placenta of *Hyrax* is non-deciduate. He shows that the placenta of *Hyrax* is deciduate, like that in the cat, which it resembles in form; it has also a large allantoic sac.

Geological Society, Dec. 15, 1875.—Mr. John Evans, F.R.S., president, in the chair.—Francis James Bennett, Alfred Allinson Bourne, Charles Thomas Clough, John Law Cherry, William Herbert Dalton, Walter Saise, James Weeks Szlumper, and Lamont Henry Graeme Young, were elected Fellows; and Prof. August Quenstedt, of Tübingen, a Foreign Member of the Society.—"Notes on the Physical Geology of East Anglia during the Glacial Period," by Mr. W. H. Penning. The author wished it to be understood that his remarks were intended to form a sketch, rather than a detailed account of the subject to which they relate. He intended to explain the origin of the so-called "middle glacial" gravels and sands, to account for their occurrence in certain areas and their non-occurrence in others, where they might reasonably have been expected. Also to briefly describe a certain series of gravels of doubtful age and origin in the

Cambridge valley. A short description of the geology and physical features of the district was given, and an inference drawn from the varying faunas of the "Crag" that the land was sinking during that era and until after the deposition of the Cromer "Forest-bed." Then Arctic conditions began to prevail, and the great glacial subsidence commenced; the "lower glacial" beds were formed, and succeeded by a large series of false-bedded gravels and sands, with intercalated patches of unstratified clay. These deposits run up only to a certain level, about 300 feet, never quite reaching the top of the chalk escarpment, where the overlying boulder-clay is invariably found resting on the older rock, without any gravel or sand between. The author inferred from this circumstance that after the deposition of the "lower" beds, and as submergence went on, the waters of the North Sea were again united to those of the Atlantic. A strong current was thus set up, which swept down from the north, bringing with it the material of which the gravels are composed, and which is found to consist of pebbles, all derived from the northern and eastern coasts, mixed with flints from the chalk. The escarpment of this formation stood at the time above the water, but when once sufficiently submerged to admit the water over its lower portions, the conditions were altered, the current lost its force, and the deposition of gravel ceased. An occasional iceberg had dropped its load of unstratified clay, which became intercalated with the gravels, but the greater number of such bergs were quickly swept away to the south. Now the waters had access to a larger area, the formation of gravel was succeeded by that of boulder-clay, which in the author's opinion is entirely composed of masses of clay enclosing boulders, brought down and dropped by icebergs *in mass*, which accounts for its want of stratification. This boulder-clay rests evenly on and at the higher level overlaps the "middle glacial" sands; it then caps the chalk escarpment and plunges down into the Cambridge valley, even to the present level of the sea; but in no instance on or beyond the escarpment does any sand or gravel intervene between it and the older geological formations, although just over the scarp (on the south side) the gravels run up to an elevation of 300 feet. The gravel-forming currents were evidently confined to the seaward side of the chalk range, and excluded from the Cambridge valley, which is undoubtedly *pre-glacial*, and which formed at the time a large inlet, land locked on every side but one, discharging its waters through the opening now occupied by the estuary of "The Wash." In the Cambridge valley there are sheets of river-gravel of recent date, some patches of doubtful age, but not traceable under the boulder-clay, and an elongated series of gravels at a level of 20 to 60 feet above the present level of the Cam. These are in some parts distant from the present course of the river, and present a striking resemblance to glacial gravels; but as they here and there contain recent shells, and taking into consideration their uniformity of level, the author concludes that they indicate an ancient course of the River Cam. The other conclusions arrived at, after mature consideration of all the evidence hitherto obtained, are—that a gradual passage will be found to exist from the base of the crag up to and through the drift-deposits to those of recent date; that in East Anglia we have evidence of but one, and that a gradual period of glacial submergence succeeded by a corresponding movement of re-elevation; and that there are no "middle glacial" deposits whatever within the area of the Cambridge valley.—"Denuding Agencies and Geological Deposition under the Flow of Ice and Water, with the Laws which regulate these actions, and the special bearing on river-action, of observations on the Mississippi and other great rivers, and their present and past Meteorological conditions, and similar remarks on Marine Deposits, illustrated by the Irish Sea and the Chesil Beach," by Mr. A. Tylor. The writer adduced evidence by measured sections and drawings to show that the Quaternary gravels were deposited rather in a wet or pluvial than in a snowy or Glacial period. He thought the denuding action of springs and the alternate action of rain and frost had been neglected. He considered Agassiz and other writers had overlooked the previous writings of Playfair, to whom he referred. The rainfall of Westmoreland, Switzerland, and the Mississippi valley were compared in summer and winter to prove that floods were not necessarily greater from land covered with snow than from land covered with trees and vegetation when height above the sea and local circumstances were taken into consideration. Mr. Dana's "Great Glacier," whose melting was to supply a Quaternary river, Mississippi, 50 miles wide, would require a supply equal to 625 times the present rainfall to fill it. The melting of snow was assumed to be of such proportions by modern writers as to equal the débâcles of older geologists. The high Swiss mountains pointed to a greater diminution of snow on high ground in the Glacial period; and he believed the clouds then discharged near the sea-level, so that the mass of snow and ice was at low levels. It appears that in Greenland in the 80th parallel, according to Nordenskiöld, near the sea in summer there is no snow on the ground 1,000 or 1,500 feet above the sea. Open water at the poles must depend upon the abstraction of the vapour from the atmosphere at lower latitudes; and probably in the Glacial period the ice-cap was thickest at the 70th parallel of latitude. Mr. Tylor thought the theories of former depressions of the land, as in the Mississippi valley, should be tested by examination for flexures. He had found (in 1868) that flexures, and fractures, had very much affected the course of the Wealden denudation in the Quaternary period. The laws of river motion are very simple and precise; and as depressions and upheavals are always unequal, any great movements in the Quaternary period would affect the courses of rivers, and be traceable in their deposits. The author had measured the *remaniés* valley gravels of Coalbrook Dale, which were associated with marine shells 200 feet above the sea, and compared their contour with ordinary valley gravels and with marine beaches, to ascertain under what probable conditions the sea had risen up the Severn valley without leaving any traces of cliffs or marine denudation except between Bridgnorth and Coalbrook Dale. The diamond gravel-deposits in Africa have a similar contour to those of Coalbrook Dale. The position of the Moel Tryfaen beds was first described by Trimmer in 1831. Trimmer, an excellent geologist, observed the scratches on the rocks covered by the gravel with marine remains, and noticed their ice-origin, but did not draw, unfortunately, the natural inference that there must have been a Glacial period in Wales. This great discovery or invention was left to Agassiz to propose in 1837. The glacier-eroded lakes, much lower than Moel Tryfaen, and close to it, are free from marine remains, therefore it seems difficult to suppose a depression of 1,300 feet and immersion in the sea of Tryfaen, and subsequent elevation, could have taken place without having left any marks on the land except at one spot. The measured section of the Chesil Beach shows its close approximation to a binomial curve, and the regularity of beaches and littoral zones along the Channel teach us what are the certain consequences of land being immersed under the sea. Mr. Tylor produced plans and sections showing how the tide actually affects the sea-bottom, and described the gorge below 50 fathoms in the Irish Sea. He treated the tide as caused by the alternate and opposite slow movement of the deep and great mass of the Atlantic, giving motion to the water at the coast almost simultaneously as if the whole water moved as one mass over an area of thousands of square miles. The velocity of the tide of one tenth of a mile per hour in a deep sea, produced by the composition of forces a tide of a velocity of three or four miles an hour on the coast. High and low water at different ports are the direct consequences of local currents in shallow water, set in motion by the greater mass of deep water. There are points in the English Channel where within a few miles there is a difference of six hours in high water. He objected to the theory of a tidal wave travelling in one direction, and moving faster in deep water than in shallow, because the tide really travels quicker in shallow water, as his plans show. In support of this he showed the chart of the Channel, and that the tide turned in the Irish Sea at all points, deep or shallow, almost simultaneously and synchronously with the slow tidal movement in the Atlantic. He found that in a large area of sea of 120,000 square miles, where the water averaged 67 fathoms off the Scilly Islands, the velocity of the tide was only one mile per hour, but in the shallows near the Channel Islands, where the depth was on an average 12 fathoms, by the composition of forces the velocity of the tide increased to 6 miles an hour. If the tide was the consequence of a tidal wave bringing high water, the tidal conditions of the Irish Sea would be very different from what they are described to be. He did not find any evidence of a plane of denudation on any sea coast, but, on the contrary, deep gorges and curved surfaces, depth varying with width, &c. The nearest approach to a plane surface was in the estuary of the La Plata; but that flatness appeared more the consequence of deposition than denudation. The great cuts or indentations out of coast lines where rivers discharge into the ocean, when compared with the absence of indentations in areas where there are no great rivers, but where the rocks are equally hard, showed that such denudation depended upon the alternate and opposite action of rivers and the tide. He referred to the removal of the bar

of the Danube, and to the great laws which regulate the flow of water, which he illustrated by diagrams. Hydraulics and meteorology must be studied in connection with the lines of denudation and deposition; and however difficult and inconvenient these subjects might be, no results would be reliable unless all the physical circumstances were taken into account.

Anthropological Institute, Dec. 28, 1875.—Col. A. Lane Fox, president, in the chair.—Major H. H. Godwin-Austin, E. Willett, Mrs. T. Cowie, and A. L. Lewis, were elected members.—Mr. John Evans, F.R.S., read a note on a proposed international code of symbols for use on archæological maps, which had been prepared by the sub-committee appointed at the Stockholm meeting of the Congress of Prehistoric Archæology. —Miss A. W. Buckland read a paper on divination by the rod and by the arrow. The author endeavoured to prove:—1. That from personal observation, rhabdomancy is still practised in England in certain localities, and that it is a survival of a very ancient superstition originating in the use of rods as symbols of power. 2. That the staff as a sceptre was probably a later form of the horn which was thus used in very early prehistoric times, and in that character adorned the heads of gods. 3. That from the use of rods or horns arose a veneration for them as possessing the inherent power of healing disease and even of restoring life. Hence their use by magicians in all ages and countries, the chief instruments employed by them being a ring or circle, and a staff and a bifurcated stick. 4. That these symbols conjoined are found in Egyptian, Assyrian, and Peruvian sculptures, and may be traced in some of the stone circles of Britain, and in the shape of Irish and African brooches and fibulæ. 5. That from the belief in the magical powers of rods perhaps arose tree-worship, or at least such veneration for trees as is observable of the oaks of Dordona and of the Druids, the ash of Scandinavia, and, for some unexplained reason, more particularly of the hazel. 6. That belomancy, or divination by marked arrows, said to be of Scythic origin, was practised in Babylon, Judæa, and Arabia, and that traces of it may still be found in the folk tales of Russia and Siberia. 7. That the mode of using these arrows had a strong resemblance to the very ancient custom of casting lots common to all peoples ancient and modern. 8. That the invention of lots and dice, as well as that of the divining rod, is ascribed to Hermes or Mercury identified with the Woden of Scandinavia, and by some writers also with the India Buddha. 9. That a strong resemblance exists between the implements of magic and the ancient alphabets, also the reputed invention of the same god or gods. 10. That many of the signs or letters forming the Archaic-Phœnician, and other alphabets, are found in the rock sculptures of Peru, thus adding one more to the many proofs of a communication existing between the hemispheres in prehistoric times. 11. That the arts of magic and divination were not of Aryan origin, but remnants of the Turanian or Pre-Aryan faith which once overspread the world. 12. That this is proved by their present existence among aboriginal non-Aryan races, and may, perhaps, even be used as a test of race, so that those who in Somerset and Cornwall are said to possess the power of divination by the rod may possibly have some remote affinity with the aboriginal inhabitants of Britain.

Victoria (Philosophical) Institute, Jan. 3.—Several new members were elected. The yearly statement showed the institute's sphere of action had been much extended of late. The Rev. R. Thornton, D.D., read a paper on "Scepticism," the concluding one of a series of four.

PARIS

Academy of Sciences, Dec. 20, 1875.—M. Frémy in the chair.—The following papers were read:—Theorems in which there are couples of segments having a constant relation, by M. Chasles.—Formula of the quantity of magnetism removed from a magnet by an iron contact, and of the portative force, by M. Jamin.—Critical remarks on the theories of formation of saccharoid matters in plants, and particularly in the beet, by M. Cl. Bernard.—Note on the order of Aug. 14, 1875, prohibiting the importation of fruit and other trees into Algeria, by M. Blanchard. —Expedition to Campbell Island; memoir on the chlorination of sea-water, by M. Bouquet de la Grye. The law enunciated by Gay Lussac and Humboldt for the saltness of the Atlantic is also true for the Pacific. Having represented graphically the relation between dilatation, temperature, density, and chlorination, the author seeks to analyse some phenomena of equilibrium of the sea.—Exposition of a new method for resolution of numerical equations of all degrees (second part), by M. Lalanne.—New researches on the interior magnetism of magnets, by MM. Trève and Durassier.—Researches on *Eucalyptus globulus*, by M. de Hartzen. The resin of *Eucalyptus* contains tannin and several fatty matters.—Action of mineral salts on the crystallisation of sugar, and determination of their coefficients, by M. Lagrange. Of the various salts contained in sugar, the chlorides are the least melassigenous; next come the sulphates and carbonates. The nitrates of potash and soda have the most prejudicial action to crystallisation.—Action of nitric acid on the phosphates and the arseniates of baryta and of lead, by M. Duvillier.—On the exchanges of ammonia between natural water and the atmosphere, by M. Schlœsing. With the same tension of ammonia in the air, the quantity of alkali dissolved in a natural water, up to equilibrium of tension, decreases rapidly as the temperature rises.—On the propagation of heat in rocks of schistous texture, by M. Jannettaz. —On aniline black; observations on a communication of M. Coquillion, by M. Rosenstiehl.—Note on the action of ozone on animal substances, by M. Boillot. Fifty grammes of beef enclosed in ozonised air were fresh and unaltered at the end of ten days.—On the myology of carnivora, by M. Alix.—On the pathogeny of deaf-mutism, improperly called congenital, by M. Tripier. Only about a fifth of those said to be born deaf are so really. In the other four-fifths deafness comes suddenly about two or three years of age.—On a crystallised boride of manganese, and on the *rôle* of manganese in the metallurgy of iron, by MM. Troost and Hautefeuille.—On the oxyfluorides of niobium and of tantalum, by M. Joly.—Determination of alkaline metals in the silicates, and in matters unattackable by acids, by means of hydrate of baryta, by M. Terreil.—On a new mode of production of trichloracetic acid, by M. Clermont.—On the classification and the synonymy of the stellarides, by M. Perrier. On T nerve-tubes, and their connection with the ganglionic cells, by M. Ranvier.—On the nerve-terminations in the electric plates of the torpedo, by M. Ranvier.—Remarks on a memoir of M. Tschermak, on the geology of meteorites, by M. Meunier.—M. Milne Edwards presented the first volume of "The Natural History of the Mammifers of Madagascar," by MM. Grandidier and Alph. Milne Edwards.

VIENNA

Imperial Academy of Sciences, Nov. 11, 1875.—MM. Toldt and Zuckerhandl communicated a paper on the changes of form and texture in the human liver during growth.

Nov. 18, 1875.—A paper was read by M. Liebermann, on the chlorophyll of the colouring matters of flowers and their relations to the colouring matter of blood. He thinks chlorophyll consists of two substances, chlorophyllic acid and phyllochromogen. The latter arises from chlorophyll through decomposition, and is probably what gives the various colouring matter of flowers by oxidation.

OUR WATER SUPPLY

THE last Report of the Commissioners appointed to inquire into the Pollution of Rivers has excited a considerable amount of public attention, and the press, in addition to giving its own views on the matters reported on, has printed a considerable number of letters from private persons interested in the question. We have, of course, had the usual remarks about the conflicting statements of scientific witnesses, and a large quantity of ingenuity has been expended in attempts to prove that this conflicting evidence is an indication of the witnesses being so wedded to pet theories that they are unable or unwilling to see facts in their true light, and hence that the best way is to let matters take their course and trust that everything will come right in the end. To a very large portion of the world this conclusion is a most comfortable one to arrive at, as it spares the ratepayer and offers no offence to the dreaded "vested interest." On the other hand, there is a considerable section of the public which cannot hear that any part of our institutions is not absolutely perfect without being thrown into a state of nervousness and dread, a section well exemplified on the occasion of a former report by a paper which stated that—"We must face the dreadful fact that no amount of filtration can free our water from the nitrates and nitrites which are amongst the most deadly of poisons!"

No person of ordinary common sense can fail to perceive the folly of the alarmist school, but to the non-scientific public the fallacies of those whose cry is *stare super vias antiquas* are much more difficult to detect. Unfortunately the education through which most of the present generation have gone is not one which can enable them to arrive at any correct judgment as to the value of statements made by one scientific witness as compared with those made by another; the natural result of their education is in fact to cause them to attach a great value to the statements of a man who has a reputation for what is known as "popular science," and to regard the real worker or knower as an amiable enthusiast or eccentric theorist who is so carried away by his fancies that he is quite incompetent to pronounce upon practical matters. The same habit of mind induces them to value the statements of those whom they are pleased to call "practical men," who are generally men having an empiric or imperfect knowledge of certain processes. The result of this is that the opinion of one who has a mere smattering of chemistry, and therefore considers himself qualified to speak on all chemical questions, is pitted against that of one who has devoted his life to chemical and physical science, and the puzzled outsider sits down exclaiming, "Who is to decide when doctors disagree?" Again, this state of things is pretty well known to the people who are put on their trial by the allegations of those appointed to inquire into sanitary affairs, and they know well enough where to lay their hands on those who will make the best of a case entrusted to them; and we cannot help thinking that if it were possible to tabulate the names of the scientific witnesses called during the last ten years on the side of sanitary reform or on the side of those who considered their interests endangered by it, some curious facts would be brought to light.

A letter from Sir Edmund Beckett, in the *Times* of January 10th, illustrates the state of the case remarkably well. The writer, speaking of letters by Mr. Denton and Lord Camperdown, says that if they had heard as much scientific evidence about water purity as he had, one would have been less puzzled and the other less alarmed; and he then goes on to say that—"They would then have known that the late Report is only what every person of experience in hearing such evidence could have predicted with certainty from the constitution of this commission." We may add to this, that any thoroughly competent commission of chemists working with a trustworthy process, could not have arrived at conclusions greatly different from those arrived at by the reporters. The writer then proceeds to say:—

"I have heard eminent scientific men assert on their oaths—and they always add that these things are 'not opinions, but facts'—that the water of a moderate-sized river receiving the unpurified sewage of half a million people was perfectly good, potable water for a town not many miles below the sewage-supplying places. That is a specimen of what we may call the impurist philosopher's view of water.

"On the other hand, there is a school which maintains, with equal positiveness, the theory that no length of run (within such distances as we are practically concerned with) purifies sewage by oxidation, but that a particle of sewage, or whatever other learned name they call it, sent into the Thames at Oxford arrives as a particle of sewage at Hampton, and may poison a man in London. It is true that they do not quite like the proposition reduced to those very bare terms, but they cannot deny, when they are pressed by a little cross-examination, that it is the logical consequence of their theory."

We very much regret that the names of the "eminent scientific men" who make the first assertion have not been given, as we should then have some means of ascertaining the value to be attached to their assertions. With regard to the latter statement we think that the writer to a great extent entirely misses the point. Very few scientific witnesses will maintain that Oxford sewage *at present* reaches Hampton as sewage; the question is, How long will the present state of affairs remain? With our rapidly-increasing population the volume of sewage yearly poured into a river at any one point must increase, as do the number of points at which sewage is poured in; and the questions really asked of the public are—How long do you suppose that this can go on before the river-bed is coated with sewer mud and becomes, as hundreds of streams which a few years back were clear and bright have become, an open sewer? And is it not better to take such measures as shall prevent such a state of things from coming about than to wait until the pollution becomes unbearable?

The writers of the report in question are perfectly well able to fight their own battles, so that we do not think it necessary to enter into any elaborate defence of their suggestions, but we must protest against their being treated as visionaries, and their statements being judged as of no more value than those of the "eminent scientific men" who say that a moderate-sized river can receive the sewage of half a million of people and yet be a "perfectly good, potable water not many miles below the sewage-supplying places."

We are in no danger of the theory of "*sanitas sanitatum omnia sanitas*" being pushed to excess by sanitary zealots; and for the present, at any rate, the teaching of the Rivers Pollution Commissioners has been nothing more than "take care of the sewage, and the water supply will take care of itself."

LIEUT. CAMERON IN CENTRAL AFRICA

THE first detailed news of the latter half of Lieut. Cameron's trans-African expedition was read at the Geographical Society on Monday night, in the form of extracts from letters of the explorer, who intends to remain at Loando until he has a chance of finding a genial climate here. We do not yet possess details sufficient to authorise us in drawing final conclusions as to the results so far as the great problem of Central African drainage is concerned; though we are quite justified in concluding that Lieut. Cameron has proved himself to be possessed of the qualifications of an explorer of the first rank, and that means ought to be found of making still further use of his valuable services. He has not been able to accomplish all he intended when he set out from Ujiji in March 1874, but he has certainly added very largely to our accurate knowledge of Central Africa. He was not able, owing to the hostility of the natives, and the want of pluck in his followers, to follow the course of the Lualaba in order to ascertain whether or not it joins the Congo. He has, however, obtained data which render it very improbable that the Lualaba and Tanganyika contribute to the Nile system; the only known outlet of the lake, the Lukuga, he has ascertained, flows into the Lualaba. This latter river at Nyangwè is only 1,400 feet above the sea, or 500 feet below the Nile at Gondokoro, and lies in the centre of an enormously wide valley, "which receives the drainage of all this part of Africa, and is the continuation of the valleys of the Luapula and Lualaba." Cameron found that the river, contrary to Livingstone's report, really turns to the west below Nyangwè, and the Arabs report that further down it flows W.S.W. A river, the Lowa, said to be as large as the Lualaba, at Nyangwè, joins it from the northward a short way farther down, besides other important rivers from the same direction. Cameron failed to make his way to Sankorra, a lake into which the Lualaba falls, and to which "trowser-wearing traders are reported to come in large sailing-boats to buy palm-oil and dust (probably gold) packed in quills."

Lieut. Cameron traces with considerable minuteness the course of the Lualaba to some distance below Nyangwè. He shows that the true Lualaba in its upper course is the river to the west of Lake Bangweolo, crossed by the Pombeiros in their trading journeys to Cassembe's Town, and that Livingstone's Upper Lualaba is properly called the Luvwa. The river receives many tributaries during its course to Nyangwè, and passes through a number of lakes, so that by the time it reaches its final destination it must be a river surpassed in volume by few others.

All this seems to indicate that the Lualaba reaches the sea on the west coast, but that it does so by means of the Congo it would at present be unsafe absolutely to assert, though if it do not, what other Central West African river is of sufficient size to carry off the immense drainage which the Lualaba evidently represents?

On account of the vexatious obstacles to his course along the Lualaba, Cameron turned southward, and during his journey south and then west to Benguela he made many valuable and accurate observations which will help greatly in filling up that portion of the map of Africa. Some distance south of Nyangwè he came upon a small lake Mohrya, fed by the rains, and apparently isolated from the rest of the water-system, but which is interesting as containing regular lake-villages. He is inclined to believe that the Albert Nyanza is much smaller than Sir Samuel Baker makes it, and he found that the Lomâmi has no connection with the Kassabè, as shown in the map published by Keith Johnston. In the southward march Cameron passed the sources of the Lulua, which runs into the Zambesi, whose sources he places in 23° E. long. and 11° 15′ S. lat.

Cameron gives the most glowing description of the productiveness of the country through which he has passed; coal was found, gold, copper, iron, and silver are abundant, and he is confident that with a moderate expenditure of capital "one of the greatest systems of inland navigation in the world might be utilised." Multitudes of tropical products abound, and the region is well adapted for the cultivation of extra-tropical ones. A canal, he thinks, of twenty to thirty miles in length, would connect the Congo and Zambesi systems, and the resulting commercial advantages would be enormous. So the enthusiastic traveller believes, and whatever may be the results in this direction, the gains which have accrued to accurate geographical knowledge from his journey are such as must earn him the warmest thanks of the friends of science. He has taken 400 observations, "and consequently," as Sir Henry Rawlinson remarked, "has soundly established all the geographical landmarks of the country."

MORELL'S "EUCLID SIMPLIFIED"

Euclid Simplified. Compiled from the most important French works, approved by the University of Paris and the Minister of Public Instruction. By J. R. Morell, formerly H.M. Inspector of Schools. (London: Henry S. King and Co., 1875.)

EUCLID simplified! "My friend M., with great painstaking, got me to think I understood the first proposition in Euclid, but he gave me over in despair at the second." Had Elia lived in these days of modern geometries perchance he had been a moderate geometer, but his wit might have been dulled. The book before us, however, is not the book we should recommend to a sucking geometer. We look upon it as one of those private ventures which we hope the Association for the Improvement of Geometrical Teaching will extinguish. There is hardly a page without its crop of faults. The title we consider to be a misnomer, for the method of Euclid (the geometer) is departed from altogether. We should look to find in a "Euclid Simplified" something far different from this. The treatise is based upon good geometrical authorities, as will be seen by a reference to the prefatory remarks; it is to the form in which these authorities are presented that we object. Who is the interpreter? A former "H.M. Inspector of Schools." We have been wont to look upon these gentlemen as masters of one or more tongues, and as having a fair acquaintance with the

"ologies." We have not formed a high opinion of the geometrical attainments of this compiler, nor do we consider him to be well versed in the French language, or even in elegant English composition. "Quis custodiet ipsos custodes?" It is "a work offered for the use of schools;" it is essential, then, that the writer should take all due precaution to be accurate. We think, further, that he should rather be disposed to retain terms with which boys are fairly acquainted, if they are correct, than to be constantly using terms and phrases which betray their Gallic descent. Thus pp. 23, 55: "angles are equal *as opposed at* the summit;" p. 40: "this corollary *gives occasion to*;" pp. 110, 112: "shows that to *have* point *c*;" p. 141: "operating in the same *measure*" (? way); p. 166: "three points taken in *equal number* on the sides of a triangle and in *unequal number* on its sides produced;" p. 168: the centre of similitude is the *meeting-place*," &c.; we shall get to rendezvous in time. The words "passing *by* a point" (*par*) occur repeatedly; on p. 108 we have "*by* point *D* draw in like maner (*sic*);" pp. 41, 42, furnish "perpendicular to the centre," "perpendicular to the middle," and so on.* It is hardly good English to say one point becomes confounded with another point, pp. 46, 97, 127; the boy-mind is apt to confound the different steps of the reasoning, and the boy often is tempted to exclaim, "Confound it altogether." "Cord" of a circle would not be difficult to make out by one who had read French mathematics, but at a "spelling-bee" we should prefer the candidate who spelled it "chord." But to return to the prefatory remarks. These have no signature, so we cannot be sure that it is Mr. Morell who writes "it is anticipated that it will prove more practically useful than most other school-books on the subject." We should expect, too, some recognition of the work accomplished by the association referred to above, the more so as Mr. Morell was at one time a member of the association. We should have been disposed to think that he has employed some one to make the compilation and translation, and has not carefully revised the work himself; but then against this we have the title-page. Were we to note and comment upon every passage we have marked, we should tire our readers. We shall content ourselves with culling a few elegant extracts. Many of the enunciations are loosely, if not always incorrectly, worded. Parallels are treated of in p. 21 before any definition of them has been given. On p. 24 we are told the term *transversal* is new to English schools: "it explains itself," and we are favoured with its derivation; in like manner, on p. 73 we are informed that *harmonics* have been "recently introduced in French geometry;" in the same note a specimen is given of "the new and interesting treatment of this question (*i.e.* harmonics) abroad;" on p. 72 we have a note on the word *capable*; "this term—used in French treatises—explains itself, if traced to its Latin root, *capax*, holding, a segment capable of an angle = a segment holding an angle." And on p. 104: "this circumference, by the well-known construction of the capable angle, will pass by point *B*."

A parallelogram is defined to be a quadrilateral, of which the opposite sides are *equal*; in theorem xxxi. he subsequently proves this. The term *lozenge* is used in the text, and a note tells us that the figure is called "*rhombus* in the old-fashioned Euclid." A terrible mess is made of *circumference* on p. 36. "*The* circumference is a plane line, of which all the points are equally distant from one same point situated in the middle and named centre." This is not so bad as the common school-boy definition: "a circle is a plain figure bounded by one straight line, and is such that all straight lines drawn from a certain point in its centre to the circumference are equal;" but it is not what we should expect in a text-book for boys. Again, "a circumference is generally described in language by one of its radii." The italicised *the* is easily accounted for when we remember the source from whence the definition is taken; here, of course, it ought to be *a*, but on p. 51 we ought to have *the* for *a* ("A polygon is inscribed in a circle when its summits are situated on the circumference). Reciprocally (Mr. Morell's term for the usual conversely), *a* circle is said to be circumscribed round *a* polygon," that is, the circle and polygon previously mentioned, otherwise the definition is incomplete. No distinction is made of *major* and *minor* arcs. Thus, p. 39: "of two unequal arcs the greater is subtended by the greater chord;" this is, of course, only true of minor arcs. On p. 66 he bisects a given arc without having shown how to bisect a given line. On p. 70 C, C' have been wrongly printed in three places. On p. 81 homologous is derived from ὁμοῖος and λόγος (p. 9, isosceles from ἴσος is doubtless an oversight). On p. 85 occurs a passage we cannot understand; he has a quadrilateral $ABCD$, and then draws EF (E on AB, F on CD) parallel to BC; he says rightly the angles of the two figures are equal, but the sides not in the same proportion; then he proceeds to say "in like manner, without changing the four sides AB, BC, CD, (*sic*), point B can be brought near or removed from D, without changing the angles." We cannot understand it, and so do not see it.

In the first note on p. 91, boys are informed that M. Chasles is "Professor of Superior Geometry at the Collége de France, and one of the first geometers of the present age;" in the second, "homothetie" is derived from ὅμοιος and θέσις; in the third, "radiivectors or vectores are the straight lines drawn from the two foci of an ellipse to any one point of the circumference of an ellipse." On p. 122 we are told that the ratio of the equilateral triangle inscribed in a circle to the radius is $\sqrt{3}$, whereas it ought to be (as is proved in the text) the ratio of the side of the equilateral triangle, &c. On this page, and also elsewhere, we have R used for a right angle; this is, we think, likely to mislead boys: nor do we approve of the expression, "each of these angles will be *worth* $\frac{2}{3}R$." R is usually employed to denote the radius of the circumscribing circle of a triangle. Pages 132, 133, bristle with blunders, due partly to the editor, but principally to the printer. On p. 134, for "pentagon" read "pentedecagon" (a purism for "quindecagon"). Page 136, on the calculation of the ratio of the circumference to the diameter, we read: "The complete solution of this problem belongs to superior mathematics. Therefore it is here less aimed at giving a method to calculate this ratio than to give a notion that it is possible to do so." This last sentence strikes us as not

* For pp. 11, 20, "two triangles are equal *as having* an equal angle,' &c., we should prefer "*because* they have," &c.

being particularly elegant. On pp. 144, 145, in the proof of the important proposition that the ratio of any two rectangles R and R' is the same as that of the product of the height and base of the first, to the product of the height and base of the second, there are two, at any rate typographical, errors which would exceedingly trouble boys or the ordinary run of self-taught students. Also in a numerical example to this proposition the writer correctly gets $\frac{R}{R'} = 4\frac{1}{2}$, and then says the first rectangle is $4\frac{1}{2}$ times *greater than* the second rectangle. On p. 148 the reasoning in theorem vi. is defective, and in the scholium there is a misprint; it is, however, not necessary to dwell fully on this Book V., which is especially faulty. We shall close our remarks on the text by quoting a sentence on p. 171, simply remarking that we could have extended our criticism to twice or thrice the dimensions of the present notice. The sentence is: "The further development of the Theory of Transversals is reserved for a special treatise on Modern Geometry, with a popular view of the recent improvements introduced by M. Chasles." May it be reserved to the Greek Calends! say we. Who and what is Mr. J. R. Morell, that he should venture to act as interpreter of M. Chasles' brilliant contributions to Geometry? Such a work brought out by a competent writer would be of great use. It was in 1871, that Mr. Morell published "The Essentials of Geometry, Plane and Solid, as taught in French and German Schools, with Shorter Demonstrations than in Euclid," &c. After the reception this little work met with one would have hoped that the author would have learnt wisdom, and before he sent forth another such work into the world would have submitted it to one or two candid and competent geometrical friends. The book might yet be made a very fair one, but as it is at present we must condemn it most strongly.

There is an appendix of 205 exercises, and we have marked upwards of forty as each containing something objectionable in language or in geometry. We must content ourselves with a selection:—30. Given a rectangle and a point *situated in the interior of a quadrilateral;* it should be "and a point within it" (or some such words; it is the billiard-table question which is given in many French text-books). 40. A triangle and any plane figure, *in general movable in a plane*, &c. 42. *Which* is the geometrical *locus*, &c. 103. A question of two concentric circles: in the *great* circle, in the *little* one. 116 is not neatly put; it is, "What is the geometrical *locus* of the centres of the circles which intersect *orthogonally*—that is, forming a right angle—two given circles?" 143, 193, he uses *in the function*, where an ordinary geometer would write *in terms of*. *In such wise* and *in* (for "into") frequently occur. Before closing our article, we must point out that the work we have examined is not to be *confounded* with "The Elements of Geometry in Eight Books; or, First Step in Applied Logic," by L. J. V. Gerard, which forms a volume in Dr. J. D. Morell's Advanced Series for Colleges and Schools. This is the work of an able and judicious writer; we must at present content ourselves with merely commending it to the notice of any of our readers interested in the subject. A word of praise we can extend to the external aspect of "Euclid Simplified," it has a neat and geometrical design on the cover.

TISSANDIER'S PHOTOGRAPHY

A History and Handbook of Photography. Translated from the French of Gaston Tissandier. Edited by J. Thomson, F.R.G.S. (London: Sampson Low and Co., 1876.)

ALTHOUGH one may reasonably object to the statement made by an eminent French *savant* that "chemistry is a French science," there is no denying the fact that photography, so far as its early history is concerned, is eminently a French art. M. Tissandier, the author of the work now before us, of course does not fail to impress this fact repeatedly upon his readers by speaking of photography as the "art of Daguerre," and indeed throughout the book he places his own countrymen in positions which might in some cases be justly considered as somewhat too prominent. The addition of some few historical notes, however, by Mr. Thomson, the editor, renders the work, on the whole, as fair a history of the subject as we could wish to read.

Of the three parts into which the book is divided the first is entirely historical, commencing with a description. of the camera obscura of Porta, and the discovery of "Luna Cornea" by Fabricius, and then proceeding to the early experiments of Prof. Charles, Wedgwood, Davy, and Watt. The connection of Daguerre with the first development of photography is of course known to all. The early life of Daguerre forms the subject of the second chapter, and the author here relates an incident which may be new to many of our readers.

It seems that in 1825 a poorly-dressed young man entered the shop of Charles Chevallier, which was at that time much frequented by amateurs, and demanded the price of one of the new cameras with converging meniscus lenses, which were then being made for the first time. The young man's manner showed that the price named was far above his means, and Chevallier then inquired for what purpose he required the camera. The stranger declared that he had succeeded in fixing the image of the camera on paper, but that the instrument he had employed was of rough construction, and he was anxious to continue his experiments with the improved apparatus. Chevallier being sceptical as to this statement, the young man placed on the counter before him a piece of paper, on which appeared a view of Paris, and on further questioning gave the optician a vial of blackish fluid, which he stated to be the liquid with which he operated. To continue, in the author's own words:—"The unknown explained to the optician how he should go to work; then he retired lamenting his hard fate, which would not permit him to possess that object of his dreams, a new camera! He promised to return, but disappeared for ever." It may be added that Chevallier could get no result with the liquid left with him. The incident was related to Daguerre, but the unknown inventor never appeared again, so that his name and fate remain a mystery. The succeeding chapters contain an account of the life and labours of Nicephore Niepce, and a history of the partnership entered into between this gentleman and M. Daguerre. Niepce's process, it will be remembered, depended upon the fact that "Bitumen of Judæa," when exposed to light, becomes insoluble in oil of lavender. Daguerre, continuing his researches under the

new act of partnership, at length discovered (accidentally, according to the present account) the action of light upon a film of silver iodide. "Photography was henceforth a fact"—unfortunately, however, at this time his partner died, and Daguerre was left to continue his work alone.

The history and progress of the new art of Daguerreotype is then traced, its purchase by the Government described, and the discovery of accelerating and fixing agents gone into. The editor at this stage reminds us that the use of sodium hyposulphite was first made known by Sir John Herschel, but Mr. Thomson erroneously terms this salt a "developing agent." We next arrive at that period of the history when the improvement in lenses effected by Chevallier enabled the time of exposure necessary for a Daguerreotype plate to be reduced, but even then the sitter had to remain motionless for four or five minutes in full sunshine! The torments of the unfortunate patient undergoing this ordeal are very graphically described. The name of Fox Talbot, who had succeeded in fixing the photographic image on paper some years before Daguerre's discovery was made known, does not appear till rather late in this history,

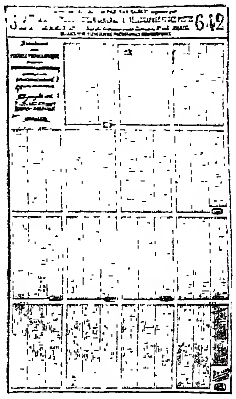

FIG. 1.—Facsimile of a microscopic despatch used during the siege of Paris.

and then in a position which we cannot but consider as too subordinate, to which effect the editor has added a note.

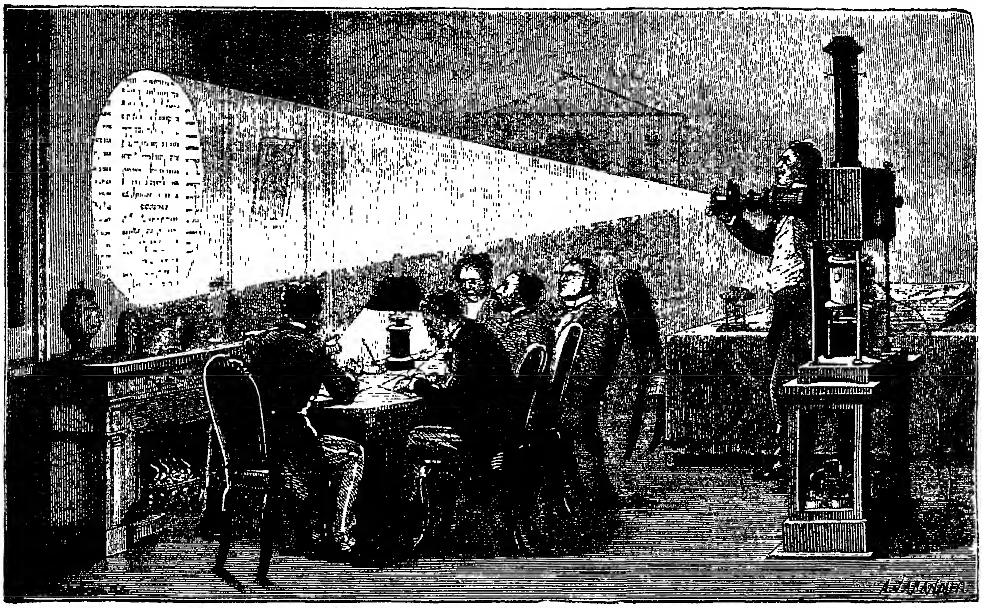

FIG. 2.—Enlarging microscopic despatches during the siege of Paris.

The next stage of photographic history brings us to the time of Niepce de Saint-Victor (nephew of the Niepce who was in partnership with Daguerre), who first discovered the albumen on glass process. The application of collodion to photography by Legray in France, and Scott Archer in England, brings the art down to its present state of development, and the author at this stage brings the historical portion of the subject to a conclusion.

In the second part of the work the operations and processes of photography are dealt with in seven chapters. The watchful vigilance which the editor has kept over the interests of British science has here for once failed. The whole credit of the bichromate of potash and gelatine process—the foundation of all the photographic permanent printing processes—is more than once in the course of the work assigned to Poitevin. "The various processes or producing positive carbon prints," writes M. Tissandier on p. 162, "are based on the principle indicated by Alphonse Poitevin in 1855." We must remind our readers that a patent for the use of bichromate and gelatine in steel engraving was taken out in this country by Fox Talbot in 1852.

Of the carbon processes that of Swan is described by the author, and the editor adds a brief account of the most recent improvements in this branch of the art adopted by the Autotype company. The last chapter of this part relates to the problems yet awaiting solution, and is chiefly devoted to an account of the attempts which have been made to photograph in natural colours.

The third and last part of M. Tissandier's book treats of the applications of photography. In the first chapter we have a description of the various heliographic and

photo-lithographic processes which have from time to time been invented, including those of Donné, Fizeau, Niepce de Saint-Victor, Poitevin, Baldus, Garnier and Salmon, Albert, and Obernetter. The second chapter, under the title of "Photoglypty," is devoted to a description of the Woodbury process, after which follow two chapters on photo-sculpture and photo-graphic enamels. Chapter V. treats of photo-micrography, and is illustrated by several excellent engravings of photographs of microscopic objects. The following chapter describes the application of photography to war. The method of sending microscopic despatches by carrier-pigeons adopted during the siege of Paris will be of interest to our readers. The despatch having been printed was reduced by photography on to a collodion film, which was then rolled up and enclosed in a quill, which was fastened to the tail of the pigeon. We here reproduce a facsimile of one of these microscopic despatches. To read the despatches sent in this way the collodion film was unrolled by immersion in weak ammonia water, dried, placed between two glass plates and a magnified image projected on to a screen by means of a photo-electric microscope (see Fig. 2).

Chapter VII. treats of astronomical photography, and touches upon the results achieved in this branch of the art by Warren De la Rue, Secchi, Rutherfurd, Grubb, &c. The author is not quite accurate when he states that for astronomical photography "it is indispensable to make use of a reflecting telescope having a speculum formed of glass silvered according to Foucault's process." The experiments of Rutherfurd show that lenses may be used with excellent results. Chapter VIII. describes photographic registering apparatus, barometric, thermometric, magnetic, electric, &c.; and Chapter IX. is devoted to stereoscopic photography.

Chapter X. treats of the applications of photography to art, while the last chapter discusses the future of photography. The author expresses a hope that among other developments which the art is destined to undergo, the time may come when it will be possible to photograph by telegraphic means.

The foregoing sketch of the book will be sufficient to enable our readers to form an estimate of its contents. The translation appears to have been carefully made, and the engravings, of which there are over seventy, are excellent. The frontispiece portrait, by B. J. Edwards and Co.'s photo-tint process, is a beautiful example of permanent photographic printing. In conclusion, we can heartily commend M. Tissandier's book as a popular *exposé* of photography.

R. MELDOLA

OUR BOOK SHELF

Morocco and the Moors: being an Account of Travels, with a General Description of the Country and its People. By Arthur Leared, M.D. Oxon, F.R.C.P., &c. (London: Sampson Low and Co., 1876.)

MANY readers, we believe, know less about Morocco than they do about Lake Tanganyika, the Fiji Islands, or the Arctic regions. Not that there are no easily accessible works on the country; no one, we conceive, who might be anxious to "get up" Morocco would have much difficulty in collecting trustworthy authorities, both in English and French. The modern general reader, however, has so much to do to keep up with a decent percentage of the literature of the day, that, unless for a special purpose, he is not likely to unshelve works of travel of a past generation; therefore, even for countries near at hand and whose names occur almost daily in Reuter's despatches, it is useful now and again to have the narrative of a recent visit. Morocco, though comparatively near us, yet in many respects is so isolated and so far behind the age, that a trustworthy account of its condition is welcome. Dr. Leared was only a few weeks in this country in the autumn of 1872. He landed at Tangier, visited the neighbourhood, sailed down the coast to Mogador, calling at one or two places on the way, and at a time of great internal disturbance visited the city of Morocco, where an attempt was made to poison him, happily without success. He managed to make a very good use of his time and his eyes and his introductions, and the reader will find many interesting observations on the people and the country. Dr. Leared has, however, not confined himself to his own observations, but has evidently diligently studied various authorities on the country, and taken trouble to acquire information from various quarters. The results he presents throughout the work as he goes along, and especially in a series of concluding chapters on the country and the people, government, law, education, superstitions, agriculture, natural history, &c. The appendix contains a variety of valuable material, including meteorological observations for Tangier and Mogador. Dr. Leared is strongly impressed with the value of Morocco as a resort for phthisical patients, the climate in some parts, he thinks, being in this respect superior to that of almost any other place. To anyone wishing to have a pretty full, and on the whole trustworthy account of the present condition of Morocco, we can honestly commend Dr. Leared's book, which, we should say, contains a small map and numerous illustrations.

Tyrol and the Tyrolese: the People and the Land in their Social, Sporting, and Mountaineering Aspects. By W. A. Baillie Grohman. With numerous illustrations. (London: Longmans, 1876.)

WHATEVER other qualities Mr. Grohman's book may possess, it is at least intensely interesting. The author is by birth half a Tyrolese, and he has spent several years in the country, evidently living frequently in all respects as a native, and thus having unusual opportunities of becoming thoroughly acquainted with the country and the people. What we have said in speaking of Dr. Leared's work on Morocco, might be applied with equal force to Tyrol, which, although the yearly resort of hundreds of tourists, is known to most only on the surface. Mr. Grohman's chapters give one a very satisfactory idea of the character and customs and general life of the people, and his sketches of the mountain scenery and of the habits of the chamois and black-cock are interesting, and in the latter case may furnish naturalists with a few additional facts. The people themselves are evidently made of splendid stuff, but at present rough and raw, and sorely in need of being polished. They are overridden with superstition, and in many of their customs, especially in the matter of social morality, have a strong resemblance to what the Scotch were generally a generation or two ago, and are still in some remote districts. The book is mostly occupied with Mr. Grohman's personal adventures, and one is sometimes inclined to suspect that these have been pieced together so as to tell effectively. This, however, simply adds to the interest, and does not detract from the value of the work. One of the most interesting chapters describes an ascent of the Gross Glockner in the dead of winter by the author and four guides. The illustrations are very beautiful, and the book, we should think, is likely to find many readers.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The Late Eclipse

An answer to Mr. Proctor (vol. xiii. p. 186) is unnecessary to those who know all that has been written on the possibility of photographing the spectrum of the corona, but I take the liberty to give a few quotations out of the literature on the subject for the benefit of those who take an interest in the discussion, yet had no opportunity of following it in detail. Want of space prevents me from quoting all the letters in full, but I believe that I have not left out anything which might alter the sense of the quotations. The passages which seem to me to be important to the point at issue are printed in italics.

1. Letter to the Editor of the *Daily News*, signed Richard A. Proctor, January 26, 1875:—

"It is said that some enthusiastic students of science propose to try to get photographs, not of the corona as seen in a telescope, but of the exceedingly faint coronal image seen with a spectroscope. If they succeed they will have achieved a clever photographic feat, but the result, so far as the corona is concerned, can have little scientific value. *It is mathematically demonstrable that this is the case, for the quantity of light actually forming the coronal image can be shown to be far less in amount than is necessary for the formation of a satisfactory photograph.*"

2. Letter signed "A Fellow of the Royal Astronomical Society" (*English Mechanic*, May 21, p. 248):—

. . . . "But if Mr. Proctor should take upon him to answer the first of these questions in the affirmative, the second in the negative, then I could ask him *whether any body or any set of men possessing the slightest knowledge of the subject could or would have issued the preposterous instructions about photographing the spectra of bright lines in the corona, which emanated from the Royal Society?* The bright lines in the corona! Why, it has been recorded again and again by skilful observers that so faint is the light of the whole corona during the totality of a solar eclipse, that it casts no shadow whatever; and we know that the outer parts of the corona failed utterly to impress a collodion plate in five seconds, upon which a sharp and effective image of the partially eclipsed moon impressed itself in 0·1 second with a longer focussed telescope!"

(I should not have quoted in your columns any remarks of this anonymous writer had not Mr. Proctor's reference to them in the following letter rendered it necessary.)

3. Letter from Mr. Richard A. Proctor (*English Mechanic*, May 28, 1875, p. 272):—

"With respect to the eclipse observations last April, I have already said, as 'F.R.A.S.' does (let. 9,113, p. 248), that the failure of the Government expedition was rendered certain by the instructions of the Royal Society Committee. I pointed this out also before the expedition started. *I agree with 'F.R.A.S.' entirely in his interpretation of the matter.*"

Taking these letters in connection with what Mr. Proctor now writes, the following seems to be Mr. Proctor's opinion:—

It is mathematically demonstrable that "the quantity of light forming the coronal image is far less in amount than is necessary for the formation of a satisfactory photograph" (*Daily News*), yet "Dr. Schuster proves very readily that the spectrum of the corona can be photographed in one minute" (NATURE).

Mr. Proctor "is not aware that anyone has questioned the fact," but he "fully agrees with an anonymous writer that no set of men having the slightest knowledge of the subject could have issued the instructions which emanated from the Royal Society."

The failure of the Eclipse Expedition was rendered certain by the instructions of the Royal Society Committee to photograph in four minutes what Mr. Proctor admits to be capable of being photographed in one minute.

Anything which Mr. Proctor could have written on the subject besides what has been quoted, as, for instance, the passage in "Science Byeways," he alludes to in his letter, can only add to the hopeless confusion which must bewilder anyone trying to form a correct and fair estimate of his view on the matter.

Everybody will agree with Mr. Proctor that such a controversy is not likely to be of any service to science.

Upper Avenue Road, Jan. 1 ARTHUR SCHUSTER

The Fossil Skeletons of Le Puy en Velay

As there is to be a meeting of the Scientific Congress of France in Auvergne and Velay next summer, it may be useful to direct attention, through the columns of NATURE, to certain difficulties connected with the supposed antiquity of the fossil human bones preserved in the Museum of Le Puy.

With respect to the position of the bones, I visited the locality they were supposed to be found in last September, in company with some friends, and we were conducted, by the peasant who professes to have found them, to a well near the little auberge, where he now resides, and which is certainly a very different spot to that indicated by Mr. Poulett Scrope in his sketch at page 182 of the "Volcanos of Central France." The locality given by Mr. Scrope is much higher up the hill than is the well we were shown near the "Hermitage." Sir Charles Lyell also, according to the "Antiquity of Man," p. 229, was conducted to a spot "not far from the summit of the volcano." The well of the Hermitage is a long way from the summit of the hill.

It has long been observed that the rocky matrix in which the human bones have been enveloped is altogether different from the matrix of the rock where they are said to be found. This is certainly the case as regards the matrix of the rock in which the well is situated, which is a coarse volcanic breccia, while the bones lie in a volcanic sandy mass with a mixture of tuff and lime. I especially wish to direct attention to the position of one of the larger bones marked (I think) as an "iliac bone" in the Museum. The laminated mass between which it rests appears to me *stalagmitic*, as if these human remains had been washed into a fissure through which the water percolates downwards to the well of the Hermitage, and of which traces may be found higher up the hill.

I would also direct attention to certain stratified breccias near the western summit of the hill of Denise, which we thought looked more like the result of melting snow and the action of running water than of "volcanic alluviums," to which they have been generally attributed. These may be seen beyond the Croix de Paille on the road to Briowde high up on the flanks of the hill west of the volcanic outburst known as "The Chimney." The black and red scoriæ shot out through this "chimney" cover the summit of the hill and overlie the stratified breccias. But these breccias are, if I read the geology of the district aright, the equivalents of those which, on the slopes of Denise, west of Polignac, have furnished the bones of the mammoth and tichorhine rhinoceros, and belong to glacial times.

The antiquity of the human skeletons must, I suggest, depend upon the correct determination of the spot where the bones were found. It is possible that they may belong to the age of the stratified breccias, and were washed into a crack or fissure during the Mammoth epoch, but they certainly do not look like it, if we may judge from the matrix in which they are enclosed. It is possible that they were enveloped in volcanic materials which were evolved during the last volcanic outbursts, for I believe that at Le Puy en Velay and in the Ardèches there have been eruptions of scoriæ and ashes through volcanic vents and chimneys since the glacial epoch, when deep snows covered the summit of Denise in the winter time and the mammoth pastured in the vales. W. S. SYMONDS

A Meteor in the Daytime

The meteor referred to by the Rev. T. W. Webb was also seen at Dorking and at Southampton. The times given were "about 1.38 P.M." and "1h. 38m. 45s. P.M.," Dec. 22. Mr. H. J. Powell, writing to me from the former town, says: "Its course was from S.S.E. to N.N.W., and it shot down the sky so—  It had no well-defined outline like the moon, but was merely an irregular luminous ball. Its size as compared with the moon was about one-sixth. Its motion was not a very rapid one, but more like a cricket ball (after it has been thrown) falling. I did not hear any sound after its disappearance." Mr. Powell, writing to the *Times*, also mentioned that it "left a long trail of fire behind it," and that the nucleus "broke up and disappeared before it had reached the horizon."

In the *Times* of the same date (Dec. 23), "F. W." writes: "In the full blaze of the sun—a rare sight in itself nowadays—I observed a bright meteor traversing the sky from south-west to north-east, in form like a common rocket."

These accounts no doubt refer to the same meteor as that observed at Hardwick. WILLIAM F. DENNING

Tyndale House, Ashley Down, Bristol, Jan. 8

Blowpipe Analysis

MAJOR ROSS (NATURE, vol. xiii. p. 186) does not appear to have thought of the impurities his soda might contain in his test for the presence of a sulphide. Had he done so he would probably have remembered that all soda (unless specially prepared from sodium) contains traces of iron. This iron, on fusing with the sulphide, forms ferrous sulphide, which, as is well known, is soluble in fused sodium sulphide; and on adding water to the fused mass a black residue of ferrous sulphide remains behind.

Again, he says "there can be no room to precipitate anything in a drop of water;" but surely this is erroneous. It is only a question of degree. Under the same circumstances a precipitate would be as certainly formed in a drop of water as in a gallon.

If Major Ross were to make allowances for the ordinary impurities of commercial reagents, a little more confidence might be placed in his tests. T. S. HUMPIDGE

Marine Aquaria

WHILE reading Mr. Wills's very suggestive article on Marine Aquaria in your last issue, the following question suggested itself to me:—Does not the "larger proportion of carbonic acid in the lowest depths of the ocean" explain, at any rate partially, the formation of the "abyssal red clay," which Prof. Wyville Thomson has proved to occupy so large a portion of the bed of the Atlantic?

"Many of the insoluble carbonates, and in particular those of lime, magnesia, &c., may be dissolved to some extent by water, charged with carbonic acid, and are deposited in a crystalline form, as the gas slowly escapes from the fluid." (Miller's "Chemistry.")

That the presence of carbonic acid in the deep water is *one* cause of the decomposition of the shells of Mollusca, &c., I think that there can hardly be a doubt. Whether it is sufficient by itself to account for the whole phenomenon, I cannot presume to decide. H. J. M'G.

Bournemouth, Jan. 10

The Glow-worm in Scotland

MR. J. SHAW'S interesting note on the Glow-worm leads me to remark that it is common about Loch Lomond, and recalls the pleasant surprise with which I met one there, shining brilliantly by the wayside, so late as twelve o'clock on a dark midsummer's night. WM. MCLAURIN

London, Jan. 10

Bryant and May's Safety Matches

THESE matches are highly electrical, and if they be rubbed against glass and ebonite they ignite, especially if the electrics be dry and warm. How far their ready ignition on amorphous phosphorus is due to chemism or to electricity remains to be proved. I am sorry I have not the opportunity just now to test this point. W. H. PREECE

OUR ASTRONOMICAL COLUMN

THE MINOR PLANET, No. 153.—This planet, discovered by Palisa at Pola on Nov. 2, 1875, and which has been named *Hilda* by Prof. Oppölzer, is found to have a period of revolution considerably longer than any other member of the group. In No. 39 of Prof. Tietjen's "Berlin Circular" is an orbit calculated by Dr. Schmidt, which represents closely the observations to the end of the year. It is as follows:—

Epoch 1875, Nov. 22, at Berlin midnight.

Mean anomaly	108° 30′ 11″	
Longitude of perihelion ...	284 41 50	1875·0
Longitude of ascending node	228 20 43	1875·0
Inclination to ecliptic ...	7 44 52	
Angle of excentricity ...	8 33 3	
Mean diurnal motion ...	452″·421	

The major semi-axis is 3·9474, and if we calculate the distance of the comet from the orbit of Jupiter at the aphelion passage, we find it 0·864, the earth's mean distance from the sun being taken for unity, which is a much closer approach to Jupiter's path than occurs with any other of the minors. Themis, for instance, the motion of which was investigated by Dr. Krueger, for determination of the mass of Jupiter, does not approach that planet within about 1·5. More than one of the small planets with the longer periods have large heliocentric latitude at the aphelion point, and do not on that account approach so near to the orbit of Jupiter as others with shorter periods and somewhat greater excentricities, and having the lines of nodes and apsides less divergent. Cybele in aphelion is 1·31 from the orbit of the great planet, Freia 1·24, and Camilla, according to the rather uncertain orbits yet available, 1·36. Hence, as suggested by Palisa, his planet Hilda is well situated for further investigation on the mass of Jupiter by the perturbations of the minor planets; it is well known, however, that this important element in the solar system is now reduced within narrow limits of uncertainty.

The above orbit of Hilda is confirmed by another computed by Herr Kühnert of Vienna from a similar extent of observations. The period of revolution is about 2,865 days, or approaching eight years, contrasting strikingly with the period of Flora, which is only 1,193 days, or a little over $3\frac{1}{4}$ years.

SATELLITES OF URANUS.—The following positions of the brighter satellites of Uranus are derived as before from Newcomb's Tables in the Appendix to the Washington Observations for 1873; they are for 11h. 30m. P.M. Greenwich time:—

	Titania. Angle.	Titania. Dist.	Oberon. Angle.	Oberon. Dist.
	°	″	°	″
Jan. 15	23·2	31·1	66·5	23·8
„ 16	3·4	34·6	34·9	35·0
„ 17	347·7	43·1	18·5	44·0
„ 18	268·7	15·8	6·1	46·1
„ 19	212·5	27·2	352·6	40·5
„ 20	190·1	34·6	331·2	29·5
„ 21	169·1	28·9	286·7	21·1
„ 22	120·1	16·5	235·4	26·5
„ 23	45·4	22·4	209·7	37·9
„ 24	16·9	33·4	195·0	45·3
„ 25	357·5	32·1	182·7	45·3
„ 26	324·2	20·2	168·0	37·8
„ 27	245·2	18·0	142·2	26·5
„ 28	202·6	30·5	90·8	21·1

THE GREAT COMETS OF 1874 AND 1680.—Now that the orbit of the fine comet of 1874 (Coggia, April 17), determined from the observations in the northern hemisphere to the middle of July, has been shown by the southern observations extending to October, to require but small corrections, we may examine with confidence the path of the comet about the passage of the descending node, when it approached near to the orbit of Venus.

Employing the elements calculated by Dr. Geelmuyden, of the Observatory, Christiania, we have the following results:—

Heliocentric Ecliptic Longitude.	Heliocentric South Latitude.	Distance of Comet from Orbit of Venus.
299° 45′	2° 17′ 48″	0·003655
299 48	2 24 38	0·003181
299 51	2 31 29	0·003323
300 0	2 51 58	0·006372

Therefore, assuming the solar parallax 8″·875, with Clarke's semi-diameter of the earth's equator, the least distance of the comet from the orbit of Venus is found to have been 293,000 miles, or only about one-fourth greater than the distance of the moon from the earth.

A very celebrated comet, that of 1680, approached the earth's orbit within even less than this distance. From the definitive elements of Encke it would appear that in 92° 3′·5 heliocentric longitude, just before traversing the plane of the ecliptic, towards the south, the comet's dis-

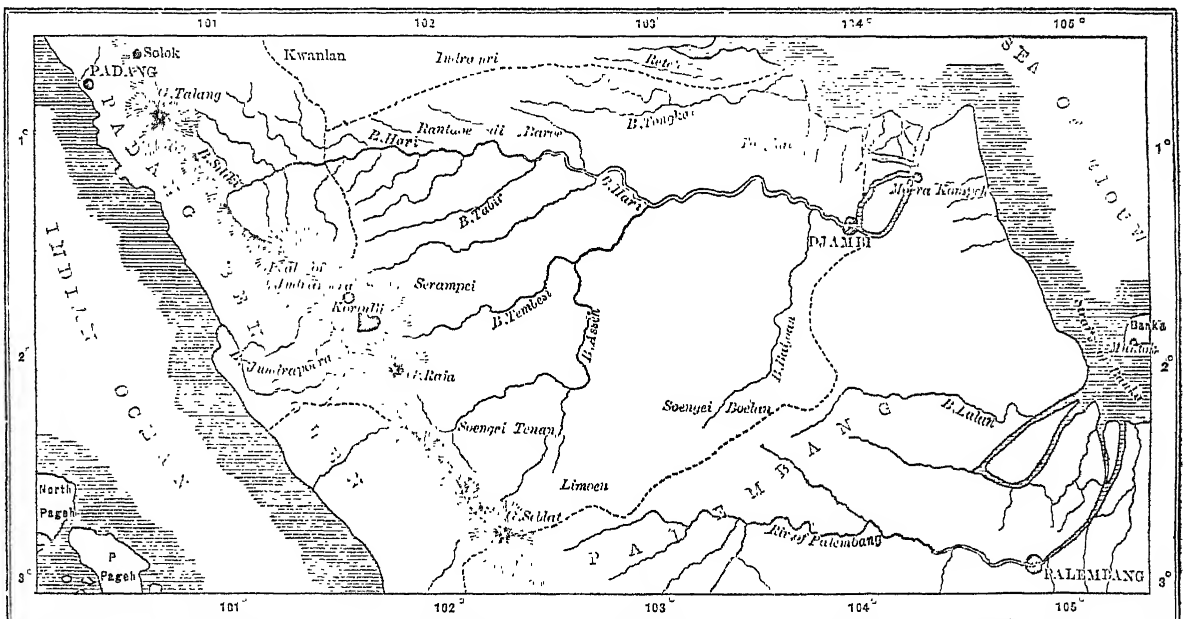
tance from our track was 0·0031, or 286,000 miles, but the earth at the time was in another part of her orbit and far away from the comet, which indeed never approached our globe within 0·42 of the earth's mean distance from the sun. To have brought the two bodies into their closest possible proximity in 1680, it would have been necessary that the comet should have arrived at perihelion at midnight on the 18th of January, 1681, in which case they would have met on the night of December 22.

No comet is yet certainly known to have been situate nearer to the earth than 1,390,000 miles, which was the distance of Lexell's comet of 1770, on July 1, at 5 P.M. G.M.T.

AN EXPLORING EXPEDITION TO THE INTERIOR OF SUMATRA

ONLY a short time ago the Geographical Society of Amsterdam took the first preliminary steps towards the realisation of a long-cherished idea,—the exploration of those parts of Sumatra which have hitherto been indicated by white patches on our maps of that island, even though they form part of the colonial territory. These regions are bounded to the south by the residencies of Palembang and Bencoolen, to the east by the Straits of Banka and the Sea of Riouw, and to the west by the highlands of Padang and the chain of volcanic mountains which traverses the island in its whole length, running parallel to the coast. All the above-named districts are tolerably well known, the native kingdoms of Reteh, Indragiri, and Kwantan, situated farther north, perhaps excepted. It is this white patch, better known under the name of the Djambi territory, which the expedition will choose for the special object of its researches.

For more than one reason this and no other part of the interesting island has been chosen. In the north the war with Atchin is for the present an impediment to a peaceful party of explorers, although a better acquaintance with those tribes of the Malayan race known as the Battaks would be highly interesting from a linguistic and ethnological point of view. This having to be given up, the question of the navigability of the Djambi River, which might, moreover, prove of so much importance on commercial grounds, induced the Geo-



J.D Cooper. Sc.

graphical Society definitely to fix its choice on the indicated parts, rather than on Indragiri, Reteh, or any of the above-named districts.

The only European who has ever visited the domains of the Sultan of Djambi, and has left any official documents about the state of things as he found them, was the Palembang resident van Ophuyzen, who, in 1869, travelled a good way up the Djambi River, with the Government steamer *Beni*. Unfortunately, he was obliged to return sooner than he wished, for reasons dictated neither by the hostility of the population, nor by the barrenness of the country; on the contrary, he has reported very favourably on both these points. He had, moreover, occasion to notice the existence of several important tributary rivers, and as far as his survey extended he found the Djambi itself everywhere navigable. His reports to the Government at Batavia have formed a valuable basis upon which the Geographical Society has drawn up its projects for the present expedition.

The body of explorers will begin by separating into two parties, one of which will ascend the river in a steamer which it is expected Government will place at their disposal, the other party starting from Padang and passing the mountain chain above-mentioned somewhere between the volcanoes of Talang and Indrapoora, will try to follow the course of one or more of the Djambi tributaries—more especially the Batang Hari—from its source up to the point where they will meet the steamer with the rest of the explorers, who will have in the meantime ascended the river as far as possible.

This junction having been effected, the next task will be the detailed survey of the different courses of the Sangit, the Teboo, the Tabir, and the Tembesi, the party all the while slowly advancing towards those mysterious valleys in the interior of Korintji, Assei, &c., which have afforded so much matter for speculation, and about the beauty and fertility of which most wonderful accounts have long been circulated. For the only reliable data we possess, we are indebted to natives who have travelled to the coast for commercial purposes, information which cannot but be very imperfect. Unacquainted with the disposition of the inhabitants towards European intruders, our travellers will have to feel their way, using the utmost circumspection not to rouse the distrust of the population, which would undoubtedly be the case if Government was directly associated with the expedition. The natives would not fail to

look upon this as a warlike demonstration, and their love of independence would then prevent the exploring party from accomplishing its task.

Not only from a geographical and ethnological point of view is this expedition expected to be a brilliant success, but also in the several departments of natural history the results are likely to be of high scientific value. A naturalist is to be appointed, who will accompany the explorers and enrich the zoological and geological departments of the national museum of Holland with interesting specimens from regions hitherto so superficially known.

There is some probability of a botanist being appointed by a committee of botanists and horticulturists, who will pay his expenses, and thus make the expedition profitable for this department of natural science as well.

The staff of the expedition will further consist of an able geographer, to whom the topographical department is to be confided, and of a linguist, who will study the languages of the tribes met with. It is a curious fact that in Sumatra the languages spoken by contiguous populations show very considerable differences. He will at the same time be able to serve as an interpreter, where this may prove necessary, and will no doubt have occasion to gather some interesting ethnological data. An artist will complete the party of explorers, which is to leave Holland in the beginning of next summer.

It is expected that one or more able naval officers will be appointed by the Indian Government to the command of the vessel in which a great part of the surveying work is to be done. They will of course bring a most welcome support to the geographer, to whom assistance of this kind may prove almost indispensable.

As to the financial side of the question, the expenses required to carry out the scheme when reduced to its most simple dimensions, have been evaluated at 2,000 guineas. The Geographical Society, having been founded only a couple of years ago, has no funds at all at its disposal, and so an appeal has been made to the public, scientific and commercial, with a view of obtaining the required money by private efforts only. Government will not be applied to before the subscriptions have surpassed the above sum, and when the possibility of realisation will thus have been assured. A Governmental subsidy will then not be a *conditio sine quâ non* for the expedition, but only a means of giving it a wider extension, of bringing within its range a larger field than the original 2,000 guineas would admit of. As the national interest in the expedition is increasing every day, it is expected that this sum will be raised within a very short time.

The Colonial Office at the Hague strongly supports the efforts of the Society, and the Government at Batavia has promised its earnest co-operation. Another favourable circumstance is to be found in the willingness of the Sultan of Djambi, now on the best terms with the Dutch colonial authorities, first, to permit of this scientific invasion into his domains, and secondly, to lend his assistance wherever this might be of any use. As a palpable proof he has already put his son-in-law at the disposal of the exploring party, for the purpose of accompanying them on their tours. Policy seems to play a part in the unexpected magnanimity of this potentate.

Let us hope the best for the realisation of all those promising plans, and may I, ere long, have the opportunity of bringing under your notice some results of an expedition by which science in general cannot but profit.

A. A. W. HUBRECHT

FERTILISATION OF FLOWERS BY INSECTS*

XII.—*Further Observations on Alpine Flowers.*

LAST year, after having spent my vacation in the observation of Alpine flowers and their fertilisation by insects, I published some articles in this journal, in order to show that, in the Alpine region, Lepidoptera are far more frequent visitors of flowers than in the plain and in the lower mountainous region, while the frequency of Apidæ, not only absolutely but to a still greater extent relatively, greatly diminishes towards the snow line (see NATURE, vol. xi. pp. 32, 110, and 169). Further, in these articles I attempted to demonstrate that some Alpine species (*Daphne striata*, *Primula villosa*, *Rhinanthus alpinus*) are adapted to cross-fertilisation by butterflies, whilst the most nearly-allied species which inhabit the plain or lower mountain region (*Daphne Mezereum*, *Primula officinalis*, *Rhinanthus crista-galli*) are cross-

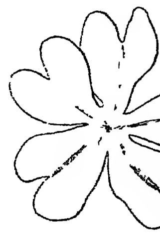


FIG 71.

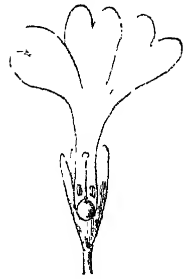

FIG. 72.

fertilised by bees; and that among the family of Orchids, by far the majority of species growing in Alpine regions are likewise adapted to Lepidoptera.

Last summer having revisited the Alps, in this and following articles I intend to show how far the results arrived at by my first excursion are confirmed, completed, or modified by my new observations.

Firstly, I will give some additional notes concerning the species treated of in my previous articles.

1. With regard to the fertilisation of *Daphne Mezereum* and *striata*, I concluded, solely from the length and width of the corolla-tubes, and from their colour and scent, that the former were adapted to cross-fertilisation by bees and some flies, the latter by Sphingidæ and moths; but direct observation of the fertilisers was wanting. Last spring, April 14th, in the valley of Poeppelsche, near Lippstadt, watching the flowers of *D. Mezereum* in calm and sunny weather, I succeeded in confirming my previous conclusions, so far as *D. Mezereum* is concerned, by

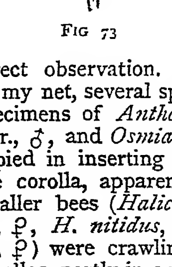

FIG 73.

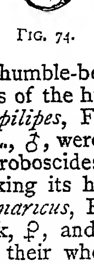

FIG. 74.

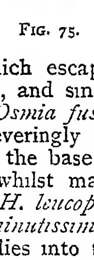

FIG. 75.

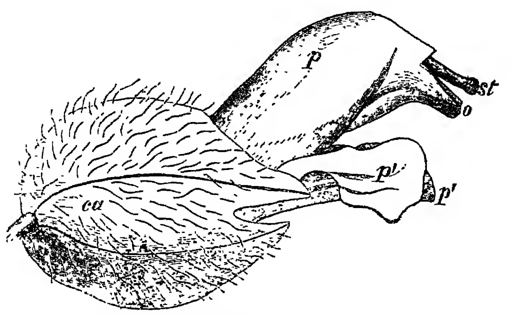
direct observation. Some humble-bees which escaped to my net, several specimens of the hive-bee, and single specimens of *Anthophora pilipes*, F., ♂, *Osmia fusca*, Chr., ♂, and *Osmia rufa*, L., ♂, were perseveringly occupied in inserting their proboscides into the base of the corolla, apparently sucking its honey, whilst many smaller bees (*Halictus cylindricus*, F., ♀, *H. leucopus*, K., ♀, *H. nitidus*, Schenck, ♀, and *H. minutissimus*, K., ♀) were crawling with their whole bodies into the corollas, partly in order to suck the honey, partly collecting the pollen. Some Muscidæ also visited the flowers, touching stigma, anthers, and different other parts, with the flaps of their fleshy mouth, and sucking the honey. Besides these Apidæ and Diptera, only one butterfly

* Continued from vol. xi. p. 191.

(*Vanessa Urticæ*) was attracted by the bright colour of the flowers, and inserted its proboscis into several of them, possibly without touching stigma and anthers.

Of *Daphne striata* I had not yet the opportunity of observing the fertilisers; but completely white flowers of this species, which I found in the pass of Strela, near Davos, may be considered as confirming my supposition that *D. striata* is adapted to crespuscular and nocturnal Lepidoptera.

2. Regarding *Primula officinalis* and *villosa*, no additional remarks are to be made. I have, however, observed another Alpine species of Primula (*P. integrifolia*), which



FIGS. 76–81. *Rhinanthus alectorolophus.** FIG. 76.—Lateral view of the flower.

is apparently adapted, like *P. villosa*, by the narrowness of the entrance of its corolla-tube, to butterflies. And with regard to some other species which inhabit higher Alpine localities (*P. longiflora*, and *P. minima*) I suppose that they are in the same condition, *Primula integrifolia*, which I found frequently on the summits surrounding the passes of Strela and Fluela, is dimorphic, like most other species of this genus. Its sexual organs are quite included, the stigma of the long-styled and the anthers of the short-styled form occupying nearly the centre, the anthers of the long-styled and the stigma of the short-styled form occupying the lower part (1½ mm. above the ovary and 3 mm. above the ground) of the corolla-tubes. (Compare Figs. 72 and 73, 74 and 75.) Honey is secreted by the ovary in such quantity that it fills up the lowermost part of the corolla-tube so far as nearly to reach the stigma of the short-styled and the anthers of the long-styled form. The corolla-tube being 10–17 mm. long and about 2 mm. wide, its dimensions would allow

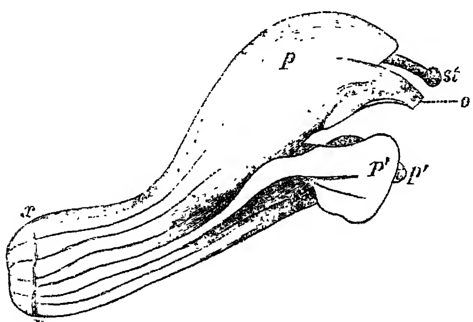


FIG. 77.—The corolla viewed laterally.

humble-bees also access to the honey; but the entrance to the corolla being contracted to 1 mm. (Fig. 71), no other insect but a lepidopterous one would be enabled to insert its proboscis into the base of the flower and reach the honey. On the other hand, the corolla is narrow enough to force also the thin proboscis of a butterfly to touch, when inserted, both the stigma and the anthers. I do not doubt, therefore, that *P. integrifolia* is also cross-fertilised by butterflies, although, from the unfavourable state of the weather, I have had no opportunity of observing its fertilisers.

3. *Rhinanthus alpinus* last year attracted my attention only during the last days of my stay in the Alps, when rainy weather prevented me from observing its fertilisers;

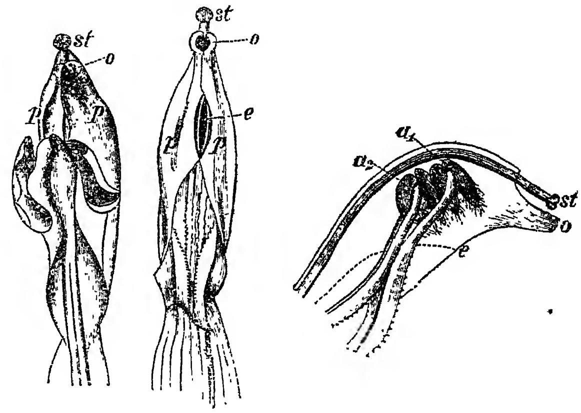

FIG. 78. FIG. 79. FIG. 80.

FIG. 78.—Front view of the upper part of the corolla. FIG. 79.—The same with the under lip removed. FIG. 80.—The upper part of the corolla, longitudinally dissected, but all four anthers reversed.

I concluded, solely from the structure of its flowers, that it was adapted to butterflies. This year it was an object of my continued attention; and in a region where Lepidoptera are predominant, but humble-bees are also very frequent, near Tschuggen (1,900 to 2,000 m. above the sea-level), Forno (1,800 m.), Valcava (1,500 m.), and St. Gertrud, Sulden (1,800 to 1,900 m.), I had large opportunities of directly observing its fertilisation by insects. But I was greatly struck by the fact that in these localities humble-bees visit its flowers far more frequently than butterflies. The number of visits which *Bombus alticola*, Kriechb. ☿. *mastrucatus*, Gerst., ☿ ♀, *terrestris*, L. ☿, *pratorum*, L. ☿, and *Proteus*, Gerst., ☿, in these localities make to the flowers of *Rh. alpinus*, is at least ten times greater than the number of visits by butterflies (*Argynnis*

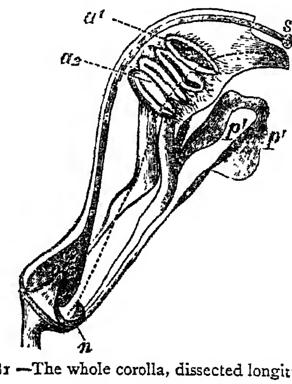

FIG. 81.—The whole corolla, dissected longitudinally.

Aglaia. L., *A. ino*, Rott., *Lycaena alsus*, W. V., *L. semiargus*, Rott., *Larentia albulata*, W. V. (?), *Botys spec.*, *Psodos quadrifaria*, Sulz.), which, of course, solely search for honey. But the humble-bees treat the flowers in such a forcible manner, that by their very visits they prove that these flowers are by no means adapted to them. Alighting on the helm-shaped upper lip, the humble-bees are obliged to turn round in order to reach the face of the flower

* All the figures are 3½ times natural size. In all figures: *ca*, calyx; *p p*, upper petals, forming together the upper lip; *p' p' p'*, lower petals, forming the lower lip; *a*[1], longer stamens; *a*[2], shorter stamens; *n*, nectary; *ov*, ovary; *st*, stigma; *e*, usual entrance for the humble-bees; *o*, minute opening for the butterflies. The dotted line in Fig. 80 indicates the path of the proboscis of sucking humble-bees; the dotted line in Fig. 81 the path of the proboscis of butterflies.

then, the entrance between the margins of the upper lip being completely closed, they forcibly break it open with their fore-legs, grasping with them between the margins, and shaking the anthers in order to gain their pollen; thus a good deal of the smooth, powdery pollen grains, falling out of the shaken anthers, is received within the brushes and feathery hairs of their fore-legs, and thence carried to the pollen-collecting orifice of the posterior tibiæ. This incommodious and wearisome labour, although performed by the humble-bees with admirable dexterity and perseverance, contrasts remarkably with the swift and light manner of their gathering pollen, and at the same time sucking honey in flowers adapted to them;* and many peculiarities of the flowers of *Rh. alpinus* would be quite unintelligible under the supposition that pollen-collecting humble-bees were the true and original fertilisers of them. The honey, so copiously secreted in the base of these flowers, would be quite useless to the plant if pollen-collecting humble-bees were its true fertilisers; the minute opening between the two lateral flaps at the tip of the beaked prolongation of the upper lip would likewise be useless, and the closeness of the usual entrance between the margins of the upper lip would be a mere embarrassment to the fertilisers. Supposed, on the contrary, that Lepidoptera are the original fertilisers of *Rh. alpinus*, all these peculiarities are easily to be understood as very useful, nay, as indispensable to the plant; for honey is the only food eagerly searched for by butterflies, and the closeness of the usual entrance, as well as the existence of the minute opening in its very place, are required in order to induce visiting butterflies to insert their proboscis in the only manner which can effect cross-fertilisation. Hence, in spite of the frequent visits of pollen-collecting humble-bees, and in spite of their probably effecting many cross-fertilisations, the flowers of *Rh. alpinus* are without any doubt to be considered as adapted exclusively to butterflies.

But considering the original function of the under lip as a landing-place for bees, and considering that the most nearly-allied genera, *Euphrasia*, *Melampyrum*, *Pedicularis*, as well as *Rhinanthus crista-galli*, are all adapted to bees, we can hardly doubt that also the ancestors of *Rh. alpinus* have been adapted to cross-fertilisation by bees, and the question may be started, by what connecting forms these ancestors could be transformed into the present form of *Rh. alpinus*. We may confidently suppose that they retained the usual entrance for humble-bees, until the beaked prolongation of the upper lip, the minute opening at its tip, and the lateral flaps of this opening were so developed as to secure cross-fertilisation by butterflies.

In this respect *Rhinanthus alectorolophus* is of especial interest; for it represents really what by reflection we are induced to suppose once existed in the connecting forms between *Rh. alpinus* and its ancestors (compare Figs. 76-81). *Rh. alectorolophus* has indeed retained the usual entrance by which humble-bees may insert their proboscis in order to suck the honey (*e*, Figs. 79, 80), and may be regularly cross-fertilised by sucking humble-bees, whilst at the same time the minute opening (*o*, Figs. 76-81) and all those peculiarities which secure cross-fertilisation by sucking butterflies, are developed.

From the structure of its flowers, as shown by Figs. 78-81, we should expect that this species would be cross-fertilised as well by sucking humble-bees as by butterflies. My direct observation of the fertilisers, however, in the same localities with *Rh. alpinus*, shows no remarkable difference between *Rh. alectorolophus* and *Rh. alpinus*. Two species of butterflies—*Colias Phicomone* and *Pieris Napi*—repeatedly inserted their thin proboscis into the minute opening at the tip of the upper lip of *Rh. alectorolophus*, apparently sucking honey; numerous specimens of *Bombus mastrucatus*, Gerst., ☿♀, *terrestris*, L. ☿, *Proteus*, Gerst., ☿, and *pratorum*, L. ☿, were occupied in collecting the pollen of *Rh. alectorolophus* in quite the same manner as in *Rh. alpinus*. Only twice I saw humble-bees (*B. mastrucatus*, Gerst., ☿) sucking the honey of *Rh. alectorolophus*, but not legitimately, by the entrance between the margins of the upper lip, but rapaciously; once by inserting their proboscis on the underside between calyx and corolla, and piercing the corolla-tube a little above its centre; another time by forcibly passing its proboscis through calyx and corolla.

Finally, it is to be noted that self-fertilisation of *Rh. alectorolophus* is apparently impossible, for the stigma always projects, just as in *Rh. major* and *alpinus*; and when the corolla drops off (in the line *x x*, Fig. 77), and brings its anthers in contact with the stigma, this is already withered.

HERMANN MULLER

* Compare Æsculus Hippocastanum in "H. Müller, Die Befruchtung der Blumen durch Insecten," p. 155.

BEATS IN MUSIC*

ONE of the subjects treated of in Helmholtz's great work on Acoustics is that of "Beats." It is one of much interest, both theoretically and practically: theoretically, because of the difficulty that attends the investigation of the phenomena, and of the discussions and misunderstandings that have taken place thereon among writers on scientific harmonics; practically, because beats might form an element of great utility in regard to certain practical operations, were it not that their nature and use are at present almost entirely unknown to practical musicians.

The history of the knowledge of beats is curious. They were mentioned as early as 1636 by Mersenne, and were afterwards noticed by Sauveur and others, but no sufficient explanation of their theory was given till the publication in 1749 of the learned work on Harmonics by the celebrated mathematician Dr. Robert Smith, Master of Trinity College, Cambridge. Dr. Young and Dr. Robison, both eminent writers on acoustics, quarrelled about Smith's work. Young said it added nothing to the knowledge of the subject, whereas Robison declared that it contained the greatest discoveries made since the days of Galileo; the fact, however, being probably that neither of them appreciated the main portions of the work at all. Chladni appears never to have studied the more difficult portion of the subject, and though he gives generally his references very freely, he does not mention Smith's name.

It was only in 1858 that Mr. De Morgan, in an able paper, published in the Cambridge Philosophical Transactions, pointed out the merit of Dr. Smith's investigation, and cleared up its learned obscurity.

Helmholtz treats the subject with his usual ability, but it is very singular that he, like Chladni, makes no allusion whatever to Smith's work, and as it is incredible that he should have passed over such a remarkable and profound theoretical investigation if he had been acquainted with it, I am inclined to believe that the book was unknown to him.

Considering the very few sources of information that exist in regard to beats, and the difficult shape in which this information is embodied, I have thought it might be useful, especially to practical musicians, to attempt to give some account of the subject in a more popular form; and in doing so I will endeavour to introduce the investigations of Smith, in combination with those of the later investigator.

There are three distinct kinds of beats, differing considerably from each other in the nature of their causes and in the circumstances that attend them, and the confusion between them has caused much error in their

* By W. Pole, F.R.S., Mus. Doc. Oxon.

investigation. Hence a correct discrimination between them is very desirable.

The first and simplest kind of beat we will distinguish by the name of the *Union Beat*, it being produced by the concurrence of two sounds nearly, but not quite, in unison with each other. Let two organ-pipes, or any other sustained sounds, be tuned first exactly in unison; the combined effect will be equable and smooth, undistinguishable from a single sound. But now let one of the notes be put out of tune, at first very slightly; the result will be a peculiar effect of wavy pulsation or *beating*. The exact description varies according to the fancy of different hearers, but it is usually said to resemble an alternation of different vowel sounds, like *waw*, *waw*, *waw*, or *ya*, *ya*, *ya*. The beating, when the notes are but slightly out of tune, will be slow; if the error is made worse, the pulsations will increase in rapidity, till they become too quick to be counted.

This fact is very commonly known, and its experimental exhibition is exceedingly simple and easy. If organ-pipes and the means of tuning them cannot be had, the two sounds may be produced on any wind instrument, which can be easily put into the adjustment necessary. Or one of two unison reeds of a harmonium may be thrown out of tune by weighting it with a little bit of wax; indeed, in the drawing-room instruments one unison stop is usually made purposely out of tune with another, the composition giving a tremulous effect resembling the shaking of the voice, the stop being named "voix celeste" (in Italian organs a stop called the "vox humana" is formed of two pipes tuned in a similar way). These are real unison beats with so short a period as to produce the tremulous effect in question. Two unison tuning-forks may also be thrown out of tune by attaching wax to the arm of one of them, which will make it a little flatter.

The beats may also be well produced on a violin. Stop A with the fourth finger on the third string, and play it along with the second string open, when the adjustment of the former may be made with the greatest nicety, and if it be put out of tune the resulting beat will sometimes be so prominent as almost to shake the instrument under the chin. On a pianoforte the beats may also be observed when one wire of a note is a little sharp or flat of another, although this case is not so favourable for observation, from the sounds not being sustained.

Now, in seeking for the explanation of this phenomenon, a homely preliminary illustration will be useful. Suppose two coffin-makers live next door to each other, and suppose that on some particular day they both strike the blows on their nails at exactly the same rate, and begin exactly together; the effect on a passer-by will be that the sounds of the two will reach his ear simultaneously, smoothly, and regularly, and he will have difficulty in distinguishing the combined sound from what would be produced by one workman only. But now suppose that by some change in the fancy of one of the men, A, he begins to strike a little faster than his neighbour, making, we will say, eleven strokes to ten of the other, B. The effect on the passer-by will be changed, the sounds will reach his ear irregularly, and, which is the important thing, there will be regular periodical phases appreciable; for it is obvious that at every tenth blow of B, or every eleventh of A, the blows will *coincide*, after which they will diverge and become irregular till they coalesce again.

To apply this illustration to the case of the sounds, it must be borne in mind that a sound is transmitted to the ear by waves of the air, each of which consists of an alternate condensation and rarefaction. The coincidences of sound-waves give rise to peculiar effects of *interference* of various kinds, but it will suffice here to say that when two condensations coincide, the effect will be different to that when the condensation of one wave coincides with the rarefaction of another. It will be easily seen that when the vibrations producing two sounds are a little unequal in time, as if, for example, one vibrates eleven times while the other is vibrating ten; there will be periodical coincidences corresponding to those of the blows just mentioned, and it is these periodical coincidences that produce the effect of what is called the *beat* on the ear.

Having thus established the nature of the beat, we may now go a little further, and see what we can find out about its time, or the length of the period which it involves, and this is a matter which requires careful attention.

We will go back to the illustration of the coffin-makers, and will now assume that the slower workman, B, makes 100 blows in a minute, whereas the quicker workman, A, makes 101. It will be evident that a coincidence will take place exactly at the end of every minute of time, so that, for these numbers, the periods of coincidence (corresponding to our beats) will be *one* per minute. Let now A increase his speed to 102 blows per minute, the other remaining the same; here there will be one coincidence every fiftieth blow of B, or every fifty-first of A, *i.e.* there will be two coincidences per minute.

It is easy to apply this to the sound-vibrations. Let one note make 100 double vibrations per second, and let the other note be sharpened to make 101. Here there will be one coincidence, or, what is the same thing, one beat per second. If the second note is sharpened a little more, so as to make 102 vibrations, there will be two coincidences, or two beats per second.

Hence the rule has been derived, that *the number of beats per second is equal to the difference of the number of vibrations per second of the two sounds.*

This is a simple rule, and it happens to be *practically* an accurate one; but hasty writers, who have deduced it from one or two simple examples, have omitted to see a curious *theoretical* difficulty that attends it. Let us go a step further, and suppose the higher note to make 103 vibrations per second, while the other makes 100: how many beats per second would this give? The rule says three, but if we examine very carefully the succession of sounds, we shall find there will *not* be three coincidences per second, there would be only *one*, and hence the rule will appear to fail. But if we try the experiment we shall hear that there *will* be three beats, and hence the theory and the fact do not correspond.

To explain the discrepancy, let us revert again to the illustration of the coffin-makers: supposing A to make 103, and B 100 strokes per minute, the interval between A's stroke is $= \frac{1}{103}$ of a minute, and between B's $= \frac{1}{100}$. The 33rd stroke of B will take place after $\frac{33}{100}$ of a minute, and the 34th of A after $\frac{34}{103}$, and as these fractions are not the same, it is clear that the blows will not coincide, neither will the 66th and 68th; in fact, there will be only one point in each minute when the blows will be heard exactly together.

Yet if the passer-by be asked to count with his watch how many coincidences per minute he hears, he will assuredly say *three*, and this discrepancy between theory and fact demands to be reconciled.

The explanation was cleverly hit upon by Dr. Young, who ("Experiments and Inquiries respecting Sound and Light," sec. xi.), treating of the subject, mentions "coincidences, *or near approaches to coincidences.*" He saw that, so far as the ear was practically concerned, a near approach would answer the purpose of an exact coincidence equally well; and this clears up all the difficulty. For although the 32rd and 34th blows do not come together with *theoretical exactness*, they come *practically* so nearly together that the difference between $\frac{33}{100}$ and $\frac{34}{103}$ is only $\frac{1}{10300}$, that is, the difference in time between the two blows is only $\frac{1}{10300}$ of a minute, which no passer-by could appreciate, and he may therefore say they coincide.

Similarly, with the sounds. Although the 103 vibration-sound and the 100 vibration-sound only coincide with theoretical accuracy once in a second, yet there is, three times per second, a coincidence so nearly accurate (within $\frac{1}{10300}$ of a second) that the practical effect in producing the beat is the same.

The rule, therefore, is practically right; but it should be qualified scientifically with the following addition:—*When the two vibration-numbers are prime to each other* (*i.e.* when they are not both divisible by any whole number) *the rule is not theoretically accurate, but if the times of vibration are very small* (*as they always are in practice*) *the error has no practical effect, and the rule consequently holds good.*

With the aid of this rule we can now tell the exact number of unison beats that will correspond to any amount by which the two notes are out of tune; and, *vice versâ*, we can tell the exact quantity by which two notes intended for unisons are out of tune by simply counting the number of beats they give. For example, suppose the A open string on the violin is played along with the fourth finger note (first position) on the third string, and that the latter is a little sharp, so as to give four beats per second, we know that the upper note will have four vibrations per second more than the other; and as at this point of the scale about twenty vibrations go to a semitone, we can tell that the upper note is about one-fifth of a semitone sharper than the lower one. To effect this, the fourth finger must be moved about one-twelfth of an inch nearer the nut than the former position, and this can be measured if any player think it worth the trouble, as a check to the calculation.

We may next inquire what effect on the ear is produced by changes in the rapidity of the beats. At first, when they are slow, no very unpleasant sensation is perceived, but as they become faster they give a sensation of roughness which is disagreeable in a marked degree. With a further increase of rapidity the effect becomes again less unpleasant, until it arrives at the slight tremulousness already mentioned in the *voix celeste* and *vox humana* stops, and which, as it is purposely produced, may be supposed to be rather agreeable than otherwise.

If we carry the error farther, the beats become so fast that the ear ceases to be able to appreciate them, and the beating effect entirely disappears.

Helmholtz, who has paid much attention to this subject, and who has founded on this property of beats some important musical speculations, is of opinion that the disagreeable effect increases gradually until the beats arrive at about thirty per second, where the harshness is at a maximum; that then the unpleasantness lessens as they grow faster, until, at about 100, or something more, per second, the beating effect disappears. Hence he calls from O to this point *beating distance* for any two notes near each other.

For example, if starting from the treble C, 512 vibrations per second, we sharpen the note to D♭, 546 vibrations, and then sound this with the original C, we shall get $546 - 512 = 34$ beats per second, which gives a very harsh effect. If we go on to D, 576 vibrations, we shall get, for the interval C to D, $576 - 512 = 64$ beats per second, which is less harsh; and if we go on to C with E♭, we shall have $614 - 512 = 102$ beats, which is hardly perceptible. For C to E, a major third, we have $640 - 512 = 128$ beats, and no one can assert that this interval, when in tune, has anything harsh or disagreeable about it.

A curious question has existed as to what becomes of the beats when they thus vanish. Are they entirely annihilated? or do they in their more rapid shape produce any other sensible effect of any kind? To explain the answer that was, by early writers, given to this question, one must mention a new phenomenon which occurs in connection with double sounds, namely, what is called the "grave harmonic." When two notes are sounded together they give rise to a third tone, of a fainter strength, and generally lower than both. Examples of this are usually taken from concords: thus, if the following two notes  are sounded on an organ, a violin, or any instrument of sustained sounds, and are perfectly in tune, the ear will, with attentive listening, hear a faint third sound resulting therefrom, which will be an octave below the lowest note of the concord, thus . If, instead of the fifth, the major third  be sounded, in like manner the "grave harmonic" will be an octave lower than before, namely, . This phenomenon was discovered by Tartini, the eminent violinist, and is often on this account called the "Tartini harmonic."

Now it happens that the number of vibrations of Tartini's harmonic, for any two given notes, is exactly the same as the number of the unison beats for the same notes, as hereinbefore described: and hence the idea arose that when the beats became so rapid as to lose their beating character, they gave rise to the grave harmonic; the explanation naturally presenting itself, that a beat recurring regularly with the proper rapidity would produce on the ear the effect of a musical sound. Dr. Young was the first to publish this explanation: he says ("Experiments and Inquiries respecting Sound and Light," sec. xi.), "The greater the difference in the pitch of the two sounds, the more rapid the beats, till at last they communicate the idea of a continued sound, and this is the fundamental harmonic described by Tartini."

Young's theory has been generally accepted until within the few last years, and in consequence the kind of beat we have been describing has been called "Tartini's beat." Helmholtz has lately thrown doubt on the correctness of Young's explanation, but the analogy of the numbers may warrant us in retaining the name, as distinguishing this beat from others which we will now proceed to describe.

(*To be continued.*)

UNITED STATES NATIONAL ACADEMY OF SCIENCES.

THE half-yearly meeting of the National Academy of Sciences was held at Philadelphia, Nov. 2, 3, and 4, 1875.

Prof. Joseph Henry has for several years been conducting the researches of the U.S. Lighthouse Board in respect to Fog Signals and the Transmission of Sound. While these experiments are not yet completed, the results up to the present time give the following indications:—The echo of sound passing over the ocean is more probably due to reflection from the surface of the waves than from the air; sound coming against the wind can certainly be heard at an elevation from a greater distance than at the sea level; with the velocity of the wind at about five miles an hour, sound was heard five times further with the wind than against it; sound is heard furthest with a moderate wind; with a strong wind it is not heard so far as in still air.

Prof. Joseph Le Conte, of California, contributed the results of his observations on mountain ranges of the Pacific coast. The author's theory is that the mountain chains in question were formed wholly by a yielding of the crust of the earth, along given lines, to horizontal pressure; not, however, resulting in a convex arch filled and sustained by liquid beneath, but by a mashing together of the whole crust, producing close folds and a swelling upwards of the squeezed mass. Prof. Le Conte went on foot through a cut made by the Central Pacific railroad from near St Francisco Bay eastward, a distance of 30 miles through the Coast

range, which consists of two sub-ranges wholly of crumbled strata. The average angles of dip are from 65° to 70°. The following estimates are made:—The folded strata are of 2½ to 3 times the length of a horizontal line drawn beneath them; *i.e.* 15 to 18 miles of sea bottom have been crushed into 6 miles, the surplus swelling upward. Numerous flattened clay pellets, chiefly ellipsoids or disks, and similarly flattened nodules of sandstone, furnished means of estimating the horizontal and vertical pressures to which the mass has been subjected. The mathematical formula employed was detailed. It was found that 2½ to 3 parts had been crushed into one horizontally, and every foot of vertical thickness had been thereby swelled up 2½ or 3 feet.

Major J. W. Powell of Washington has spent many years in scientific exploration of the cañons of Colorado latterly under the auspices of the Smithsonian Institution. He regards the geology of the Colorado region as so different from any other, that a new system will have to be devised to meet it. Major Powell offered the outlines of a new system for the details of this region, proposing to retain as far as possible the names that mark the labours of previous explorers in the field; and to give in addition geographical names as a provision expedient till the full order of the strata should be determined. The plateau region drained by the Colorado River of the West was more particularly under review in the essay before the Academy. Springing from the plateaus are single mountains, short ranges, and volcanic cones disposed in groups; the affluents of the river have their source in high mountains on the edge of the drainage basin. The river and its chief tributaries differ from other great rivers in the absence of considerable valleys along their course, at least north of 35° latitude. The streams run in deep cañons, and these, with other topographic features, separate the plateaus. This is part of the whole region of the United States west of the 100th meridian, which is distinguished by being everywhere of great altitude, with the trifling exceptions of a strip on the Pacific coast and some valleys of the larger streams. The rivers descend so rapidly that they are of little service for navigation; the valleys are exceedingly narrow; the table-lands and mountains are treeless, arid, and almost desolate. Bare rocks rarely masked by any soil give character to the "Rocky Mountain" region. Here there is everywhere an open book to the geologist, as the formations can be clearly traced, and the sections given by cañons display in regular succession the strata of palæozoic, mesozoic, and cainozoic eras, a total depth of 60,000 feet being thus revealed. The characteristics of the formations of this region were discussed at considerable length. As an instance of the irregularities of strata, the observations on lignite may be cited. It is frequently found through a horizon of 11,500 feet, in beds of varying thickness, distributed all the way from the lower Cretaceous up through three divisions of the Tertiary; but no particular bed of lignite is persistent over a large area. In one instance—the Rock Springs group—eleven beds of lignite were found, varying from 10 inches to 4 feet in thickness; but three miles away, careful observation showed all these beds represented by carbonaceous shales. In places separated by only a distance of a few miles, the succession of lignites is found to differ materially; they appear in general to have been formed in small irregular basins.

One of the most interesting papers read at the meeting was that of Prof. Raphael Pumpelly, of Newburgh, N.Y., on the Influence of Marine Life and Currents on the formation of Metalliferous Deposits. Beginning with the list of chemical elements which are found in the sea—now numbering 29 and likely to be largely increased—the author gave disinctive particulars as to the proportions of these substances, and the material in which they are found, whether sea-water, marine organisms, or structures that are products of marine life. All elements which compose the land are ultimately carried to the sea. The cycles through which different substances pass in their progress from land to sea, and thence again to the material of land, were traced in the cases of carbonic acid, lime, phosphoric acid, fluorine, and sulphur. As to the first of these, the sea is charged with nine per cent. of CO_2, the charge varying with the surface condition of the water and the immediate atmospheric conditions. The activity of the wave surface aids the escape of surplus carbonic acid into the air. Plant life in the sea as on land effects the decomposition of CO_2, using the carbon to build vegetable structure and freeing the oxygen to sustain marine vegetable life. But the carbon that is withdrawn to form coal, owing to its insoluble character, has been practically abstracted from this circulation. The ultimate result, the author thinks, would have been the decay of all life on the planet, for the want of the carbon thus locked up. Hence the work of man in mining and burning coal restores the balance of this circulation, by bringing the carbon into a condition in which it can be dissolved by moisture and enter into plant life through the leaves.

In describing the cycle of lime, Mohr's theory was alluded to. Sulphate of lime, decomposed by plants, supplies sulphur towards forming albumen by combining with carbon and ammonia, the oxygen being set free; carbonate of lime may perform a simpler operation in the plant, leaving behind the carbon and lime while liberating oxygen. The hydro-carbons are afterwards oxidized in the respiration of animals that feed upon the plants, and secrete structures of limestone.

Phosphoric acid and fluorine have slight chemical affinity, yet they are continually found associated in mineral deposits. Phosphate of lime and fluoride of calcium offer nearly equal resistance to solution by atmospheric and aqueous agencies. The first is a constant constituent of marine plants; both are found in the lower marine animals, and by their means are presumably brought together again in rock formation. Land plants and animals take a frequent part in this circulation. Disintegrated rocks form soil-supporting vegetation afterwards eaten by animals, whose digestive processes bring the substances in question into the more soluble states, in which they are most readily carried to the ocean.

The sea contains much dead organic matter, and in decomposition the sulphur of the sulphates and of the albumen plays an important part. As to the sulphates, the direct process of their decomposition in decaying organisms may be stated thus:—The carbon of the organic substance takes the oxygen from sulphuric acid and its base, giving a sulphide of the base and free carbonic acid; water and carbonic acid decompose the sulphide again, giving sulphuretted hydrogen and a carbonate. Oxidation of the sulphuretted hydrogen gives sulphuric acid, which in time, uniting with lime, completes the circuit of sulphur. On land the processes are far more intricate. It is probable that in the circuit of sulphur in marine organisms is to be found the key to their powers of eliminating from sea-water the heavier metals. The habitat of marine plants is determined by ocean currents, the growth and development being dependent upon freedom from such disturbance. Animal life follows vegetable. The accumulation of organic existence at certain localities in the ocean—as for instance the sargossa—determines there, in the process of its decay, the position of the material of rock formations, including the heavy metals which have been thus eliminated from their dispersion in sea-water. A thorough and minute chemical analysis of the earth brought up by the soundings of the *Challenger* and the *Tuscarora*, would be apt to throw light on some of the details of these problems.

The "Difference Engine," a calculating machine devised by Mr. George B. Grant, and now in course of construction for the University of Pennsylvania, was described by Prof. Fairman Rogers. The frame of the machine is 8 feet by 4 feet. To this frame are attached, though removable at will, 100 similar parts or elements, each of which is a small adding machine, representing a single decimal place during operation. When these elements are combined in groups, each group represents a certain difference of numbers, such as by consecutive additions to a starting number gives the required mathematical table or series. The difference thus added may be constant or variable. A table of squares is made by adding two differences, one constant, the other variable; cubes add three differences of which only one is constant. Logarithms are obtained similarly, though the operation is more complex In this machine certain groups of elements are set to constant differences, and transfer their products in figures to other groups, which in turn transfer their variable values to groups above them. Babbage's machine was more costly, and Scheutz's more complicated than this; its chief advantages are: interchangeableness and ease of grouping of the elements, a constant introduced by simple apparatus in each element; an improved method by which the figure produced by any element is sent to the corresponding element in a higher group, and greatly improved arrangements for the operation of "carrying." The main figure-wheel of each element is moved forward by a carrier, which is released at the proper point by an inclined edge that takes it out of the way of the wheel. When a carriage is to be made, as for instance, if the wheel be at 8 and 3 be added, making 11, the next wheel standing at 0, which must be turned to 1, is so contrived that at the proper moment its inclined edge is slipped one tooth forward, and the carrier moves that wheel one step further than it otherwise would. This principle is so extended to successive carriages that if a long row

of nines is up, and unity be added on the wheel on the right, all the nines are at once replaced by zeros and one is added to the figure on their left. The machine presents a *cliché* of figures, the basis for a stereotype plate; it will calculate and print a table to ten decimal places at the rate of about forty turns per minute. A two-horse power engine will be required to drive it to its full capacity.

An arithmometer, or multiplying machine, devised by Mr. Grant, was also shown with, for comparison, those of Thomas de Colmar and Baldwin, it being adapted to the same purposes as those, but constructed on the principle of the difference engine.

Prof. R. E. Rogers gave some facts of interest respecting the silver mines known as the Comstock Lode. In the deeper drifts the temperature is much higher than can be explained by the usual hypothesis of interior heat; it frequently reaches 150° F. Water trickling from the roofs of these drifts is so hot as to be almost scalding; workmen have to be protected from it by iron screens. An application of ice-water to the head at intervals is found necessary to the support of life. The heat is due to chemical action, principally to the decomposition of sulphide of silver deposits which takes place when water containing chloride of sodium reaches them. There is some saline material in the ore. It is a singular fact that while there appears to be no trace of copper in the ore, the washing from the quicksilver mills, which runs into a pond and there evaporates, leaves a deposit which is only 300 fine instead of 700, all the rest being copper. To extract the silver, this deposit is put into a cap-like receptacle of felt, and hot quicksilver is turned upon it, which strains through, and carries with it the copper and gold, leaving the silver. The next process is to separate the gold from the copper in the drippings. To effect this the combined substance is heated to fusion and allowed to cool, when the two metals segregate, and the gold cracks off the copper. Before the discovery of this process the "tailings" of the mills had no value; now they prove of considerable worth.

Prof. J. Lawrence Smith has been studying a crystalline product obtained from the graphite of meteoric iron, that proves soluble in ether and crystallises in acicular form. Wöhler and Roscoe have announced the discovery of a similar substance in carbonaceous meteorites. Prof. Smith finds it in carbon nodules in the very centre of large masses of meteoric iron. Wöhler and Roscoe regard it as a hydro-carbon; Prof. Smith gives reasons for considering it a sulpho-hydro-carbon.

In another communication Prof. J. Lawrence Smith described a pendulum designed to meet the wants of a cheap and efficient compensating arrangement for common clocks. Prof. Smith has taken advantage of the great expansibility of vulcanite under changes of temperature. His experiments, in common with those of others, prove that its coefficient of expansion is about that of mercury, between 0° and 212°. In applying this simple form of compensating pendulum to clocks, he states that it need not add more than twenty or thirty cents to the cost of the pendulum ordinarily in use. He has constructed one with more perfect means of adjustment, yet very simple in character, which he thinks can be attached to regulators and astronomical clocks. Prof. Smith is now engaged in investigating any possible change in the materials used that may interfere with the permanency of this instrument; from the nature of the subject it will take some time to arrive at the necessary results. In these experiments he is assisted by a very competent associate.

The following were the papers presented at the session, in addition to those already mentioned:—Contributions to Meteorology, by Prof. Elias Loomis; Exposition of several peculiar Astronomical Phenomena, by Prof. Stephen Alexander; Confirmation of same author's Theory of the Zodiacal Light, by the same; Composition of Schorlomite, by Prof. George A. Koenig; Modern System of Chemical Terminology, by Prof. R. E. Rogers; Steam Geysers of California, by the same; the Annular Nebula in Lyra, by Prof. Edward S. Holden. Prof. C. E. Dutton's paper on certain Igneous Rocks of Southern Utah was read by title only.

NOTES

PROF. HILDEBRAND HILDEBRANDSSON has published in the "Transactions" of the Royal Society of Sciences at Upsal, a clear and interesting account of a tornado which occurred near Hallsberg, in the province of Nerike, Sweden, on the 18th August, 1875. From the full details he gives it is evident that it closely resembled the tornadoes which have been described by the American meteorologists and the well-known tornado of Chatenay of 18th June, 1839, described by Peltier. Upwards of 1,000 large trees (*Pinus abies*), covering a space 1,000 feet in length by 500 feet in breadth, were totally destroyed, the greater number being torn up by the roots, whilst those about the margins of the path of the tornado were snapped across. On emerging from the forest, where its course had been directed to N.N.E., it turned in the direction of N.E., uprooting trees, overturning solid buildings, and carrying the *débris* of the ruins, in some cases, many miles from the scene of destruction. From the positions of objects thrown down, which are shown on a map, Dr. Hildebrandsson points out that in this instance the destructive force was compounded of two forces, one being directed towards the centre of the tornado and the other in the line of its course. The true theory of these terrible phenomena can only be arrived at by such carefully observed and collated facts as Dr. Hildebrandsson here presents us with; and much light would be thrown on this difficult question if barometric and thermometric observations were made within and near the district swept by the tornado.

YESTERDAY'S *Standard* contains a letter from the *Challenger* correspondent of the paper, dated Valparaiso, Nov. 19. Honolulu was left on August 11 and a call made at Hilo (Hawaii), when the crater of Kilauea was visited. On the 19th the *Challenger* left and made for Tahiti, soundings and dredgings being carried on by the way, the average depth being 2,800 fathoms, with a bottom of red clay. Oxide of manganese was brought up in large quantities, and "many things of great interest to the naturalist." Several excursions were made on the Island of Tahiti, and every opportunity was made use of to get acquainted with the productions, soil, climate, and inhabitants. Sail was again made on Oct. 2, and Juan Fernandez reached on Nov. 13, the average depth of the section being 2,160 fathoms. Hill and dale were tramped over by the naturalists and others during the two days' stay, and numerous specimens of birds and plants obtained. Valparaiso was reached on the 19th.

PART II. of the first volume of the new series of the "Transactions" of the Linnean Society, just published, contains a paper by Dr. J. D. Macdonald, on the external anatomy of *Tanais vittatris*, occurring with *Limnoria* and *Chelura terebrans* in excavated pier-wood, and another by Dr. M'Intosh, on *Valencinia armandi*, a new Nemertean. The first part contains Mr. Parker's memoir on the skull of the woodpeckers, one by the late Dr. R. v. Willemoes-Suhm on some Atlantic Crustacea from the *Challenger* Expedition, and one by Dr. Allman on the structure and systematic position of *Stephanoscyphus mirabilis*, the type of a new order of Hydrozoa.

SOME living specimens of the gigantic Tortoises of the Galapagos Islands, which were on their way to this country in H.M.S. *Repulse*, were lost, we regret to say, in a gale which did some damage to the ship and caused the death of two of the crew.

A NEW journal, *The Scientific Monthly*, devoted to the natural and kindred sciences, has been quite recently started at Toledo, Ohio, Mr. E. H. Fitch being the editor.

MESSRS. H. HOLT AND CO., New York, will publish during the month a work entitled "Life Histories of Animals, including Man," by Mr. A. S. Packard, jun. This work having appeared in parts in the *American Naturalist*, we can most certainly vouch for its excellence.

WE regret to have to announce the death of Mr. S. T. Davenport, well-known as an active and energetic officer of the Society of Arts. Mr. Davenport's connection with the Society had lasted for thirty-three years, and it was in great part to his unceasing and zealous efforts that the present prosperity of the

institution is due. All who take an active interest in the Society of Arts will feel his loss severely.

AN unfortunate difficulty at present prevents the Algerian Meteorological Service from sending telegrams daily to M. Leverrier for tabulation. It appears that the hour chosen at which to take the readings is seven in the morning instead of eight, the hour that has been adopted by all European nations. M. Leverrier could not by any means make use of the Algerian data in his daily weather maps. It is to be hoped that Algerian meteorologists will see the necessity of conforming to the rule universally adopted in European observatories. But some resistance is expected from those who have adopted the unusual hour for taking observations, as they contend that the readings taken then give a closer approximation to the mean state of weather. This assumption is hardly justifiable by facts: at any rate it cannot be considered as an objection to the taking of a reading at eight o'clock, and sending it by telegram to Europe.

AT Christ Church, Oxford, there will be an election on Saturday, March 11, to at least two junior studentships in Physical Science, of the annual value of either 100*l*. or 85*l*., tenable for five years.

THE *Geographical Magazine* announces the discovery of a voluminous journal kept by Father Desideri, who resided and travelled in Thibet in the early part of last century.

THE Dutch Government have adopted a plan for draining the Zuyder Zee at an expense of nearly 10,000,000*l*. The area to be drained is estimated at 759 square miles.

THE Bureau of Agriculture of the United States Centennial Commission (not the United States Agricultural Department) has lately issued a circular, which announces that it is proposed to have an exhibition of living fish of many varieties, for which purpose plans have been prepared for the erection of twenty-five tanks of approved construction, ranging from two to twenty feet in length and from one to six feet in depth, the whole containing about six thousand cubic feet of water. The cost of these aquaria is estimated at $6,000. The Bureau of Agriculture desire to render this enterprise in a measure self-supporting, and the circular invites those interested in the subject to purchase one or more ten-dollar shares of the Centennial stock, with the understanding that the proceeds, although going into the general fund, are to be considered as contributed to the fish exhibition.

MR. G. S. BOULGER, F.G.S., has been appointed Professor of Natural History in the Agricultural College, Cirencester.

THE North-German *Allgemeine Zeitung* of Jan. 7 publishes a long article on the Hamburg Naval Observatory. It appears that this establishment commences operations to-day, and professes to include the several branches of scientific seamanship. The establishment is said to have been fitted up according to the most improved method, regardless of cost.

TWO Parisian daily papers, the *Bien Public* and the *Opinion Nationale*, publish daily the weather maps designed by M. Leverrier for the international meteorological service.

THE list of the members of the French Bureau des Longitudes has been published. Besides the ordinary members appointed either by the Bureau or by the Academy of Sciences, the War Office, and the Marine Department, a number of correspondents have been appointed, including M. Stephan at Marseilles, M. Tisserand at Toulouse, M. Marie Davy at Montsouris (Paris), Admiral La Ronciere le Nourry, &c.

THE meteorological *Annuaire* of the Montsouris Physical Observatory has been published by M. Marie Davy. Excellent woodcuts show the details of the several anemometers and magnetometers used by the institution. The results of all the readings taken in the preceding year have been carefully tabulated. The maximum registered velocity of the wind was 80 kilometres an hour, and the maximum pressure 47 kilogrammes per square metre.

M. LEVERRIER may come to London in order to be present at the distribution of medals by the Royal Astronomical Society. The printing of his tables for Saturn is progressing favourably. The verifications made have been satisfactory.

A VERY useful and complete summary of the geographical progress of 1875 will be found in *The Colonies* for January 8. The same well-conducted paper has commenced a series of "Ethnographical sketches of the various aborignal or indigenous races inhabiting countries and islands that are becoming daily more known to us through the rapid development of trade and commerce," but whose inhabitants are disappearing or being greatly changed. The first sketch, under the head of Pacific Islands, is of the Hawaiians or Sandwich Islanders.

THE Italian Minister of Public Instruction has made a grant of 1,000*l*. for the scientific expedition to Central Africa (see NATURE, vol. xiii. p. 155).

A PITHY article in the Hastings and St. Leonard's *News* of the 7th inst. calls attention to the scientific destitution of that favourite watering-place. There seems at one time to have been an apology for a museum, but its dusty contents have long ago been scattered. So far as we know, Hastings has not even a local scientific society or field-club, although the district around, including the sea and its shore, would furnish a fertile field for such an association. Indeed, with the exception of a science and art class, Hastings seems to be quite destitute of any means of fostering a love of science or of scientific pursuits and recreations among its people. Surely there are a few men in the town who know the value of science; at all events, we hope the forcible remarks in the *News* will have the effect of rousing the people to bring their town abreast of its neighbours in the matter both of a well-furnished museum and a scientific society and field-club.

WE take the following from the *Geographical Magazine*:—Announcement was made at a recent meeting of the Society for the Encouragement of Commerce and Industry, in St. Petersburg, that a person who does not wish his name to be known has offered a sum of 25,000 rubles (3,125*l*.) towards a scientific expedition to explore a commercial route from Northern Russia to Behring's Straits. Prof. Nordenskiold has agreed to accept the leadership of the expedition, which will start next summer. Subscriptions to the amount of 26,000 rubles (3,250*l*.) have also been received towards the cost of another expedition composed of two vessels, which shall last three years, and shall explore the Gulf of Obi as well as the sea-route between Archangel and the great rivers of Siberia. The command of this one will be entrusted to Capt. Wiggins, of Sunderland, who has, however, stipulated for full liberty of action in unforeseen circumstances, and who has remained in St. Petersburg, waiting for the replies of the Mayors of Irkutzk, Krasnoyarsk, Tobolsk, Tiumen, Tomsk, and Ekaterinburg, who have been invited by telegraph to co-operate in forwarding the enterprise. A reply has since been received from a proprietor of gold mines at Krasnoyarsk contributing 500*l*. to the expenses of the undertaking.

"FROM Vineyard to Decanter" (Stanford), the second edition of which has come to hand, is "a book about sherry." We would recommend it to all of our readers who love "a good glass" of that favourite British beverage. It gives a clear account of the processes through which the wine goes in all its stages, and the conclusion of the whole matter seems to be that if you wish to drink good sherry you must make up your mind to pay a good price for it.

THE *Revue Scientifique* announces the death of the naturalist M. Pictet.

THE *Cologne Gazette* states that Herr Heuglin, the African traveller, has declined the offer of the Khedive to take the command of the troops sent to Abyssinia, in place of the late Munzinger Pasha, but is organising an Abyssinian exploration for scientific purposes.

DR. VON RICHTHOFEN, the well-known traveller and geographer, has been appointed Professor of Geography at the University of Bonn. He is still occupied at Berlin with the editing of his great work on China.

THE additions to the Zoological Society's Gardens during the past week include a Le Vaillant's Cynictis (*Cynictis penicillata*) from South Africa, presented by the Viscount Mandeville; a Hooper Swan (*Cygnus ferus*), European, presented by Mr. Montague Kingsford; a Weeper Capuchin (*Cebus capucinus*) from Brazil, presented by Mr. August Kettner; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. T. J. Dunn; two Darwin's Pucras (*Pucrasia Darwini*) from China, purchased.

SCIENTIFIC SERIALS

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Nov. 15, 1875.—Dr. Billwiller, of Zürich, contributes an article on a local occurrence of the northerly "Föhn." It was formerly believed that the Föhn came from the Sahara Desert, whence it derived its warmth and dryness, but Hann showed a few years ago that, according to known physical laws, descending air becomes warmer and drier, that winds of the Fohn kind are not confined to the Alps but occur in other mountainous regions, and that the southern slopes of the Alps have a north wind, which is the exact counterpart of that called the Föhn. A mass of observations made in Switzerland have since proved the correctness of his theory. Herr Billwiller, from the data he has as yet examined, finds that isolated Föhn winds prevail only when a broad current flows over the whole Alps in the same direction, ascending on one side and descending on the other. But there are cases in which no perceptible upward movement can be traced on one side, and yet on the other the Föhn descends into the valleys from above. A difference of density, often great, is the cause of this. The lower strata being obstructed the outflow of air necessary to restore equilibrium comes from above. The merely local Föhn blows strongly down a valley, but on reaching the colder air of the plain mixes with it and quickly comes to rest. Tables are given showing meteorological conditions in particular cases.—The next article, written by Dr. Wild, and quoted here from the Annual Report of the Imperial Observatory at St. Petersburg, is a review of the work of the Meteorological Congresses of 1873 and 1874. Perhaps the most important result of these congresses will be the general use of more trustworthy instruments by official and private observers. The following advantages have already been gained: an international system of ciphers for telegraphic despatches throughout nearly the whole of Europe; an international form of publication in the following countries: Norway, Sweden, Denmark, Russia, Austria, Switzerland, Italy, and part of Germany; and lastly, the establishment in many States of central institutions. We shall thus obtain better, more uniform, and more accessible data as a consequence of the late congresses.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Jan. 6.—On the refraction of sound by the atmosphere, by Prof. Osborne Reynolds, Owens College, Manchester. Communicated by Prof. Stokes, Sec. R.S.

This paper may be said to consist of two divisions. The first contains an account of some experiments and observations undertaken with a view to ascertain how far the refraction of sound caused by the upward variation of temperature may be the cause of the difference in the distances to which sounds of the same intensity may be heard at different times.

Some rockets, capable of rising 1,000 feet, and then exploding a cartridge containing 12 oz. of powder, having been procured, an effort was made to compare the distance at which the rockets could be heard with that at which a gun, firing $\frac{3}{4}$ lb. of powder and making a louder report than the rockets, could be heard under the same conditions of the atmosphere. In the first instance the rockets and the gun were fired from a spot in Suffolk, around which the country is tolerably flat, observers being stationed at different distances. Owing, however, to the effect of the wind and the time required for the observers to proceed to the distant stations, these experiments were not successful in establishing the comparative merits of the gun and the rockets. They were, however, important as showing that on hot calm days in July the reports of the rockets never failed to be distinctly audible at distances of four and five miles, although the sun at the time was shining with full force on the ground, and rendering the air near the surface so heterogeneous that distant objects seen through it appeared to wave about and twinkle.

The next attempt was made during a cruise on the east coast. After three weeks cold and windy weather, the 19th of August was a fine day, and some experiments were made in Lynn Deeps, which revealed a very extraordinary state of the atmosphere as regards the transmission of sound. A party rowed away from the yacht in one of her boats, it having been arranged beforehand that either a rocket or a large pistol was to be fired from the yacht when signalled for; also that when those on the yacht heard those in the boat call they should answer. The boat proceeded to a distance of five miles, until those on the yacht had completely lost sight of it; but all the time the calls from the boat were distinctly heard by those on the yacht, although after they had lost sight of the boat they ceased to answer the calls. On the boat also not only were the reports of the pistol and rockets distinctly heard, but every answer from the yacht was heard plainly. The last came after an interval of thirty-five seconds, which gave the distance $3\frac{1}{2}$ miles. Nor was this all; but guns, and on one occasion the barking of a dog, on the shore eight miles distant, were distinctly heard, as were also the paddles of a steamer fifteen miles distant.

The day was perfectly calm, there was no wind, the sky was quite clear, and the sun shining with great power—conditions which have been described as most favourable to the stoppage of the sound by the heterogeneity of the atmosphere, and which may also be described as most favourable for great upward refraction. On this day, however, it was observed that all the time distant objects *loomed* considerably, *i.e.*, appeared lifted. This showed that the air was colder near the surface of the sea than it was above. It is to this circumstance that the extraordinary distances to which sounds were heard on this day is supposed to be due. The diminution in the temperature of the air being downwards, the sound, instead of being lifted as it usually is, was brought down, and thus intensified at the surface of the water, which, being perfectly smooth, was thus converted into a sort of whispering-gallery.

The report of the pistol and the sounds of the voice were attended with echoes, but not so the reports of the rockets; and it is suggested that these so-called echoes may be found only to attend sounds having a greater intensity in one direction than in another.

The second part of the paper refers to a phenomenon noticed by Arago in his report of the celebrated experiments on the velocity of sound made on the nights of the 21st and 22nd of June, 1822.

It was then found that, although the guns fired at Montlhery could be distinctly heard at Villejuif (eleven miles distant), those fired at Villejuif could not be heard at Montlhery without great attention, and at times (particularly on the second night) they were not heard at all; although on both nights the wind was blowing from Villejuif to Montlhery, the speed of the wind, which was very light, being about 1 foot per second. No explanation of this phenomenon was offered by the observers, although it was much commented on. And on the second night the gun at Villejuif, which on the previous night had been pointed upward, was brought down in the hope that this might improve its audibility (this step was, however, found to render matters worse than before).

From this lowering of the gun at Villejuif it seemed as though there was probably some difference in the conditions under which the guns at the two stations were placed, as if that at Villejuif was fired from a level, while that at Montlhery might be fired over a parapet. An inspection of the district confirmed this view; for Villejuif is on a low, flat hill, while Montlhery is on the top of a steep cone; and not only is it 80 feet above Villejuif, but it is surmounted by the mound of an old castle, which

is supported by a vertical wall towards Villejuif and surrounded by a low rampart. Hence it is suggested that in all probability the advantage of the gun at Montlhery was due to its being fired over this parapet, while that at Villejuif was fired from the level ground.

The fact that the wind blowing from Villejuif did not reverse this advantage, suggested the possibility that at night, when the diminution of temperature is downward, a light wind may not produce the same effect upon sound as when the diminution of temperature is upward, as it generally is during the day.

To ascertain if this is the case, some observations were made on some calm nights in May and June of the present year, from which it was found :—

(1) That the sky was cloudy and there was no dew. The sound of an electric bell 1 foot above the grass could always be heard further with the wind than against it; but

(2) That when the sky was clear and there was a heavy dew, the sound could invariably be heard as far against a light wind as with it, and in some cases much further. On one occasion, when the temperature at 1 foot above the grass was 38° and at 8 feet 47°, and the speed of the wind was 1 foot per second at 5 feet above the grass, the bell was heard 440 yards against the wind and only 270 with it.

Since, therefore, on the nights of the experiments at Villejuif and Montlhery it is stated that the sky was clear, that there was dew, and the temperature recorded at the two stations shows the diminution to have been downwards, it is argued that the effect of the wind to render the sound less audible at Villejuif was completely balanced by the downward refraction of temperature.

Another phenomenon recorded by Arago is, that while the reports of the guns at Montlhery as heard at that station were attended with prolonged echoes, this was not the case with those at Villejuif. It is thought that this difference is sufficiently accounted for by the fact that while Montlhery is surrounded by high hills with precipitous or wooded sides, which must produce echoes, the country in front of Villejuif is very flat and has not a tree upon it for miles.

In concluding the paper reference is made to the Appendix to the last Report of the American Lighthouse Board, in which Dr. Henry, the Chairman, gives an account of his experiments, extending over thirty years, and the conclusions to which they have led him; both of which are in favour of the apparent stoppage of the sound being due to refraction.

Zoological Society, Jan. 4.—Prof. A. Newton, F.R.S., vice-president, in the chair.—An extract was read from a letter addressed to the Secretary by Mr. George Brown, dated Port Hunter, Duke of York Island, stating that he had shipped for the Society to the care of Dr. G. Bennett, of Sydney, two cassowaries and some other birds from New Britain and Duke of York Island.—A letter was read from Mr. R. Trimen, Curator of the South African Museum, Cape Town, containing some remarks on *Canis chama*.—Dr. Hector, F.R.S., exhibited and made remarks on three ancient feather-mats, made by the Maoris of New Zealand, which had been obtained by Dr. Buller, from a chief on the Upper Wanganui River.—Prof. W. H. Flower, F.R.S., gave a description of the skull of a fossil species of the genus *Xiphodon*, Cuvier, from a specimen belonging to the Museum of the Royal College of Surgeons, supposed to have been found near Woodbridge in Suffolk.—Prof. Huxley, F.R.S., read a paper on *Ceratodus*, in which he pointed out the special characters presented by this remarkable fish in the structure of its nasal apertures, brain, skull, and fore-limb. Prof. Huxley also called attention to the close connection shown by certain details of structure between *Ceratodus* and the Chimæroid fishes, especially as regards the skull.—A communication was read from Dr. Julius Von Haast, F.R.S., containing the description of a new Ziphioid whale from the coast of New Zealand.—Mr. Sclater read a paper on some additional species of birds from St. Lucia, West Indies, which had been sent to him by the Rev. J. E. Semper of that island. The collection contained one very remarkable form which appeared to be referable to a new genus of *Mniotiltidæ*, and was proposed to be called *Leucopeza semperi*.—A communication was read from Mr. W. H. Hudson containing some notes on the spoonbill of the Argentine Republic.—A paper was read by Messrs. Sclater and Salvin, on Peruvian birds collected by Mr. Whitely, being the ninth of a series of communications on this subject.—A communication was read from Dr. Otto Finsch, containing notes on some Fijian birds, including description of a new genus and species proposed to be called *Drymochæra badiceps*.—Mr. A. H. Garrod read a note on the *cæcum coli* of the Capybara, as observed in a specimen recently deceased in the Society's menagerie.

Royal Microscopical Society, Jan. 5.—Mr. Chas. Brooke, F.R.S., vice-president, in the chair.—Messrs. W. A. Bevington and B. D. Jackson were elected auditors of the Society's accounts, and a list of gentlemen nominated for election as officers and council for the ensuing year was read by the Secretary.—Attention was called to a number of specimens sent to the Society a short time since by Mr. Hanks, of San Francisco, and which had since been mounted for the cabinet by Mr. Loy; also to some slides of *Aulacodiscus kittoni*, presented by Mr. Thos. Curties from material collected on the late Congo Expedition, by Mr. Martin, H.M.S. *Spiteful*.—Mr. C. Stewart then gave an interesting account of the structure and development of sponges, freely illustrating his remarks by drawings upon the black-board, and concluded by stating his reasons for believing that the well-known perforations in oyster-shell were really made by the sponge.—Mr. Hickie exhibited to the meeting some photographs from Germany of *Navicula crassinervis* and *Frustulia saxonica*, and read some letters from Dr. Rabenhirst and Herr Seibart in support of his opinion that the two were widely distinct.

Entomological Society, Jan. 5.—Sir Sidney Smith Saunders, C.M.G., president, in the chair.—Messrs. F. J. Horniman and D. G. Rutherford were elected ordinary members, and Prof. W. Dickson, of Glasgow University, and Mr. F. Enoch were elected subscribers.—The Rev. R. P. Murray exhibited a collection of Lepidoptera taken by himself on the Higher Alps, amongst which were some interesting mountain varieties.—Mr. S. Stevens exhibited a specimen of a dragonfly, rare in this country (*Æschnia mixta*), which he had picked up, nearly dead, in his garden at Upper Norwood, in the middle of November.—Mr. Champion exhibited some rare British Coleoptera.—Mr. H. W. Bates communicated a paper entitled "Additions to the list of Geodephagous Coleoptera of Japan, with synonymic and other remarks."—Mr. W. H. Miskin, of Queensland, communicated a description of a new and remarkable species of moth belonging to the genus *Attacus*, of which a male and a female specimen had been taken in the neighbourhood of Cape York. He had named the species *A. Hercules*. The expanse of the wings measured nine inches, and the hind wings were furnished with tails. The specimens had been deposited in the Queensland Museum.—Mr. C. O. Waterhouse forwarded a paper on various new genera and species of Coleoptera belonging to the *Geodephaga*, *Necrophaga*, *Lamellicornia*, and *Rhyncophora*.—Part IV. of the "Transactions" for 1875 was on the table.

MANCHESTER

Literary and Philosophical Society, Dec. 14, 1875.—Mr. Edward Schunck, F.R.S., &c., president, in the chair.—On graphic methods of solving practical problems, by Prof. Osborne Reynolds. In the first part of this paper it is pointed out that, when dealing with practical problems by the aid of the graphic method, it is not necessary to break off the operations of drawing, and find numerical values for the quantities represented, in order to perform on them the operations of multiplication and division. For by the aid of a parallel ruler the operations of multiplication and division may be performed graphically with great facility. The only geometrical proposition involved being that of finding a fourth proportional to three distances. When two distances have to be multiplied or divided the one by the other, a third distance is chosen equal to unity, and a fourth proportional found which represents the product or ratio of the first according as unity is the first or third of the given quantities. The method was illustrated as applied to the determination of areas, centres of gravity, and moments of inertia. In the second part of the paper a graphic method is described by which the velocity and acceleration of a moving point can be determined when the times at which it occupies certain positions are known, *i.e.* the curves representing the velocity and acceleration of the point may be drawn from the curve representing the positions of the point. Also a converse method by which the position of a point at any time may be found from the curve representing either its velocity or displacement.—On explosions of fire-damp. E. W. Binney, F.R.S., said that the fearful loss of life in our coal-mines deserved the careful attention of all societies like ours. It ought to be one of the objects of science to endeavour to find out the cause of these explosions, and to devise some means to prevent their occurrence or lessen their frequency. No doubt Government inspection had been of service, and the examination of managers would tend to improve the efficiency of

mining officers; but still, notwithstanding these improvements, the explosions of fire-damp are sadly too frequent. The lamentable events which have taken place within the last few weeks clearly show that they sometimes occur without any great change in the barometric pressure of the atmosphere, although undoubtedly sudden depressions in a barometer ought to caution miners against emission of gas from the seam of coal and coal-wastes, and put the men more on their guard at such times. It has been stated in this Society that certain conditions of the atmosphere quite irrespective of barometric pressure may have something to do with causing the "drag" in the currents of air circulating through a mine, as explosions have frequently occurred during an east wind and a muggy state of the atmosphere, and a vesicular condition of water in the air has been suggested as the probable cause of this lessening of the speed of the air passing through the galleries of mines. Now, careful observations with a good anemometer in the return air-course of a mine ought to determine whether or not such an effect is produced, and thus settle this point by direct experiment. Another source of accidents at this time of the year has to be taken into consideration. Before Christmas and in cold weather there is often a brisk demand for coal, and both managers and men are in a hurry to increase the output, and under such circumstances probably there may be sometimes not so much care and caution exercised as are necessary for them to use in the dangerous work in which they are engaged. In the management of a fiery mine, in my opinion—1. There ought not to be any unventilated wastes. 2. The mixed use of Davy lamps and naked lights should not be permitted where the former are commonly employed. 3. Blasting of coal by gunpowder should not be sanctioned where Davy lamps are in common use. 4. An anemometer under the care of a competent man should be in constant use, in order to see that a sufficient current of air is passing through the workings to insure perfect ventilation of the mine. 5. When there are marked indications of firedamp in a mine, shown by a cap on the flame of a lamp, the men engaged in hewing and drawing coal should be removed from the pit until by ventilation the place is cleared of gas and rendered safe for a working collier. The above precautions may probably cause an increased cost in the getting of coal, but they are necessary for the preservation of human life if such catastrophes as now frequently occur are to be prevented. It is now pretty generally admitted that all explosions of fire-damp are caused by there being too little pure air and too much of that gas in a mine.—Chemical notes, by M. M. Pattison Muir, F.R.S.E., Assistant Lecturer on Chemistry, Owens College.

Paris

Academy of Sciences, Jan. 3.—Vice-Admiral Paris in the chair.—M. Peligot was elected vice-president for 1876; and MM. Chasles and Decaisne were elected to the Central Administrative Commission. The following papers were read:—On the interior constitution of magnets, by M. Jamin.—New thermic researches on the formation of organic compounds; Acetylene, by M. Berthelot. The heat liberated by combustion of acetylene with free oxygen = + 321 cal. for C_4H_2 = 26 grs.—Final reflections on the production of saccharoid matters in plants, by M. Duchartre.—Ephemerides of the planet (156) determined by M. Rayet, from observations at Marseilles, by M. Lœwy.—On the way in which caloric vibrations may dilate bodies, and on the coefficient of dilatation, by M. de Saint-Venant.—Sixteenth note on the electric conductivity of moderately conducting substances, by M. Du Moncel. Minerals, when truly conductors, have but two kinds of conductivities, an electrolytic conductivity and one which is proper to them and approximates more or less to metallic conductivity. The electrotonic conductivity proper to dielectrics exists only in rocks known to be isolating and in crystals. But there are effects which imply a characteristic polarity of a moderately conducting medium.—New crystallised hydrate of chlorhydric acid, by MM. Pierre and Puchot. Mixing two parts of snow with one part of hydrochloric acid (cooled previously to − 15° or − 16°), one may obtain a temperature of − 35° C.—On a new fundamental law of electro-dynamics, by M. Clausius.—On the study of thermic motors, and on some points of the theory of heat in general, by M. Hirn. This is an outline of Vol. II. of the author's work on Thermo-dynamics.—Osseous heads of fossil and actual human races; history of ethnic craniology; Negrito race, by MM. Quatrefages and Hamy.—Report on M. de Magnac's method for representing the daily course of chronometers.—Determination, by the principle of analytical correspondence, of the order of a geometric place defined by algebraic conditions, by M. Saltel.—On a point of infinitesimal geometry, by M. Serret.—On left cubics, by M. Appell.—Physiological conditions influencing the character of unipolar excitation of nerves, during and after the passage of a battery current, by M. Chauveau. He studies four cases: nervous system intact, spinal cord separated from brain, cord destroyed, and nerve cut above point of application of electrode.—On a commensal Amphipodan (*Urothoe marinus*) of the *Echinocardium cordatum*, by M. Giard.—Elliptic elements of the planet (157) Dejanire, and calculated ephemerides, by M. Stephan.—Researches on the law of transmission, by the earth's atmosphere, of calorific radiations from the sun, by M. Crova.—On the phenomena of induction, by M. Mouton. He studies the electric state of an induced bobbin with the ends unconnected, and too far apart for a spark to pass; a series of oscillations in potential is observed.—On the *rôle* of acids in dyeing with alizarine and its congeners, by M. Rosenstiehl.—On the phosphates of sesquioxide of iron and alumina, by M. Millot.—On a secondary hexylic alcohol, by M. Œchsner de Coninck.—On the assimilability of fossil phosphates, and on the danger of exclusive use of azotised manures, by M. Roussille.—On the preparation of gaseous bromhydric acid, by M. Bertrand.—Researches on the functions of glands in the digestive apparatus of insects, by M. Jousset. He was able, in *Blatta orientalis*, to obtain the liquids in the gland itself before entrance into the alimentary canal.—On the floral glands of *Parnassia palustris*, new physiological functions, by M. Hæckel. These glands are a carnivorous organ.—Undulations of the clay in the north of France, by M. Hebert.

Vienna.

Geological Society, Dec. 7, 1875.—After welcoming Dr. E. Tietze on his return from Persia, M. von Hauer presented some papers sent in by Dr. K. Peters on the interesting limestone from the Sauerbrunngraben, near Stainz, in Styria, which encloses crystals of a plagioclastic felspar belonging to the species Albite.—Dr. A. Feistmantel, on the minerals of the peculiarly large-grained granite (Pegmatite) from the districts of Behar and Rangun, in Bengal. Among them large plates of mica are very remarkable, which the inhabitants make use of as ground for paintings, but they are also, like the Russian mica, brought to Europe for sale.—Dr. Kapf, of Stuttgart, on some very interesting remains of Saurians found in the so-called Stuben sandstone of Wurtemberg.—Dr. Mojsisovics presented the second volume of his work on the Mountains of Hallstadt, and gave a short account of its contents. In this volume the genera Arcestes (with 112 species), Didymites (with 6 species), and Lobites (with 26 species) are described, and illustrated in thirty-eight lithographic plates.—Dr. Dölter reported on the composition of the Melaphyres from the Southern Tyrol. Among the essential constituents of them, he recognised in some cases Amphibole, in others Augite.—R. Hörnes exhibited some remains of *Anthracotherium magnum*, from the coal-mines of Trifail, in Styria, and expressed the opinion that the carboniferous strata of Trifail and Sotzka are not identical with those of Eibiswald and Wies, but belong to an older stage of the tertiary period.

THE "ENCYCLOPÆDIA BRITANNICA"

Encyclopædia Britannica. Vol. III. (Edinburgh: Adam and Charles Black.)

First Notice.

THERE are several important scientific articles in this third volume which we shall briefly notice, the articles generally being quite up to the standard of the preceding volumes. In this first notice we shall refer especially to the articles "Birds" and "Biology." The former article is the joint production of two authors, Professors W. K. Parker and Alfred Newton.

Prof. Parker has undertaken the anatomical portion of the subject. Allowing himself to be led away in the direction of his favourite line of research, the author has persuaded himself that in the space allotted to him for his article "there is merely room for justice to be done to one category of organs; and as the skeleton and especially the skull is of most direct importance to the zoologist and palæontologist, and as its form determines, as it were, all other organs . . . it seems to be that on which election should fall for the fuller treatment." From this opinion we disagree *in toto*. If the space allotted for the subject is insufficient, it must be a fault of the general management of the "Encyclopædia." If the skull "determines, as it were," all other organs, then the study of anatomy is on a very different footing from that on which it seems to stand. By a glance at the earlier volumes of the work, in which, as in the case of the article "Anatomy," by Prof. Turner, apparently unlimited space is allowed to the author, we come to the conclusion that there is no fault in the editorial department, in this direction at least. As to the "determining" influence of the skull the true relationship of three groups of birds—the woodpeckers, toucans, and barbets — which will be found explained below, is quite sufficient to demonstrate how unwarranted is the assumption.

In 1867 Prof. Huxley propounded a classification of birds, not entirely, but mainly based on the nature of a portion of the palatal region of the skull. This valuable addition to ornithological and zoological literature has given a great stimulus to more minute investigation of avian structure. It brought to light many new facts, and placed prominently forward others previously too much neglected. The classification was, however, only an artificial one, for, according to that author's own words in the article "Biology" before us, "in an *artificial* classification some prominent and easily observed feature is taken as the mark of resemblance or dissemblance." The features employed in this case were two—the fusion or non-fusion of the maxillo-palatine plates of the maxillary bones, and the shape of the vomer. In a hobby-run-wild manner, Prof. Parker, in his article "Birds," has further elaborated this artificial arrangement to a degree which, more than anything else, demonstrates its untenability. He begins by dividing the "Carinatæ" into two sections, firstly, the Dromaeognathæ (*Tinamous*), and secondly, all the others; because in the *Tinamous* the vomer is broad behind and interposes between the pterygoids, the palatines, and the basi-sphenoidal rostrum (which, however, is also the arrangement in some of the penguins at least.) Among the other carinate birds, Prof. Huxley's divisions are retained, except that the woodpeckers are removed from the Ægithognathæ to form an independent group of equal importance with them, the Saurognathæ! The Desmognathæ (Huxley), we are told, do not form a well-collected group, and Prof. Parker does good service by indicating the different ways in which desmognathism may be produced.

According to this classification, there are some so great anomalies, when it is looked at from the aspect based on the totality of the morphological resemblances in the bird-class, that it is certain that the palate, *per se*, is in reality of secondary importance in the determination of the relationships of many birds.

For instance, according to Prof. Parker, the Woodpeckers (*Picidæ*) form a main division (Saurognathæ) of the non-desmognathous carinate birds, at the same time that the Toucans (*Ramphastidæ*), together with the Barbets (*Capitonidæ*) form part of a minor section (Coccygomorphæ) of the desmognathous birds. In other words, they would be made to have as little to do with one another as they well can. Now the structure of the rest of the body, other than the head, tells quite a different tale. From the form of the feathers and the pterylosis, there being no after-shaft, a tufted oil-gland and quite a characteristic distribution of the peculiarly narrow feather-tracts; from their osteology, the sternum and other bones being almost identical in all of them; from the anatomy of the alimentary canal, in which the colic cæca are absent; from the arrangement of the toes in the scansorial foot; from their myology, in which they are identical when dissected, muscle by muscle, and different in points from all other birds, it is certain that the three groups, viz., the Woodpeckers, Barbets, and Toucans, are most intimately related, and have not, in reality, a family difference between them; their dissimilarities—the Toucans and Barbets merging into one another—leading to their being arranged in two sub-families.

As another example of the different teaching of the artificial and the natural classifications, the Swifts (*Cypselidæ*) and the Humming Birds (*Trochilidæ*) may be referred to. These two groups, from the details of their internal structure when examined one by one, are most certainly related as intimately as are the Woodpeckers with the Toucans. There is, in fact, not a family difference between them, and yet, from their palates, Professors Huxley and Parker place them in quite different divisions, because the vomer is truncated in the one and pointed in the other.

We think that we have said enough to shew that the structure of the skull does not alone suffice to determine the mutual affinities of birds, the head in them being subject to rapidly developing peculiarities which are associated with their habits of life.

With the exception of the skeleton, the rest of which is described in fair detail, Prof. Parker devotes but few columns of his article to the organs, muscles, vessels, and nerves; he in most cases quoting verbatim from Prof. Huxley's "Anatomy of Vertebrated Animals."

Prof. Newton's portion of the article "Birds" forms a valuable memoir on the topics he discusses. The elegance of the style, and the careful manner in which the

relative importance of the facts which are introduced is weighed, adds a charm to the subject equal to that which it already possesses. "Fossil Birds," "Sub-fossil Birds," "Birds recently extirpated," "Birds partially exterminated," "The Geographical Distribution of Birds," "Migration," "Song," "Nidification," "Eggs," and "Moult," are the headings of the various sections of his subject; the whole occupying about fifty pages of the "Encyclopædia;" that on Distribution being of considerably the greatest length, as it is fairly exhaustive in its account of the avifauna of the different regions. Speaking of the general principles of zoogeography, first laid down by Mr. Sclater in 1857, Prof. Newton remarks that "without infringing upon what must be deemed the generalities of biological distribution, it is proper to observe that Mr. Sclater's success is to be attributed to the method in which his investigations were carried on—a method in which he had but few predecessors. Instead of looking at the earth's surface from the point of view which the geographer would take of it (a point of view which had hitherto been adopted by most writers), mapping out the world according to degrees of latitude and longitude, determining its respective portions of land and water entirely regardless of the products of either element, or adhering to its political divisions—time-honoured as they were—he endeavoured to solve the question simply as a zoologist should, by taking up the branch of the subject with which he was best acquainted, and by pointing out and defining the several regions of the globe in conformity with the various aspects of ornithic life which they present. But herein there was at once a grave difficulty to be encountered. Birds being of all mammals most particularly adapted for extended and rapid locomotion, it became necessary for him to eliminate from his consideration those groups, be they large or small, which are of more or less universal occurrence, and to ground his results on what was at that time commonly known as the order *Incessores*, or *Passeres*, comprehending the orders now generally differentiated as *Passeres* (*veræ*), *Picariæ*, and *Psittaci*. On this basis, then, Dr. Sclater was enabled to set forth "that the surface of the globe exhibited *six* great regions," an account of each of which is given in detail, with the light thrown upon them by more modern research.

As might be imagined, the section on "Birds recently extirpated" is a more complete and accurate *résumé* of their history than any other extant, the Starling of Réunion (*Fregilupus varius*), the Solitaire of Rodriguez (*Pezophaps solitarius*), and the Crested Parrot of Mauritius (*Lophopsittacus mauritianus*), being figured as well as described.

The article "Biology" is by Prof. Huxley and Mr W. T. T. Dyer. The subject is treated generally by the former author in his well-known style, whilst Mr. Dyer gives the principles of classification of the vegetable kingdom as they are now understood by the most advanced botanists.

Prof. Huxley classifies the phenomena of life under four headings:—1. Morphology; 2. Distribution; 3. Physiology; and 4. Etiology. The last of these, from its theoretical nature, presents features of more especial interest. With reference to the doctrine of spontaneous generation we read: "It has been pointed out at the commencement of this article that the range of high temperatures between the lowest, at which some living things are certainly killed, and the highest, at which others certainly live, is rather more than 100° Fahr. It makes no sort of difference to the argument how living beings have come to be able to bear such a temperature as the last mentioned; the fact that they do so is sufficient to prove that, under certain conditions, such a temperature is not sufficient to destroy life. . . . Thus it appears that there is no ground for the assumption that all living matter is killed at some given temperature between 104° and 208° Fahr." Again, "it is argued that a belief in abiogenesis is a necessary corollary from the doctrine of evolution. . . . In the eyes of a consistent evolutionist any further independent formation of protoplasm would be sheer waste."

Prof. Huxley gives his powerful and entire sanction to the docrine of Ontogeny, explaining the facts that in many forms there are gaps and irregularities in the order of production of the organs, by assuming that the series of developmental stages of the individual organism never present more than an abbreviated and condensed summary of ancestral conditions.

Mr. Dyer devotes himself to the "Limits and Classification of the Vegetable Kingdom," and concludes his article with a synoptic view of the relations of plants, which shows how much attention has recently been paid to the lower forms. Schwendener's hypothesis is assumed, and "Lichens must now be regarded as composite structures, partly consisting of an alga, partly of a fungus." The Thallophyta are classified according to the method of Sachs, and the Cryptogams according to Cohn. The stepping-stones between these last and the Phanerogams are excellently sketched.

We think we have said enough to show the great importance of the two articles which we have been attempting to criticise.

A. H. GARROD

FOSSIL BUTTERFLIES

Fossil Butterflies. By Samuel H. Scudder. (Published by the American Association for the Advancement of Science, Salem, 1875.)

THE memoir now before us will be a boon, not only to geologists, but to entomologists, inasmuch as it reproduces in a small compass, as Mr. Scudder says, "all that has been published of this group of fossils, whether of text or illustration."

After giving a complete list of all the works treating of the subject, the author proceeds to characterise the genera and species, beginning with *Neorinopis sepulta*, from Aix in Provence, a fossil more discussed than any other ancient Lepidopteron. He confirms Mr. Butler's determination of its affinities, but adds that, from a careful study of the original, he has been enabled to correct an error as regards the actual condition of the fossil, which he thus describes:—

"The thorax, hind legs, and both pair of wings of the left side are preserved, almost completely; all the rest is lost. The thorax is viewed from above, and somewhat on the left side; the hind coxæ seem to be almost torn away from their immediate connection with the trunk. The two hind legs are stretched out, bent at the femoro-tibial articulation; the left leg lies above both the wings,

and is apparently attached throughout, although its base is covered a little by the crushed body; the right leg lies below both the wings, and is apparently partially detached, though but slightly, from the coxæ; the tibio-tarsal articulation can be distinguished, but not the tarsal joints. The wings are bent over downward in a position the reverse of that of repose. The fore-wing covers the hind-wing, as in nature, but to such an extent as to conceal the greater part of it; the guttered portion of the inner margin of the hind-wings is almost fully expanded, but apparently has a fold next the submedian nervure. The fringe of the fore-wing seems to be gone, but that of the hind-wing is preserved nearly throughout. Head, fore and middle legs, wings of the right side, and abdomen are wholly wanting.

"The upper surface of the wing is, therefore, the part which attracts most attention."

The above description throws an entirely new light upon this fossil, and is exceedingly interesting.

Lethites reynesii, another Eocene species, is placed next to the genus *Lethe*; the latter comes close to *Melanitis* in Westwood and Hewitson's "Genera of Diurnal Lepidoptera," a fact which Mr. Scudder considers of some interest; the two groups, however, are widely separated in some recent classifications, in which the structural relations of the genera of *Satyrinæ* have received special attention.

The Tertiaries of Radoboj afford another remarkable fossil (*Mylothrites pluto*) which Mr. Scudder, differing widely from all previous writers, refers, on we think insufficient grounds, to the sub-family *Picrinæ*, inasmuch as the spots on the wings are not of the same simple character as those of *Hebomoia* and allies, but are true ocelli, the zones of which are clearly visible even in the drawing on Plate II. (compare Figs. 14 and 17). The portion of a hind wing (Fig. 15) has been also somewhat rashly referred to *Mylothrites*, its venation being markedly different, and agreeing more nearly with the Eastern genus *Terinos* than with any other group known to us.

Mr. Scudder seems to have indicated the correct position of *Coliates proserpina* and *Pontia Freyeri*. In the case of the former, his task, owing to the obscure character of the original, must, as he says, have been a difficult one.

Spots on the wings, such as are represented on Plate II., Fig. 5, are rarely to be met with among the *Picrinæ*, but do occur in some males of the genus *Appias*.

It is probable that Mr. Scudder is again correct with regard to the position of *Thaites ruminiana*, although the general pattern, form of the wings, and large abdomen are all far more like *Dynastor* or *Castnia*.

Thanaites vetula and *Pamphilites abdita* have manifestly the proper places assigned to them, and great credit is due to the author for the labour which he has expended in their determination.

Mr. Scudder's conjectures respecting the "food-plants of Tertiary Caterpillars" are exceedingly interesting, as also his remarks on "the present distribution of Butterflies most nearly allied to fossil species." Asiatic forms having the facies of *Pamphilites abdita* are not, however, as he supposes, unknown; the *Urbicolæ* of East India are perhaps not as yet largely represented in American collections.

In his "Notice of Insects which have been erroneously referred in recent times to Butterflies," Mr. Scudder dwells upon the discussion between himself and Mr. Butler respecting *Palæontina oolitica*, and gives facsimiles of that author's illustrations, with an additional sketch representing his own view of the characters of the species. From a comparison of the five illustrations it is difficult to conclude that Mr. Scudder has proved his case. The venation, as given by him, not only does not agree with that of any genus of *Lepidoptera*, but is entirely at variance with what is found in any insect. To associate it with the *Cicadinæ* is impossible, seeing that these insects have irregular neuration, whereas Scudder's figure furnishes us with a Lepidopteroid type having anomalous cross-veins and an incomprehensible discoidal cell.

The assertion that "none of the median nor any of the inferior subcostal nervules are ever branched certainly requires modification; the genus *Amathusia* has a well-marked spur on the third median branch, which conveys the impression of a fourth median nervule, whilst the genus *Moschoneura* emits its upper discoidal from the inferior margin of the subcostal.*

Mr. Scudder, in America, is surely a little too hard upon his entomological brethren on this side of the Atlantic, when he speaks of the new Linnæan room at Burlington House in which they held their meeting as "a poorly lighted hall." See p. 95.

We cannot conclude without expressing our admiration of the beautifully executed plates which accompany the letterpress.

BURCHETT'S "PRACTICAL PLANE GEOMETRY"

Practical Plane Geometry. By E. S. Burchett. (London and Glasgow: W. Collins, Sons, and Co., 1876.)

THIS is a carefully got-up and good work on the subject of which it treats. After the usual preliminary matter on definitions and the use of instruments are given 333 problems. This may appear to be too large a number for school teaching, but the work is principally intended for students in Art schools. For school purposes, and we have more than once recently pointed out that the subject is taught as affording a good initiation to the study of pure geometry, we should recommend the master to make a selection such as he thinks adapted to the attainments of his pupils or fitted to the end he has in view in taking up the study. Plates LII. to LXIII. are devoted to Applied Geometry (such as curves of mouldings, Gothic tracery, construction of scales, &c.). An Appendix (Plates LXIV. to LXXI.) treats of the Elements of Orthographic Projection. This last portion we are told is given expressly to meet the requirements of the more extended range of the Second Grade Examination of the present day. We have verified most of the constructions, which are clearly given, and in the main admit of demonstration on pure geometric principles. Some relating to the construction of polygons, three on the contact of circles, and some few relating to the areas of circles, are founded on approximative methods. The arrangement of the text and of the plates appears to us to be a good one. The book must be used in a position at right angles to the usual one, and then the text is on

* See Westwood's "Oriental Entomology," p. 49, and compare "Trans. Ent. Soc.," 1870, p 486; also "Cistula Entomologica," i p. 54.

the left-hand page, and so above the plates, which are immediately under the pupil's eyes. The printing and the plates (the only figure that does not please us is the oval on Plate II.) leave nothing to be desired.

We proceed to point out a few matters which we think admit of improvement. Plate II. in the definition of a circle *invarying* is used; why not "constant?" The construction of Fig. 6 (Plate IV.) is hardly satisfactory to our view, though it is one very frequently given; the tangent to the two arcs is not obtained by a legitimate method. We cannot make out the definition of an harmonic *mean* given on Plate VII., but the *means* are correctly constructed. In Fig. 31 (text), for GH : HA, read *vice versa*. We may remark that it is a curious fact that the approximative construction given in Fig. 87 is true in the cases of regular figures of three, four, and six sides. In Fig. 99 (text) read "through F and E." In Fig. 112 (text) arcs "cutting in C," not G. Constructions to Figs. 123, 125 give particular ellipses; so in the case of the parabolas in Figs. 138, 139, we note that certain figures are stated to be *co*-centric and certain curves have assym ptotes. In Fig. 271 (text) read to cut in "I and H." We object, on pure geometric grounds, to the constructions in Figs. 278, &c., where a line is found equal to the semi-circumference of a circle, &c.; also the inscribed circle of a square and the inscribed triangle are stated as being in the ratio, triangle : circle : square, as 2 : 3 : 4. In Fig. 279 (text) the two last A's should be D. The construction to Fig. 297 (to draw a line to bisect any triangle from a given point within it) is new to us, and on a cursory examination of it we have not satisfied ourselves of its correctness. In Fig. 314, for XY, read ZY. In Fig. 316, "the square on," or some such words have been omitted. In Fig. 323 the limitations have not been laid down. In Fig. 329, "*join* point X," &c.; in 331, for "rectangle" read "parallelogram." These trivial oversights will serve to show how correctly the text has been printed.

OUR BOOK SHELF

Observaciones Magneticas y Meteorologicas del Colegio de Belen de la Compañia de Jesus en la Habana, 1873 y 1874. (Habana, 1874 and 1875.)

THE observations made at the College of the Society of Jesus, Havana, are peculiarly valuable for the fulness and care with which they are made, and for the completeness with which the observations themselves and the monthly means and extremes are given in each monthly table and its accompanying diagram. The diagrams, which have been published in their present improved form since June 1873, and which exhibit on one sheet the two-hourly observations as made daily from 4 A.M. to 10 P.M. of all the meteorological and magnetical elements, will very much facilitate the study of those inquiries which deal with the inter-relations of these elements. To these observations are added the daily amounts of the rainfall and evaporation—the latter being of great interest as contributing to our knowledge of the evaporation in inter-tropical regions, of which so little is known. Whilst only the daily amounts of the rainfall is given, each hour during which rain falls is noted, together with the hour of occurrence of thunder and other irregularly recurring phenomena. As regards the diurnal variations of the wind it changes from about S.E. in the early morning, through E. and N.E. to N.N.E. its most northerly point, which is usually reached about 2 P.M., and thence in the reverse direction through N.E. and E. to E.S.E., which is reached about 10 P.M. The diurnal velocity is at the minimum at 4 A.M., rises to the maximum at 2 P.M., and thence falls steadily to the minimum. The N. and N.E. winds are decidedly the strongest, and the S.E. the weakest, the ratio being as two to one; in other words, the sea-breeze blows with double the velocity of the land-breeze at this station.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Blowpipe Analysis

MR. HUMPIDGE (vol. xiii. p. 208), on the entirely gratuitous assumption that I use "commercial reagents"—whatever that term may mean—says that there is probably iron in my soda.

To this I only reply that I will undertake to show pyrologically the presence of 0·01 per cent. of iron oxide in a fragment of a salt the size of a pin's head; and that, when Mr. Humpidge can do as much without using the dangerous test potassium ferrocyanide (which itself contains iron), I will admit his right to assume that he knows his tools better than other workmen.

No one has ever doubted the proportional relativity in precipitating power between a drop and a gallon of water, but if Mr. Humpidge will only do me the justice not to mutilate my statements in the reproduction, he will repeat that a *precipitate* could not be shown in a drop of water "*on a fused mass* upon an aluminium plate." The D-line Spectrum

WILL Prof. Stokes give us the reason of his now holding that his first—to all appearance, extremely rational—conclusion, that, in consequence of "the powerful affinities of *sodium*, it could not exist in a *free* state in the flame of a spirit-lamp," is "erroneous"?

Shepherd's Bush, W., Jan. 8 W. A. ROSS

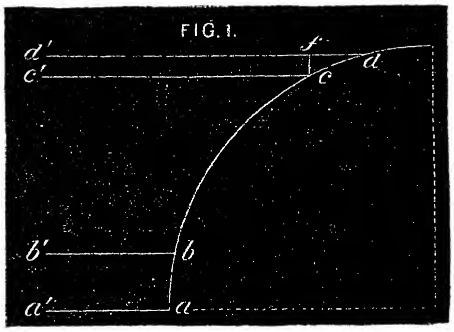
The Difference of Thermal Energy transmitted to the Earth by Radiation from different parts of the Solar Surface.

THE tenor of certain letters received from scientific persons on the above subject induces me to lay the following statement before the readers of NATURE:—

1. Previous to undertaking a systematic investigation of the mechanical properties of solar heat, I examined thoroughly the merits of Laplace's famous demonstration relating to the absorptive power of the sun's atmosphere, proving that only one-twelfth of the energy developed by the sun is transmitted to the earth. The demonstration being based on the assumption that the sun's rays emit energy of equal intensity in all directions, my initiary step was that of testing practically the truth of that proposition. It has been asserted that Laplace did not propound the singular doctrine involved in such a proposition, I therefore feel called upon, before proving its unsoundness, to quote the words employed by the celebrated mathematician. (See "Mécanique Céleste," tome iv. page 284.) Having called attention to the fact that any portion of the solar disc as it approaches the limb ought to appear *more brilliant* because it is viewed under a *less angle*, Laplace adds:—"Car il est naturel de penser que chaque point de la surface du soleil renvoie une lumière égale dans tous les sens." Let *a b c d*, in the annexed diagram, Fig. 1, represent part of the border of the sun, and *b a*, *c d*, small equal arcs; *a a'*, *b b'*, *c c'*, *d d'*, being parallel rays projected towards the earth. Laplace's theory asserts that owing to the concentration of the rays the radiation emanating from the portion *d c* transmits *greater* intensity towards the earth than *b a*, in the proportion of *c d* to *f c*. The proposition is thus stated in "Mécanique Céleste": "Call θ the arc of a great circle of the sun's surface, included between the luminous point and the centre of the sun's disc, the sun's radius being taken for unity; a very small portion *a* of the surface being removed to the distance θ

from the centre of the disc, will appear to be reduced to the space $a \cos \theta$; the intensity of its light must therefore be increased in the ratio of unity to $\cos \theta$."

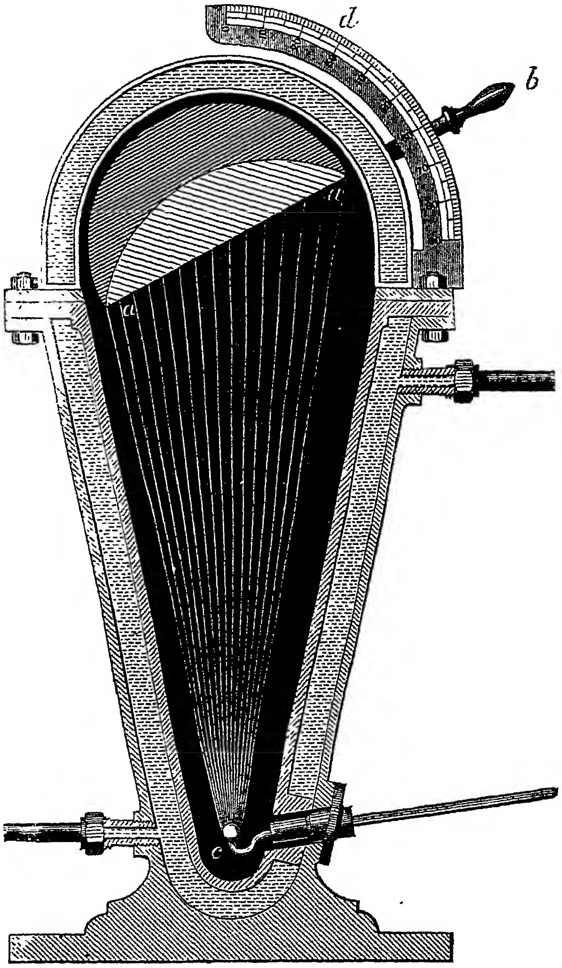
2. In order to disprove the correctness of the stated demonstration, I have measured the relative thermal energy of rays projected in different directions from an incandescent metallic disc, by the following method:—Fig. 2 represents section of a conical vessel covered by a movable semi-spherical top, the vessel being surrounded by a jacket through which water may be circulated. A revolving circular disc, *a a*, composed of cast iron, the back being semi-spherical and protected by fire-clay, is suspended across the top of the conical vessel supported by horizontal journals attached at opposite sides. The angular position of the disc is regulated by a radial handle, *b*, connected to one of the journals; the exact inclination to the vertical line being ascertained by means of a graduated quadrant, *d*. An instrument, *c*, capable of indicating the intensity of the radiant heat transmitted by the incandescent disc, is applied at the bottom of the conical vessel. The mode of conducting the experiment is extremely simple. The movable cover and its lining of fire-clay having been removed, the cast-iron disc is heated in an air-furnace to a temperature of 1,800° F. It is then removed by appropriate tongs, and suspended over the conical vessel, the lining and cover being quickly replaced. The temperature, shown by the instrument at the bottom of the conical vessel, resulting from the action of the radiant heat of the disc, is then recorded for every tenth degree of inclination. The investigation, it may be briefly stated, shows that the temperatures imparted by radiation to the recording instrument is exactly as the sines of the angles of inclination of the disc. Hence, at an inclination of 10° to the vertical line, the temperature imparted to the thermometer is scarcely one-sixth of that imparted when the disc



faces the thermometer at right angles; yet in both cases an *equal amount of surface of an equal degree of incandescence* is radiating towards the instrument! Laplace and his followers have evidently overlooked this important and somewhat anomalous fact, proving that radiation emanating from heated bodies is incapable of exerting full enegy in more than one direction. Our practical experiments with the revolving incandescent disc have thus fully demonstrated the truth of the proposition intended to be established, namely, that the rays emanating from incandescent planes do not transmit heat of equal energy in all directions, the energy transmitted being as stated, proportionate to the sines of their angle of inclination to the radiating surface.

3. The next step in the investigation of solar heat, before adverted to, was that of measuring the radiant energy transmitted in a given direction by an incandescent solid metallic sphere. For this purpose I employed a double conical vessel similar to the one represented in Fig. 2, the incandescent sphere being suspended over the conical vessel in the same manner as the revolving disc. The nature of the arrangement will be readily understood by inspecting the annexed diagram, which represents four spheres, Figs. 3, 4, 5, and 6, each sphere being divided into four zones, A, B, C, and D, occupying unequal arcs, but containing equal convex areas. Semi-spherical screens composed of non-conducting substances were applied below each sphere, provided with annular openings, arranged as shown in the diagram. Through these annular openings the radiant heat from the incandescent zones, D, C, B, and A, was transmitted to the thermometers, *f*, *g*, *h*, and *k*, respectively. Père Secchi, and other followers of Laplace, will be surprised to learn that when the suspended sphere was maintained at a temperature of 1,800° F., the radiation from the zone C, Fig. 4, imparted a temperature of 27°·49 F. to the thermometer *g*, while the radiation from the zone A, Fig. 6, imparted only 6°·19 F. to the thermometer *k*. Let us bear in mind that the radiating surface *l m* of the zone A is equal to the radiating surface *p q* of the zone C. The stated great difference of temperature produced by the radiation from zones of equal area furnishes additional proof that Laplace based his remarkable analysis on false premises. "The sun's disc ought to appear more brilliant towards the border, because viewed under a less angle," we are told by the great analyst. The instituted practical tests, however, prove positively that the energy of the rays projected from the border of an incandescent sphere is greatly diminished *because viewed under a less angle* from the point occupied by the recording thermometer.

FIG. 2.

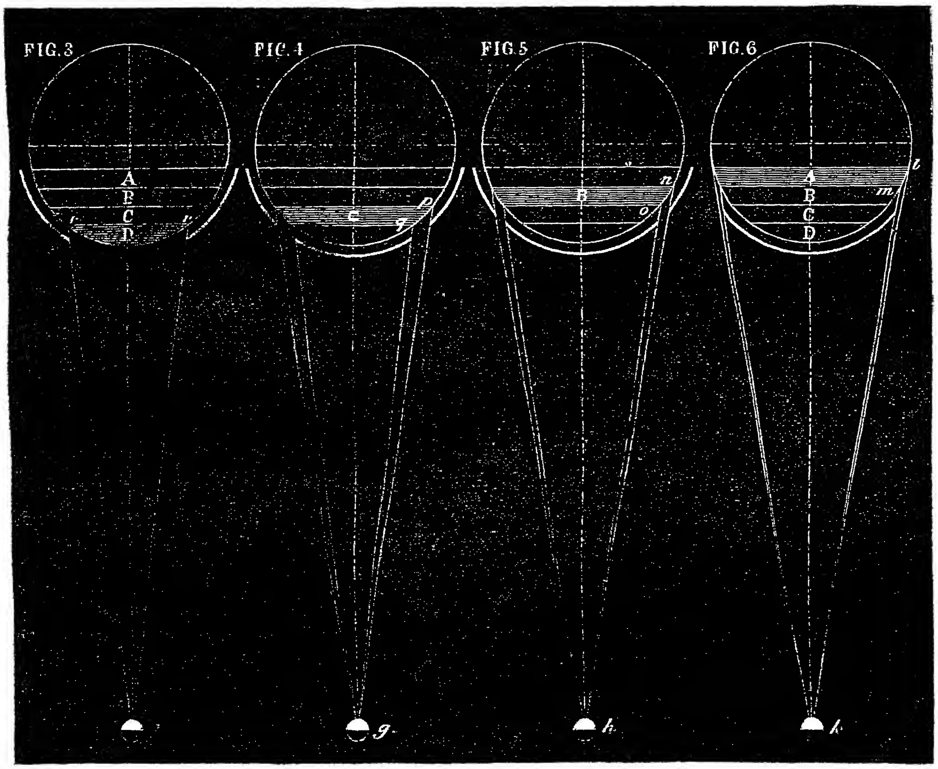


4. The result of our experiment with the revolving incandescent disc shows that if the small arc *b a*, in Fig. 1, be reduced until the field represented by *b' a'* becomes equal to the field represented by *c' d'*, the radiant energy transmitted through each of those fields will be alike; the reason being that the number of rays of diminished intensity passing through *c' d'* will be as much greater than the number of rays of maximum intensity passing through *b' a'*, as *c d* is greater than the reduced *b a* = *f c*. It should be observed that *c d* is so small that we may without appreciable error regard it as a straight base, and *f c* as the sine of the angle *c d f*. It follows from this demonstration that if the solar atmosphere exerted no retarding influence, the radiant heat transmitted towards the earth would be alike for equal areas of the solar disc—more correctly, for areas subtending equal angles, since the receding part of the solar surface is at a greater distance from the earth than the central part.

Encouraged by the practical result of the instituted investiga-

tion, I devised the method described in NATURE (vol. xii. p. 517), showing that the polar and equatorial regions of the solar disc transmit radiant heat of equal intensity to the earth, and that the sun emits heat of equal energy in all directions. Adopting Secchi's doctrine relating to the retardation suffered by calorific rays in passing through atmospheres, viz., that the diminution of energy is as the depth penetrated by the rays, it may also be shown by an easy calculation based on the result of our investigations, that the absorption by the solar atmosphere cannot exceed one-seventh of the radiant energy emanating from the photosphere.

5. Concerning the plan resorted to by the Director of the Roman Observatory, and others, of investigating the sun's image instead of adopting the method of *direct* observations, I will merely observe that the information contained in the several works of the Roman astronomer furnishes the best possible guide in judging of the efficacy of *image investigation*. Let us select his account of the investigations conducted between the



19th and 23rd of March, 1852. Having pointed out that in these experiments it was impossible to approach within a minute of the edge of the sun, and that during a later observation—date not mentioned—he had approached within a minute, the investigator observes: "But at this extreme limit, even making use of the most accurate means of observation, we find difficulties which it is impossible to overcome completely." In addition to this emphatic expression regarding the difficulties encountered, the author adds: "Moreover, it is impossible to study the edge alone, for the unavoidable motions of the image do not admit of its being retained at exactly the same point of the pile; we have therefore been unable to push the exactness as far as we hoped; and we have discontinued the pursuit of these researches, although the results obtained are quite interesting." (See revised edition of "Le Soleil," vol. i. p. 205.) It is needless to institute a comparison between a system of which its founder speaks so despondingly, and one which enables us to push our investigations to the extreme limit of the solar disc, admitting of entire zones being viewed at once, instead of only small isolated spots.

J. ERICSSON

The Glow-worm in Scotland

THE Glow-worm is not uncommon on the Island of Cumbrae, Buteshire. I have seen it there occasionally for the last thirty years (see vol. xiii. pp. 188, 208). DAVID ROBERTSON

Millport, Island of Cumbrae, Jan. 18

OUR ASTRONOMICAL COLUMN

STAR WITH SUSPECTED LARGE PROPER MOTION.—It would appear by a communication from Prof. Winnecke, Director of the Imperial Observatory at Strasburg, that the large proper motion exhibited by a comparison of Argelander's positions of the ninth magnitude star, No. 11237-8 of Oeltzen's catalogue (southern zones) with Taylor's observations at Madras in 1838 or 1839, to which reference was lately made in this column, does not really exist, there being evidently an error in Taylor's mean place for 1840 given at p. clxiii. of vol. v. of the Madras Observations. Prof. Winnecke finds that the differences of right ascension and declination between this star and Oeltzen 11226, are sensibly the same as at the time of Argelander's observations (1851), and the latter star is known to have but very small, if any, proper motion. Taylor's star must therefore be struck off the list of cases of great proper motion lately given.

ATLAS – 27 *f* PLEIADUM.—A very interesting observation was made at Strasburg on the occasion of the occultation of this star—a Struve's *difficillima*—on the 7th of the present month. As we recently stated, this star does not appear to have been seen double since the last Dorpat observation in 1830. On the 7th inst., however, Herr Hartwig observing at Strasburg with an excellent Fraunhofer, of 42 lines aperture, power 159, remarked that the star did not disappear instantaneously; after the principal mass of light had vanished there remained a luminous point for about six-tenths of a second, a circumstance which favours the duplicity of the object, notwithstanding the failure of recent efforts to divide it. It brings to our recollection Burg's observation of the

occultation of Antares 1819, April 13, when at emersion the star appeared to suddenly increase from one of the sixth or seventh magnitude to one of the first, a phenomenon no doubt attributable to the existence of the small companion on the parallel, preceding the principal star (NATURE, vol. xii. p. 308).—The next occultation of Atlas-Pleiadum, on February 3, will not be visible in this country, but may be well observed in the United States. The American Ephemeris gives the time of immersion for Washington; at the Observatory of Hamilton College, Clinton, N.Y., so actively conducted by Prof. Peters, the immersion takes place at 11h. 13m., and the emersion at 12h. 4m., Clinton M.T.

VARIABLE STARS.—In No. 2071 Dr. Julius Schmidt, of the Observatory, Athens, continues his elaborate researches on the three short-period variables U, W, and X Sagittarii, the periods of which are now given thus :—

	d.	h.	m.	s.
U Sagittarii	6	17	53	1·4
W = γ′ Sagittarii	7	14	15	34·1
X = 3 Flam.	7	0	17	42·5

So assiduously have these stars been watched by their discoverer, Dr. Schmidt, in the fine skies of his locality (little success could be expected to attend their observation in England), that he believes he has detected perturbations of the light curve or period in each instance, though not quite ten years' observations are yet upon record.

The following are Greenwich times of geocentric minima of Algol, according to Prof. Schönfeld's elements :—

	h. m.		h. m
1876. Feb. 2	18 37	1876. Feb. 25	17 11
5	15 26	28	14 0
8	12 15	March 2	10 49
11	9 4	5	7 39
14	5 54		

Similar times of geocentric minima of S Cancri, according to Prof. Schönfeld, are :—

	h. m.		h. m.
1876. Jan. 29	13 46	1876. April 14	10 54
Feb. 17	13 2	May 3	10 12
March 7	12 19	22	9 31
26	11 36		

RECENTLY-DISCOVERED MINOR PLANETS.—No. 152, discovered at Paris by M. Paul Henry on Nov. 2, has been named *Atala*, and for No. 157, the small planet, detected by M. Borrelly at Marseilles on Dec. 1, the name of *Dejanira* is proposed; elements of this planet have been calculated by M. Stephan. The following are first approximations to the positions of the ascending node, inclination, and periods of the newer minors, with dates of discovery :—

No.	Ascending Node. ° ′	Inclination. ° ′	Period in years.	Date of discovery, 1875.
150	207 55	2 2	5·16	Oct. 18
151	40 2	7 52	4·15	Nov. 1
152 (Atala) ...	41 29	12 10	5·54	Nov. 2
153 (Hilda) ...	228 20	7 45	7·84	Nov. 2
154	37 35	20 49	5·78	Nov. 4
155	40 16	8 52	{ Circular elements	Nov. 8
156	246 11	7 29	5·29	Nov. 22
157 (Dejanira)	62 25	11 50	4·16	Dec. 1

[Since the above was in type No. 158 is announced in the *Berlin Circular* and Leverrier's *Bulletin International*, as having been discovered at the Observatory of Berlin, by Herr V. Knorre, on the morning of the 5th inst., in R.A. 7h. 19m. 58s., and N.P.D. 67° 58′. Magnitude 11-12.]

THE NEW MUSEUM OF THE GEOLOGICAL SOCIETY

WHEN it was first announced to the Council of the Geological Society that the Government proposed to offer a suite of rooms in Burlington House in lieu of the apartments the Society occupied in Somerset House, it was at once seen that the most formidable work the change involved would be the removal of the collections of minerals and fossils. The transference of the library, though an extensive one, would be a comparatively easy matter, but there is always the danger in the mere handling of fossils that they may be damaged. Besides this, the collection had gradually grown to such a size that it was evident the cost of the removal would be considerable. So far as the preparation of the rooms at Burlington House was concerned, the Government showed every desire to conform as far as possible to the wishes of the Council.

Some of the Fellows counselled that the whole collection should be offered to the British Museum or to the School of Mines Museum in Jermyn Street, on the ground that though in the early days of the Society it was of high value when it was the only museum that existed, it was now so far surpassed in magnitude by the national collections that it was practically of small value. Fortunately wiser counsels prevailed. There were in the museum, it was urged, many typical collections formed by the early leaders of geological science, which were bequeathed in illustration of papers they had read and work they had done. These collections, obtained by their own personal labour in the field, arranged and named in their own handwriting, were of historical value and had a European reputation, and ought to be religiously preserved by the Society. It was true that the integrity of some of the collections had been destroyed in the endeavour at one time to make one general collection illustrating the whole of England, and arranged in stratigraphical order; but in most cases the original labels and references to catalogues were preserved, and it was hoped it might be possible in the new buildings to regroup the specimens much as they were at first. It was therefore determined that the museum should be maintained, not as a general geological collection, but mainly as a repository of specimens referred to in papers, and that before the removal commenced it should be carefully weeded, so that in all cases where, through the accidental removal of a label or other causes, the history of any specimen had been lost, it should be discarded, but not until every effort had been made to try to ascertain any possible clue. This work has been carried out by Prof. Rupert Jones, aided by Mr. Woodward, the assistant curator. The accumulation of specimens had caused much crowding in the museum, and in such a case a certain amount of damage and loss of labels was almost inevitable. As a consequence of this weeding, many specimens have been omitted in the new arrangement, and the result has been to leave greater space for those that have a real historic value.

Like many other institutions of gradual growth, the history of this museum has never been written, and very few people, few even of the Fellows of the Society, know what it contains, for there never has been a printed catalogue. As the collections are the private property of the Society and are not open to the public, this perhaps has not been thought requisite.

Among the principal collections preserved which have now historic value, first in point of general interest should perhaps be mentioned the extensive series of fossils presented by Sir Roderick Murchison, from which were drawn the figures in his world-renowned "Siluria." The fossils figured in the papers by Murchison and Sedgwick in describing the structure of Wales and the Lake district are also there, so are the fossils that illustrated Murchison's description of Brora. The fossils connected with Webster's well-known paper of 1814, the first paper on the Tertiaries of Hampshire; most of those illustrating Fitton's celebrated paper on the "Strata below the Chalk" (1827); those belonging to Buckland and Conybeare's comprehensive paper "On the South-west of England" (1824) are all there. Large additions to the general col-

lection were also made by Dr. Mantell, Dr. Macculloch, and Mr. Leonard Horner.

It will be recollected that the Society was originated in 1807, at a time when mineralogy was a fashionable study, or at least when collections of minerals formed part of the "furniture" of the apartments of the Queen and many of the nobility. Collections of shells and of fossils were also fashionable, but they were valued only for their beauty or their rarity, and not for any knowledge of nature they afforded. For some time the young society seems to have followed fashion. Indeed, the value of fossil organic remains as giving a clue to the consecutive sequence and relative order of strata was then but just beginning to be understood. It was not till the end of 1799 that the first MS. table of the sequence from the Carboniferous beds upwards was constructed, and no map of the strata of England was published till 1815. The earliest MS. catalogue of specimens belonging to the Society, begun in 1808 or 1809, is labelled "General Catalogue of Minerals," and some of the early entries of organic fossils refer rather to the rock in which the fossil is imbedded; the presence of the fossil being but casually noticed, such as "limestone containing shells." These early collections of fossils illustrating the labours of the first geologists in using organic remains to trace the chronological sequence of beds, and to compile some chapters of the earth's history, have a profound interest, laying as they did the foundations of a science which has placed at rest many wild theories of the origin of the earth, and has, too, proved to be of such practical value. The first donation recorded is Feb. 5th, 1808, of specimens from St. Anthon's Colliery, Newcastle-upon-Tyne, by the Right Hon. Sir J. Banks. It would occupy too much space to mention all the collections that the Society has preserved, but among the donors are the well-known names of Sir Henry de la Beche, Sir Charles Lyell, Greenough, Warburton, and Sir Woodbine Parish. McEnery's collection that first brought Kent's Cavern into notice is there, and so is a splendid series of Daniel Sharpe's "Brachiopoda." The old red sandstone fishes presented by Lady Gordon Cumming are remarkable for their beauty as well as for the extent of the collection.

Many distinguished living geologists have private collections of their own; for example, the Earl of Enniskillen, Sir Philip Egerton, Prof. Prestwich, Mr. Searles Wood, Dr. Bowerbank, &c., which fully explains why their contributions are not so numerous as might be expected from the valuable work they have done. Prof. Phillips, though so energetic a worker, is not largely represented in the museum, for firstly York, and afterwards Oxford, had stronger claims on him. The same remark applies somewhat to the claims of the Woodwardian Museum on Prof. Sedgwick. As illustrating the geology of England generally, the Jermyn Street Museum and the British Museum are more useful, but as a record of early geological work the museum of the Society is unique.

The rearrangement of the foreign collections has not yet been completed, though it is in progress. Suites of specimens are to be seen there from all parts of the known world from which it has been possible for travellers to send them. These foreign collections are, to some extent, the result of contributions by officers in Her Majesty's services. Central Africa is not represented, but there are several collections from both coasts. For the future it is intended to add to the British collection only those specimens that are sent in illustration of papers read to the Society, but foreign specimens will be received as before.

Among the treasures of the museum, besides the rocks and fossils, there are the original drawings of Agassiz's "Poissons Fossiles," presented by the Earl of Enniskillen, the first manuscript geological map of England (1799), and the first table of strata, by W. Smith (1799).

The previous changes in the locality of the museum have been as follows:—In No. 4, Garden Court, Temple, the first fixed habitation of the Society (June 1809), the collection was commenced. In June 1810 it was removed to 3, Lincoln's Inn Fields; in June 1816 to 20, Bedford Street; in the autumn of 1828, to Somerset House; at Somerset House it has remained till this last move to Burlington House.

CONDENSED AIR TRAMWAYS

FOR some weeks the North Paris Tramways Company has been trying on the line from Courbevoie to the Arc de l'Etoile a new system of locomotion, in which the motive power is compressed air. Some details of M. Mékarski's (the inventor) system are given in the *Revue Scientifique.* It is capable of considerable developments and of varied applications, since it has solved in a very satisfactory manner the double problem of the industrial production of air condensed to very high pressures, and of the storage of the air in reservoirs intended to discharge into a cylinder placed in any apparatus whatever, at any distance from the condensing pump.

The "Voiture Automatique" of M. Mékarski is characterised by the absence of an imperial and by a platform in front and another behind. This car carries the reservoirs of condensed air, the apparatus for distribution, and the cylinders. M. Mékarski places under the truck of the car the sheet-iron cylinders, which contain the condensed air; on the front platform is placed the distributing apparatus which the engine-man works; the two cylinders are placed, as in certain locomotives, outside the framework, horizontally, and act directly, by means of a crank, on the front wheels of the car. No doubt this arrangement might be advantageously modified; but the important point is the possibility of manufacturing compressed air in sufficient quantities to be of use as a motive power.

The condensing apparatus used by M. Mékarski consists of two pump-barrels of cast-iron, placed vertically, communicating respectively with two horizontal pump-barrels, in which move two pistons worked by a steam-engine. This is, in reality, a double condensing pump, the former bringing the air to the pressure of from ten to twelve atmospheres, and the second raising the pressure to twenty-five atmospheres. The pistons act upon a mass of water which compresses the air directly and absorbs by degrees the heat disengaged by compression. By an ingenious contrivance the supply of water is continually renewed, and the temperature thus kept down. But this arrangement does not absorb a sufficient amount of the heat disengaged, a difficulty which M. Mékarski has met as follows. The external air drawn into the pump raises a valve constantly covered by a layer of water of several centimetres; besides, a large cast-iron tube, constantly traversed by the air already condensed and the excess of water, communicates with the two vertical pump-barrels; finally, the second pump is fitted with a tap by which the heated water escapes.

In M. Mékarski's automatic car the compressed air is stored, under the truck, in sheet-iron reservoirs or cylinders. The total capacity is about 2,000 litres; 1,500 litres serve as an ordinary supply; 300 litres constituting a reserve; the remaining 200 litres are intended to serve as a brake. The air is compressed in the cylinders to the pressure of twenty-five atmospheres. On the line from Courbevoie to the Arc de Triomphe, 7,500 metres going and returning, the resistance is unusually great. In one experiment the ordinary feeding cylinders contained 1,500 litres of twenty-five atmospheres at departure, and the pressure, on arrival, was not more than four and a quarter atmospheres. The expenditure had thus been about 1,250 litres at twenty-five atmospheres for a run of 7,500 metres, or 166 litres per kilometre.

But unless it is possible to heat the air gradually

during its detention, and before it reaches the cylinder, unless, in fact, the heat abstracted in condensation be restored to it, the loss of power is very great. This has hitherto been the stumbling-block of compressed air engines, and M. Mékarski seems to have completely met the difficulty. He adopts as a re-heater a cylinder holding about 100 litres of water, taken from the boiler of an engine, at five atmospheres, and to obtain the maximum of effect possible, the condensed air is delivered from the reservoirs to the cylinder only after traversing the entire mass of water.

By a clever contrivance M. Mékarski regulates at pleasure the action of the compressed air upon the piston. Two hermetically-closed boxes are placed vertically upon the re-heater; their common face is formed by a caoutchouc diaphragm, in direct connection with an obturator, which opens or shuts more or less the opening which communicates between the lower box and the chamber containing a mixture of compressed air and vapour in the upper part of the hot-water cylinder. It will be seen that this orifice will be more or less uncovered according as the pressure in the lower box will be above, or not, the pressure in the lower box. This second box is itself filled with air, and constitutes a small pump-barrel, in which a large plunger piston works. The rod of the piston is a screw, and is fitted outside with a small regulator, on which the driver works. This may rapidly be made to vary the presence of the air in the upper box, and consequently the pressure be increased or diminished of the air which is delivered from the lower box to the motory cylinder.

THE GREAT TELESCOPE OF THE PARIS OBSERVATORY

WE have from time to time noted the progress of the great telescope which for years has been in course of construction for the Paris Observatory, and now that it is completed and in its place we are glad to be able to present a view of the instrument, for which, and for the details which follow, we are indebted to *La Nature*.

In 1855 M. Le Verrier purchased in England two large discs, the one of flint and the other of crown glass, intended to form the material for an object-glass. The late Léon Foucault, the eminent physicist of the Observatory, was charged with the investigation of the processes which should be employed to cut these large glasses, whose dimensions were much greater than those to which opticians had been accustomed. It is known how Foucault was led, by his series of investigations, to make mirrors of silvered glass. Successive attempts enabled him to present French observatories with reflectors of 40, of 50, and finally of 80 centimetres in diameter, having a tube in length only six times the diameter of the mirror. The largest of the telescopes constructed by Foucault himself, of 80 centimetres aperture, is at Marseilles, under the care of M. Stephan; by means of it this astronomer has seen all that Herschel saw with his enormous metallic reflector of 1·45 m. diameter, all that Lord Rosse has been able to see with his leviathan of 1·70 m., and he has added hundreds of new nebulæ to the list given by his illustrious predecessors.

To crown his labours, L. Foucault wished to construct the largest mirror which it would be possible to make by his admirable method. This superior limit is 1·20 m. diameter. M. Le Verrier caused to be cast at St. Gobain a block of glass weighing 700 kilogrammes, which was rough-ground and shaped in the workshops of MM. Sauter and Lemonnier. But to construct this telescope, with its tube of 16 metres in length, required special funds, the ordinary budget of the Observatory not being sufficient. M. Le Verrier sought to obtain them from the Corps Législatif, which, in 1865, voted a sum of 400,000 francs.

By the beginning of 1868, Foucault, notwithstanding his researches on regulators and the fatigue caused by the active part he took in the Exposition of 1867, had prepared the plans for the large reflector, when death snatched him from his work, and deprived France of one of the most original and finest geniuses she has possessed. This fatality, and the troubles which soon after and for long disturbed the Observatory, seemed to have lost to the country the work of years, and to have rendered useless the liberality of Government. Happily, the Minister of Public Instruction, M. Duruy, was willing to lend an attentive ear to the suggestions of men of science, and place at their service an intelligence eager for progress. At the request of the friends of Foucault he ordered the work which had been begun to be continued, and the authorities of the Observatory eagerly complied with his orders. An eminent mechanician, M. Eichens, indicated to M. Le Verrier by the Grand Prize in Mechanics which he obtained at the Exposition of 1867, and by his construction of large instruments for the Observatory, received the order for the construction of the telescope. M. Adolphe Martin, whom Foucault had instructed in his methods and associated with himself in his optical undertakings, was charged with the polishing of the mirror. Finally, M. Le Verrier entrusted to one of the astronomers of the Observatory, M. Wolf, the general superintendence of the work.

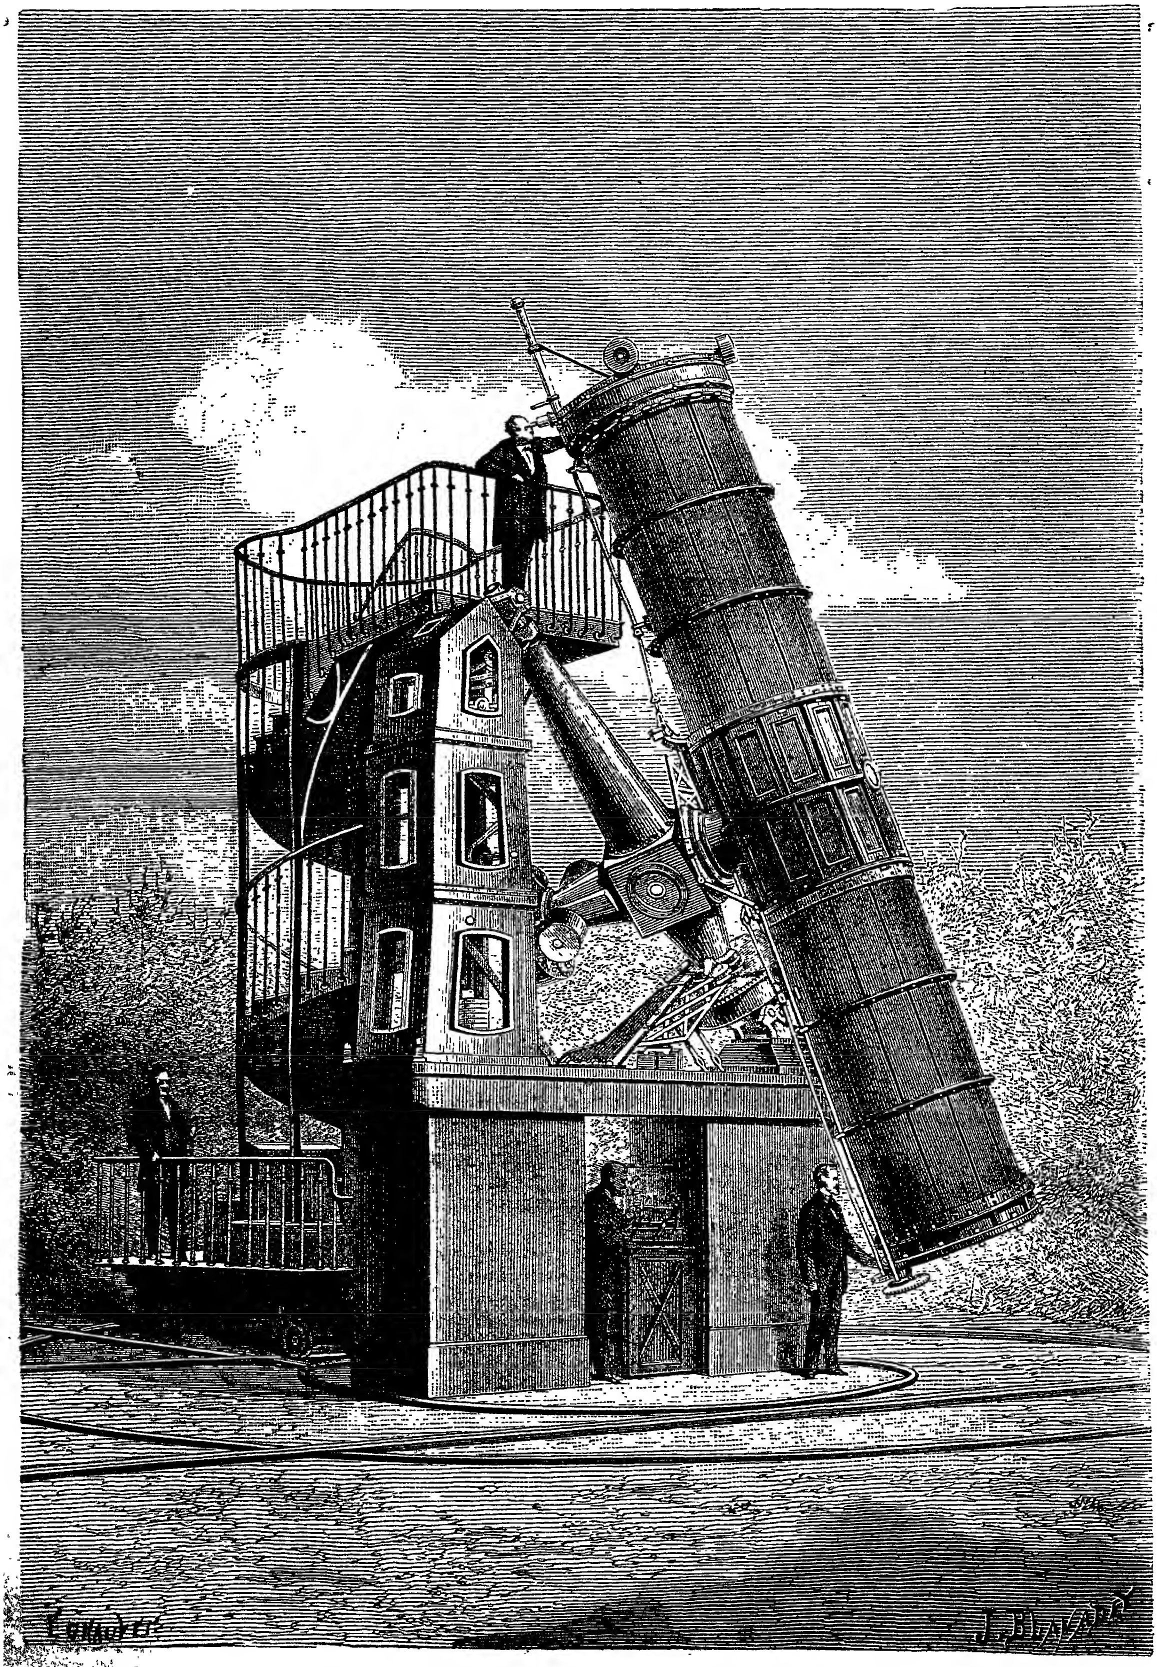
The construction ought to have been completed in three years. The war and the changes in the Observatory caused the work to languish, and it was not resumed with vigour until the return of M. Le Verrier as Director in 1873. At the commencement of 1875 the mirror was completed and tried upon terrestrial objects; M. Wolf had got a shelter constructed for the telescope and the staircase for the observer; finally, in the month of October, M. Eichens sent in the instrument complete in all its main details.

The total cost of the instrument and of the observatory amounts to 190,000 francs.

The illustration which we give represents the telescope in a position for observation. The wheeled hut under which it usually stands, a sort of wagon seven metres high by nine long and five broad, is pushed back towards the north along double rails. The observing staircase has been fitted to a second system of rails, which permit it to circulate all round the foot of the telescope, at the same time that it can turn upon itself, for the purpose of placing the observer, standing either on the steps or on the upper balcony, within reach of the eye-piece. This eye-piece itself may be turned round the end of the telescope into whatever position is most easily accessible to the observer.

The tube of the telescope, 7·30 metres in length, consists of a central cylinder, to the extremities of which are fastened two tubes of 3 metres long, consisting of four rings of forged iron bound together by twelve longitudinal bars also of iron. The whole is lined with small sheets of steel plate. The total weight is about 2,400 kilogrammes. At the lower extremity is fixed the barrel which holds the mirror; at the other end a circle, movable on the open mouth of the telescope, carries at its centre a plane mirror, which throws to the side the cone of rays reflected by the great mirror. The telescope is thus on the Newtonian system. That of Melbourne, so admirably constructed in England, is a Cassegrain telescope; the metallic mirror is pierced at its centre by an aperture which receives the eye-piece, a system so far advantageous that the observer always remains at the lower part of his instrument, and has to raise himself only a very short distance above ground, but less calculated perhaps to produce a perfect image than the Newtonian system adopted by Foucault.

The weight of the mirror in its barrel is about 800 kilogrammes; the eye-piece and its accessories have the same weight. Such is the load under which the tube of



THE NEW TELESCOPE OF THE PARIS OBSERVATORY. (From a Photograph.)

the telescope, suspended by its centre, must not bend more than a millimetre in the most unfavourable positions, according to the calculations by which M. Wolf determines its dimensions. Experience has verified his calculations; the two mirrors remain exactly centred upon each other in all positions of the telescope.

It is necessary, however, to be able to direct the tube toward any point of the sky, and it is necessary, moreover, that when the star is once in the field of the instrument, that should be able to follow it, by a simple movement, in its apparent course through the heavens. This is accomplished by what is called the *equatorial* mounting of the telescope. This revolves on an axis, cast of iron and steel, whose direction is parallel to the axis of the celestial sphere. Then it may be inclined more or less on this axis, by turning round in a second axis of steel, which crosses the former at a right angle, and partakes in its movement of rotation. The whole of the arrangement of double axes, a veritable wonder of mechanism, from the precision and ease of the movement, weighs with the telescope 10,000 kilogrammes. Such is the mass which, like the hand of a gigantic chronometer, must follow with precision the march of the stars in the vault of heaven, obedient to the action of clockwork, controlled by a Foucault regulator.

To realise this wonder, M. Eichens had to put together the most delicate apparatus of the mechanics of precision, and, preserving their delicacy intact, give them the strength necessary to support great weights. We cannot explain in detail the series of these wonders, tell how friction is almost annihilated throughout, how all the parts are in equilibrium, whatever be the position of the telescope: how, in fine, at the same time that the instrument follows the movement of the sky, the observer may at his pleasure move it with perfect ease in all directions by means of contrivances placed at his hand.

The perfection of mechanism would be nothing if it did not serve the purpose of observing the stars with an optical apparatus of equal perfection. Let us at once say that the first attempts which have been made with the instrument have completely satisfied the astronomers. Not only has the mirror acquired, under the hand of M. Martin, the rigorously parabolic form which gives it the property of collecting in a single point the rays of a star, but the very complex eye-piece, by means of which the luminous point is observed, is itself without a single defect. It now only remains to silver the surface of the mirror, an operation at present easy, by the processes of M. Ad. Martin, and which will be accomplished in a large dish 1·30 metres in diameter. Meantime, the surface of the polished glass reflects sufficient light to make it possible to observe the most feeble stars; directed towards the moon, the telescope concentrates in the eye a light almost intolerable. It may be judged from this what will be the brilliancy of celestial images when the silvered mirror will throw upon the eye, not merely scarcely one-half, but more than nine-tenths of the light which it receives.

The comparison which we made above between the Marseilles telescope of 0·80 metre aperture and the most powerful instruments elsewhere, allows us to predict the results which science has a right to expect from a telescope whose mirror is greater by half, and whose mechanism has reached the latest limits of perfection. M. Wolf, to whom the use of the telescope has been entrusted, proposes to employ it in observing the planets and their satellites. At the same time the new telescope will be fitted with all the apparatus necessary for photography and the spectroscopic observation of the stars. It should be remembered, however, that the use of such a gigantic instrument requires a long apprenticeship; the Melbourne instrument had two observers before it came into the hands of an astronomer who knew how to make good use of it.

In a few weeks will be completed the first of the great instruments promised to France by MM. Le Verrier and Foucault. The construction of the telescope has been undertaken first, that it may serve as a study for the construction, much more delicate, of the great refractor of 16 metres in length, with an object-glass of ·75 metre aperture. The success of the reflector is a guarantee that M. Le Verrier, with his eminent colleagues, will accomplish satisfactorily the second part of his great and patriotic enterprise.

THE LOAN EXHIBITION OF SCIENTIFIC APPARATUS AT SOUTH KENSINGTON

ON the 3rd inst., as we have already intimated, Her Imperial Highness the Crown Princess of Germany invited to her palace forty of the representatives of science of Berlin, to lay before them the plan of the London Exhibition of Scientific Apparatus, and to ask their co-operation for this purpose. Amongst those honoured by invitations were the Ministers of Education and of Commerce, the Postmaster-General, and the following professors of the University:—MM. Braun (botanist), Dove, Helmholtz, and Kirchhoff (physicists), Du Bois-Reymond (physiologist), Kiepert (geographer), Förster (astronomer), Peters (zoologist), Kronecker (mathematician), Websky (mineralogist), Hofmann, Oppenheim, and Sell (chemists), Wichelhaus (technologist). Orta (agriculturist); the following professors of the Polytechnic School:—MM. Reulaux (mechanician), Liebermann (chemist), Vogel (photographer), and Scheibler (agricultural chemist); the director of the South Kensington Museum, Mr. Cunliffe-Owen, the directors of the German Industrial Museum, MM. Gruner and Lessing, the manufacturers, Dr. Werner Siemens (member of the Academy), and Dr. Martius. The illustrious hostess, as well as His Imperial Highness the Crown Prince, pleaded warmly for the worthy representation of Germany in the London Exhibition. Although the short time left for preparation, and the coincidence of the exhibition with that of Philadelphia, were generally felt as serious drawbacks, some of the men of science present taking the lead assembled the following day, when a general committee was formed under the presidency of Dr. A. W. Hofmann; with the view of forming special committees for the different branches of the exhibition, and of inviting one member of every German University and Polytechnic School to co-operate with them. An invitation to the men of science and the manufacturers of scientific apparatus has already been issued.

"Science," the invitation says, "being the common property of all nations, the exhibition of the appliances by which it is promoted partakes of an international character. The objects pursued by the English Commission in organising the Exhibition have in Germany also been recognised as worthy of attainment, and, in order to give an impulse in our Fatherland to German participation in the Exhibition, a Committee has been formed, at the special instance of the Crown Prince and Princess of Germany, which has been intrusted by the English Commission with the collection and selection of objects worthy of being exhibited."

The invitation then proceeds to detail the conditions of exhibition settled by the Science and Art Department, and concludes as follows:—

"The Exhibition of Scientific Apparatus in London essentially differs from the former Exhibitions, as it pays less regard to merely commercial interests, but keeps in view the higher aim of disseminating as widely as possible the knowledge of the different methods of science. In order to render full justice to this task, the British Government (Science and Art Department) will bear all the costs of packing, sending, and returning any objects that may be confided to its care."

The Minister of the Admiralty has promised to send every instrument which should appear suitable for the purpose. The Committee of the German Chemical Society have elected superintendents to procure a worthy representation of chemical apparatus and specimens of chemical compounds of scientific interest. It has been decided to address an invitation to the members of the society to send such specimens to Berlin, in order to form a systematical and uniform collection of rare and interesting chemicals.

We may state generally that the Governments of Belgium, France, Germany, Italy, the Netherlands, and Switzerland, have now appointed committees to act in concert with the general committee in London. The Government of the United States has, through Mr. Fish, intimated that it is in communication with the various Departments and Scientific Institutions, with the object of forwarding the Exhibition.

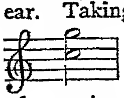
---

*BEATS IN MUSIC**

II.

THE second kind of beat differs from the first in that it arises from the imperfection, not of unisons, but of wide-apart consonances, such as the third, fourth, fifth, sixth, and octave.

This beat is well known practically to organ tuners, and may be soon rendered appreciable to any musical ear. Taking the fifth as an example, let the two notes



be sounded on an organ, or any instrument of sustained tones. If they are perfectly in tune, the united sound will be smooth and even ; but if one of them be sharpened or flattened a little, a beat will be heard just as in the case of the imperfect unison ; and which, like it, will increase in rapidity as the note is made more and more out of tune. That this is not the same beat as Tartini's is obvious from the failure of the rule for the latter when applied to the former ; for example, when the concord is in tune the upper note vibrates 768, and the lower one 512 vibrations per second, therefore there ought to be 256 beats per second ; but in reality there are no beats at all, they only begin when the notes are put out of tune ; hence the Tartini-beat rule is useless and inapplicable in this case.

This beat may be called the *consonance* beat, and it has also been termed "Smith's beat," from its having been first investigated by him.

The theory of Smith's beat, as given by Smith himself, is complicated and difficult to describe ; but we will endeavour to give some idea of its nature and cause.

We must return to the illustration of the coffin-makers. Suppose one of them to have sold his business to another man in the trade, who was so much more active and energetic that he could drive his nails half as fast again as ordinary workmen. Call him A, and suppose that when he began to work it was found that he struck exactly three blows to two of his neighbour B. As B struck 100 per minute, A will now strike 150. And assume that on a certain day they both begin exactly together. The passer-by will hear that every third blow of A exactly coincides with every second of B ; so that he will notice fifty coincidences in a minute ; or to describe them more correctly, he will notice per minute fifty *phases of compound effects*, in each of which there is a coincidence. This phase constitutes *Tartini's beat*, but now very much augmented in rapidity from what it was before : then there were only one or two coincidences per minute, now there are fifty.

Now suppose that A, from some slight exhilarating cause, begins to strike a little faster ; *i.e.* that he makes 151 blows in a minute instead of 150. Let us endeavour to find out what will be the result on the listener. Still supposing the two strokes to begin with a coincidence, the third blow of A will still coincide *very nearly indeed* with the second of B ; it will only differ from it by $\frac{1}{7500}$ of a minute, a quantity inappreciable to the ear. Hence the Tartini phase will at this time be practically unharmed. But after a few repetitions the divergence of the blows will be so great as to become appreciable, and the listener will begin to notice a series of *changes of form* of the Tartini phase, in which there is now *no coincidence* of the blows, but only a variation of their arrangement, which, moreover, is itself constantly varying. After a time, however, these changes will exhaust their possible varieties, the listener will notice that two of the blows begin to approach again, and at last will *coincide*, as they did before. He thus notices a *long cycle* of the Tartini beats, and this long cycle is the *Smith's beat*. It is, in fact, a beat of what mathematicians would call the second order ; the first, or Tartini's beat, is a cycle of differing periods ; the second, or Smith's beat, is a cycle of differing cycles.

Let us next attempt a numerical estimation of the length of this second cycle in the case of the coffin-makers. To effect this we must inquire when the coincidences of two blows will recur. It is plain that they will recur at the *end of the minute*, i.e. if the first blow of A coincided with the first of B, then the 151st of A will coincide with the 100th of B. This will give one long cycle, or one Smith's beat, per minute. A careful comparison of the times of the respective blows will show, moreover, that (since 100 and 151 are prime to each other) there will be *no other* exact coincidence during the minute ; and a hasty reasoner may conclude that one beat per minute will be the proper number. But if the listener be asked to describe what he hears, he will dissent from this and say confidently that there are *two* places in the minute where he hears a coincidence. To test his assertion, let us apply Young's principle mentioned before, and inquire whether in the course of the minute there is any other place where the blows *so nearly* coincide that the ear may mistake them for real coincidences. The 74th blow of A will occur at $\frac{74}{151}$ of a minute after starting, whereas the 49th blow of B will occur at $\frac{49}{100}$ of a minute. The difference between these is only $\frac{1}{15100}$ of a minute, which is quite inappreciable. Hence, practically, there will be two parts of the minute where the blows coincide, and there will be consequently two Smith's beats in the same time.* If we were to suppose A to make 152 blows per minute (or 148, for a deficiency would produce the same result as an excess) to B's 100, we should, calculating on the above plan, find *four* cycles or beats per minute. Or we may alter the proportion : suppose for example, A, intending to make five blows to B's four, makes really 126 per minute instead of 125 as he ought to do ; it will be found by calculation that there will be *four* places of coincidence in the minute, or four Smith's beats ; if he strikes 127 blows, there will be eight Smith's beats—and so on.

We hope the foregoing homely illustration will help to render clear the nature of the Smith's beat as applied to sounds. Although the Tartini beat may not be really converted, as Young supposed, into the Tartini harmonic, but, according to Helmholtz, remains as a beat, inappreciable by reason of its great rapidity, it certainly has a physical and mathematical existence ; and it as certainly changes its phases by reason of the small divergence of the times of vibration from those due to the true concord, and it is the recurrence of similar phases in a long cycle

* By W. Pole, F.R.S., Mus. Doc. Oxon. Continued from p. 214.

* Mr. De Morgan, in his admirable paper elucidating Smith's profound investigation, unfortunately omits to notice this important element of the *approximate* coincidences. The consequence is that his explanation is not easy to follow, and indeed would *appear* wrong, although his results are perfectly correct.

which gives rise to the phenomenon in question. Smith contrived, with profound ability, to account for and calculate the beat independently of the Tartini beat, or whatever it may be called, but the introduction of this by De Morgan has wonderfully simplified the comprehension of the thing.

The accurate rule for finding how many beats per second will result from the concord being any given quantity out of tune; or for finding how much out of tune any concord is when it makes a certain number of beats per second, is remarkably simple.

Let n represent the denominator of the fraction, expressing, in the lowest terms, the true ratio of the concord (*e.g.* for the fifth $\frac{3}{2}$, $n = 2$; for the minor sixth $\frac{8}{5}$, $n = 5$, and so on); then let q = the number of vibrations per second either in excess or deficiency of the number which would make the interval perfectly in tune; also let β = the number of Smith's beats per second:

$$\text{then } \beta = nq,$$
$$\text{or } q = \frac{\beta}{n}.$$

A few examples will show the easy application of these formulæ. Take the concord of the fifth, . When this is true the upper note should make 768 vibrations per second to 512 of the lower one; but if it is tuned by equal temperament the upper note will be slightly flat, making 767·15. Hence $q = 0·85$; and as $n = 2$, we shall get $\beta = 1·7$, *i.e.* there will be 102 Smith's beats per minute.

Again, suppose we find the concord of the major third  give 120 beats per minute (= 2 per second), how much is it out of tune? As in this case $n = 4$, we have

$$q = \frac{2}{4} = \frac{1}{2};$$

i.e. the upper note vibrates half a vibration per second either more or less than it ought to do.

The number of beats per second due to imperfections in the various consonances will be as follows, q being always the number of vibrations by which the upper note is untrue:—

Tartini's Beat.

For the unison ... ... $\beta = q$.

Smith's Beats.

For the unison or octave ... ... $\beta = q$.
" " fifth... ... ... $\beta = 2q$.
" " fourth ... ... $\beta = 3q$.
" " major third ... ... $\beta = 4q$.
" " minor third ... ... $\beta = 5q$.
" " major sixth ... ... $\beta = 3q$.
" " minor sixth ... ... $\beta = 5q$.

In the case of the *unison*, the Tartini beat and the Smith beat are synonymous, and this identity is the reason why so many writers on beats have gone wrong; they have so often taken unison sounds as the easiest and simplest for popular illustration, and have either assumed, without further investigation, that the same principles would apply for other consonances also, or have omitted notice of the other consonances altogether.

It will now be easy to understand why beats are capable of such great utility in a practical point of view—namely, as giving a means of measuring, with great ease and positive certainty, the most delicate shades of adjustment in the tuning of concordant intervals. To get, for example, an octave, a fifth, or a third perfectly in tune, the tuner has only to watch when the beats vanish, which he can observe with the greatest ease, and which will give him far more accuracy than he could possibly get by the ear alone. Whereas if he desires to adopt any fixed temperament, he has only to calculate the velocity of beats corresponding to the minute error which should be given to each concord, and the required note may be tuned to its proper pitch with a precision and facility which would be impossible by the unaided ear.

The delicacy of this method of tuning would hardly be believed, if it did not rest on proof beyond question. To recur to our example, the difference between 95 and 100 beats per minute would be appreciable by anyone with a seconds watch in his hand; and yet this would correspond to a difference of only $\frac{1}{24}$ of a vibration per second, or in pitch less than $\frac{1}{1000}$ of a semitone!

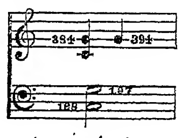
This use of beats has been long practised by organtuners to some extent, but its capabilities, as amplified by the aid of calculation, are certainly not appreciated or used as they ought to be.

The third kind of beat is what we may call the *overtone* beat, and was brought into prominent notice in 1862 by Helmholtz, who uses it for important purposes in regard to his musical theories.

It is known that nearly all musical sounds are compound; they consist of a fundamental note, which is usually the strongest (and by which the pitch of the note is identified), but which is accompanied with several fainter and higher *harmonic* notes, or, as Helmholtz calls them, *overtones*. The first of these is an octave above the fundamental, the second a twelfth above, the third a fifteenth, the fourth and fifth seventeenth and nineteenth respectively, and there are others still higher which we need not mention here. The number and strength of the overtones vary for different kinds of sounds, but the five lowest ones are very commonly present and distinguishable. Now, suppose we sound two notes, having such a relation to each other that any of the overtones of one will come within beating distance either of the other fundamental, or of any of its overtones, then a beat will be set up, which is the kind of beat now in question.

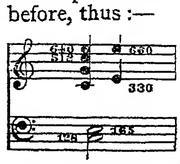
A few examples will make this clear. The bass fundamental C shown by a minim in the following example, has its overtone 
an octave above, as shown by the crotchet. Now if another fundamental C be sounded an octave above the former one, as the second minim, and if it be a little out of tune, there will be a unison beat between it and the overtone of the first note. This is one of Helmholtz's beats, and the simplest of them.

Again, take an interval of a fifth; the fundamental notes being shown in minims in the following illustration, and their respective overtones in crotchets:—



Here, if the G is not a perfect concord with the C, the two G's in the treble stave will be also out of tune with each other, and a unison beat will ensue. This is another Helmholtz beat, and a little more complex than the last, as both the beating notes are overtones.

Again, take an interval of a major third, expressing the notes and such of their respective overtones as we require in the same way as before, thus:—



Here, if we suppose the fundamental E to vibrate 165

instead of 160, *i.e.* five vibrations too sharp, the two upper E's in the treble stave will clash, and a beat will result.

In all these three cases Smith's beats also will naturally be present, and it is curious that in each case when we come to determine the rapidity of the beats, we find it come out the same, whether we calculate it by Smith's formula or by the unison beats of Helmholtz's overtones. We have added the vibration-numbers to the notes, to facilitate the calculation, and we find the number of beats per second to be—

For the imperfect octave	= 5
For the imperfect fifth	= 10
For the imperfect major third	= 20

each arising from a sharpness of five vibrations in the upper note of the concord.

Hence we may lay it down as a principle that in consonances slightly out of tune, the beat given by the two fundamentals on Smith's plan, and those given by the first corresponding overtones on Helmholtz's principle, are synchronous, and may be considered identical.

The two kinds of beats, however, must not be confounded, as their cause is so distinct. The Helmholtz beats arise from the overtones only, whereas Smith's explanation applies to the fundamental notes, independently of the overtones altogether.

Helmholtz notices (Ellis's translation, pages 302-3) that beats of consonances will occur when sounded by simple tones, but accounts for them in another and very ingenious way, namely, by calling in the aid of the *grave harmonics*, or, as he calls them, the *combination tones*.

Taking our first example of the octave consonance given above, when the two notes of 128 and 261 vibrations are sounded together, they will give rise to a combination tone of 123 vibrations, and this, clashing with the 128 note, will give beats at the rate of five per second.

For the next example, the consonance of the fifth, this explanation will not suffice, and Helmholtz has to resort to a cause of the second order, namely, the beat of a grave harmonic, not with an imperfect unison, but with an imperfect octave. Taking our former example, an out-of-tune fifth C and G, of 128 and 197 vibrations respectively; these two notes will give a combination or difference tone of 69 vibrations, or an octave below the C, but out of tune. Then Helmholtz says this lower C will beat with its imperfect octave, on account of a new or *second order of difference-tones* formed from them, as in the former case.

In a similar but still more remote way, Helmholtz accounts for the beats of other consonances, the fourth, third, &c.

Without questioning the sufficiency of these explanations, I must say they seem to me somewhat far-fetched, and less satisfactory than Smith's, which account for the beats by a more positive and direct method, without calling in the aid of any sounds but the simple fundamental ones. There is at any rate the satisfaction that whichever explanation be adopted, the numerical value of the number of beats per second comes out the same and agrees with the fact; so that in a practical point of view it is immaterial which explanation be adopted.

I have alluded above to one important practical use of beats, namely, in tuning; but there is another use of them, also very interesting, *i.e.*, that they furnish a means of ascertaining the positive number of vibrations per second corresponding to any musical note. This may be done either by the unison or by Smith's beat, and I will give both methods.

For the unison beat:—Take two notes in unison on an organ, a harmonium, or other instrument of sustained sounds, and put one of them a little out of tune, so as to produce beats when they are sounded together. Let V and v represent the vibration numbers of the upper and lower notes respectively. Then by means of a monochord it will be easy to determine the ratio $\frac{V}{v}$, which call m. Count the number of beats per second, which call β. Then, since $\beta = V - v$, we obtain the simple equation,

$$v = \frac{\beta}{m - 1}$$

which gives the actual number of vibrations per second of the lower note of the two.

The method of deducing the vibration-number from the Smith's beat was pointed out by Smith himself; but as this method, so far as I know, is not to be found anywhere, except buried under the mass of ponderous learning contained in his work; I give it here in a simple algebraical form. If $\frac{m}{n}$ represents the true ratio of the interval, N the actual number of vibrations per second of the lower note, and M the same number for the upper one, the formula for Smith's beats becomes

$$\beta = \left(m - n\frac{M}{N}\right)N; \quad \text{or } N = \frac{\beta}{m - n\frac{M}{N}}$$

Now, as m and n are both known for any given concord, if we can tell by any independent means the actual ratio of the notes $\frac{M}{N}$, we may, by simply counting the beats, calculate the actual number of vibrations N of the lower note. If the interval is too flat, β must be $+$; if too sharp, it must be $-$.

The following example will show how this may be done. Let it be required to determine how many vibrations per second are given by the note  on an organ. Tune three perfect fifths upwards, and then a perfect major sixth downwards, thus— , which will give the C an octave above the original note. But, by the laws of harmony, we know that this octave will not be in tune; the upper C will be too sharp, the ratio being $\frac{81}{40}$, instead of $\frac{2}{1}$, as it ought to be. Hence $\frac{M}{N} = \frac{81}{40}$, and $\frac{m}{n} = \frac{2}{1}$. Count the beats made by this imperfect octave, and suppose them = 192 per minute, or 3·2 per second; then, as the interval is sharp,

$$N = \frac{-3{\cdot}2}{2 - \frac{81}{40}} = 128;$$

i.e. the note  is making 128 double vibrations per second.

This method has the advantage of dispensing with the use of the monochord, which was necessary in the former case.

NOTES

A METEOROLOGICAL Commission, appointed by the Ministers of Public Instruction, Agriculture and Commerce, Marine, and Public Works, to inquire into the possibility and practicability of a more intimate co-operation being effected among the various meteorological systems of Italy, have just issued their report. The Commission consisted of fourteen members, including most of the well-known meteorologists of Italy, with Prof. Cantoni as president, and Prof. Pittei as secretary, and met daily at Palermo from Aug. 30 to Sept. 6, 1875. The more important of the conclusions arrived at are these:—That all methods of observing at the stations of the various systems connected with the State be

brought into accordance with those adopted by the Minister of Agriculture and Commerce; that harmonious action be based on the number, quality, and hours of the observations, a preference being given to those stations which from their position will best meet the requirements of local and international meteorology; that the instruments and modes of observing be strictly uniform; that inspection of stations be made at least once every two years, and that the reduction and publication of meteorological results be remitted to a directive council composed of meteorologists elected from the directors of the principal observatories and meteorological institutes, whose decisions will be carried out by a secretary and suitable staff.

AT the meeting of the Paris Academy of Jan. 10, General de Nansouty submitted a report on the project of a physical observatory on the top of the Pic du Midi de Bigorre, Pyrenees. As our readers know, a small hotel on the Col de Sencours has been provisionally used for observations since 1873, but amid great difficulty, from avalanches, cold, &c. The Pic is 2,877 metres high, and only 527 short of the highest, but is easily accessible.

THE Observatory on the Puy de Dôme is being rapidly completed, and will be opened this year. A semaphoric system of telegraphy will be used to keep the Observatory in constant communication with Clermont, the chief town of the district, at the foot of the mountain.

THE fourth part of the second series of Mr. William H. Edwards' work on the Butterflies of North America has just been published by Hurd and Houghton, and contains five quarto plates of butterflies, drawn with the utmost excellence by Miss Peart. The forms illustrated are species of *Argynnis*, *Grapta*, *Melitæa*, and *Papilio*, most of them new species recently described by Mr. Edwards himself.

AN addition to the list of American scientific journals has been made in the form of a *Botanical Bulletin*, edited by Mr. John M. Coulter, of Hanover, Indiana. At present it is a sheet of four pages, appearing monthly, with the promise of increase in size with increase in subscribers. It is in form and general scope much like the Bulletin of the Torrey Botanical Club.

DR. HOFMANN of Berlin has been elected a foreign associate of the Italian Society of Science in room of the late Sir Charles Wheatstone. This Society was founded in 1782; the Italian members are limited to forty, and at present the Society has only twelve foreign associates, among whom are Sir George Airy, Prof. Cayley, and Sir Edward Sabine. Its rules are numerous, and somewhat stringent.

THE Paris Academy of Sciences at Monday's sitting nominated Prof. Nordenskjöld a Correspondant in the section of Geography and Navigation.

THE Central Section, or governing body of the Geographical Society of Paris, has appointed as its president for 1876 M. Malte-Brun, the son of the celebrated Danish geographer.

THE Geological Society of Paris has elected as its president for 1876 M. Pellat, an amateur geologist, holding a high position in the finance department of Government.

THE warlike habits of the Papuans and their implements of warfare are described in a private letter recently addressed to Dr. Hooker. The writer says that no man leaves his dwelling for his bit of cultivation even without his powerful bamboo bow and a few deadly poisoned arrows. These poisoned arrows are only a few amongst a great number not poisoned, the former being distinguished by elaborate carving and painting, probably to prevent accident amongst themselves. They are each pointed and barbed with human bone brought to almost needle-like sharpness, most carefully and neatly finished; they are poisoned by plunging in a human corpse for several days. Poor Commodore Goodenough and his men suffered from arrows so poisoned. It is a sort of blood-poisoning that, like other kinds of inoculation, does not develop itself for several days, the slightest scratch being sufficient to render almost inevitable a horrible death. The symptoms are accompanied by violent spasms like tetanus, with consciousness until the last.

CAPTAIN MORESBY'S work on New Guinea and Polynesia will be published shortly by Mr. John Murray. It will include discoveries and surveys in New Guinea and the D'Entrecasteaux Islands, a cruise in Polynesia, and visits to the pearl-shelling stations in Torres Strait of H.M.S. *Basilisk*, and will be illustrated by a map and wood-cuts. It will be interesting to compare this book of Captain Moresby's with Captain Lawson's "New Guinea," noticed in NATURE some time back.

M. E. QUETELET has called attention to the cold experienced in Brussels in December, 1875, when the temperature fell to freezing every night from 25th Nov. to 6th Dec., falling on the 2nd to 18°·5, which is lower than has occurred any time up to the 4th December, during the last forty-two years. In thirteen out of the forty-two years the temperature observations present a relation somewhat analogous to those of 1875. It is remarkable that with this low temperature and a persistent E.N.E. wind, the barometer has continued low and the air humid and constantly cloudy. On the 7th December the temperature fell to 5°·9.

PROF. F. W. PUTNAM, Dr. Packard's late colleague, the *Nation* announces, has been appointed Civilian Assistant on the U.S. Surveys west of the 100th meridian conducted by Lieut. G. W. Wheeler, and is already occupied in preparing a report on the abundant and very valuable archæological and ethnological material collected by the exploration in Arizona, New Mexico, and California. The report will be profusely illustrated, and the *Nation* ventures to predict, will be the beginning of our scientific knowledge of the prehistoric civilisation of the above-named regions.

A CONVOCATION of the University of London was held on Tuesday, at which, after a long discussion, a resolution was passed affirming the desirability of obtaining a new charter, and declaring that no such charter would be acceptable to convocation which did not enable the University to grant degrees to women.

THE Ladies' Classes at University College, London, began on Monday last the second term of their eighth session. There was a slight decline in the number of students for the session 1874-75, but the first term of the session 1875-76 showed a considerable advance beyond the highest success hitherto attained. In the Michaelmas term, 1874-75, the whole number of individual students was 199; in the Michaelmas term, 1875-76, just elapsed, the number of individual students was 265. The whole number of tickets taken in Michaelmas term, 1874-75, was 257; in the same term of 1875-76 it was 367.

IN a paper on the Chalk in the Channel district read at the Paris Academy on Monday, Prof. Hebert stated that he expected great obstacles to be met with in the attempt to bore a Channel tunnel.

IT is announced that all communications and notifications in connection with the next International Congress of Medical Sciences, to be held at Geneva on Sept. 9, 1877, be sent to the Committee before June 1, 1876, the time when the Committee will definitely settle the regulations and programme, and appoint reporters. The present president is Prof. C. Vogt, and the secretary Dr. T. L. Prevost.

M. ADOLPHE PICTET, who died at Geneva on Dec. 20 last, at the age of 76 years, was one of the most eminent writers on

ethnology and comparative philology of the present century. In 1839, the French Institute awarded him the Volney Prize for his work on the affinity of the Celtic Languages with Sanscrit. In 1863, this same prize was awarded him a second time for the publication of his great work, "Les Origines Indo-Européenes, ou les Aryas primitifs." M. Pictet was also an eminent man of letters. He was a corresponding member of the Royal Society of Edinburgh.

AN ingenious toy, apparently of Japanese origin, has recently been introduced into London. It consists of a small picture, on paper, of an individual pointing a firearm at an object—bird, target, or second person. By the application of the hot end of a match, just blown out, to the end of the gun, the paper commences to smoulder towards the object aimed at, and in no other direction. When it is reached a report is heard from the explosion of a small quantity of fulminating material. The toys are sold in London by Mesdames Jinks and Ashton, of Glasshouse Street.

ABOUT midnight on the 22nd of December, 1875, two earthquake shocks were felt at Washington, Richmond, Weldon, North Carolina, U.S., and other places in that section. There were two distinct shocks at Richmond, the first continuing about ten seconds, while the other was briefer and not so severe, and was accompanied by a concussion in the air.

THREE distinct shocks of an earthquake are stated to have been felt at Comrie, near Crieff, Perthshire, on Sunday—two at about three in the morning and the third in the afternoon.

THE *Gazette d'Augsbourg* states that a commission which has been visiting the Russian Universities has laid its report before the Czar. The chief recommendations are to increase the salaries of some of the professors, and to create a few new chairs.

THERE are several important papers in this month's part of Petermann's *Mittheilungen*. The editor himself takes occasion, on the conclusion of the new edition of Stieler's fine Hand-Atlas, to give a brief history of that work, and to point out the great advances in geography since the last edition was published. The first part of a paper appears, giving some account of Przewalsky's travels in Mongolia and the land of the Tanguts during 1870–73. We believe the author's narrative of this important expedition is being translated into English; a map accompanies the article in the *Mittheilungen*. A translation from the Russian gives an interesting description of the ruins of Mestorjân, in the Turkoman steppes. Some account of the Paris Geographical Congress is given by the delegates from Perthes establishment. A valuable paper by Dr. G. Hartlaub describes the great amount of work done by that indefatigable traveller in China, the Abbé Armand David. Along with a brief summary of discovery in the interior of Australia there is a fine map, showing the routes of Warburton, Forrest, and Giles.

SUPPLEMENT No. 44 of Petermann's *Mittheilungen* contains the first part of a narrative of the expedition which, under the engineer Josef Cernik, in 1872-73, explored the region of the Euphrates and Tigris, for the purpose of estimating its industrial capacities, and to mark out a route for a railway. The narrative will be found to contain much valuable information on the various aspects of the region visited. We need hardly say the narrative is accompanied by admirable maps.

THE Japanese Government is said to have adopted a singular method for extending a knowledge of the Arabic numerals with their English names; these are printed on cloth, which is sold at a low price to the peasantry.

THE *Annuaire* of the Bureau des Longitudes for 1876 was published a few days ago with an unusual number of useful tables and a map showing the magnetic declination for all French towns.

M. WALLON, the French Minister of Public Instruction, has abolished the fees of the several examiners in the degree examinations in Law, Medicine, Science, Literature, and Theology. The salaries of the professors and fellows have been raised on a scale varying from 6,000 francs to 18,000 francs, the professors of theology excepted. It is believed that these reforms are preparatory to the gratuitous conferment of degrees, which will be instituted by the new assembly.

WE have received the "Transactions" of the Clifton College Scientific Society, vol. ii. part 1, including the period from Dec. 1872 to June 1875. There are a number of very fair papers, though it seems to us that the members generally need to be wakened up and urged to attempt to rival similar societies in some of our other public schools. The "Transactions," however, contain one paper which alone reflects great credit on the Society, and especially upon its author, R. A. Montgomery. The paper is on the Isle of Unst, in Shetland, and describes, from personal observation, its geology, natural history, antiquities, and scenery, in a manner which would entitle it to a place in the "Transactions" of a more ambitious society. The paper is illustrated by maps and section.

AN important publication has lately been commenced in the form of a Bulletin of the U.S. National Museum, consisting of a series of memoirs illustrating the collections of the museum. It is printed, by direction of the Secretary of the Interior, at the Government printing-office, from materials prepared by the Smithsonian Institution, which, as is known to our readers, has charge of the museum referred to. The first number of the *Bulletin* consists of a check list of the North American batrachia and reptilia, with a systematic list of the higher groups, and an essay on geographical distribution, as based on the specimens in the National Museum, and as prepared by Prof. Edward D. Cope, the well-known herpetologist and naturalist. The list of species is the first systematic enumeration of American reptiles since the time of Dr. Holbrook, and embraces 101 species of frogs, toads, salamanders, &c., 132 of serpents, 82 of lizards, 41 of turtles and tortoises, and 2 of crocodiles. Each species is accompanied by a reference to some work where it is described or figured. The list of the higher groups embraces those of the whole world, and will form a convenient basis for the arrangement of such collections in public museums.

THE scientific expedition, commanded by M. Mouchez for the survey of the coast of Algeria, will last ten months. During the latter part of the expedition M. Mouchez will resume the exploration of coral reefs, and will be accompanied by M. Lacaze-Duthiez.

MR. J. CLIFTON WARD has reprinted from the *Quarterly Journal* of the Geological Society his paper "On the Granitic, Granitoid, and Associated Metamorphic Rocks of the Lake District."

THE tenth edition of the Prospectus of Sir Joseph Whitworth's Scholarships for Mechanical Science has been issued, containing the papers set at the examinations in May 1875.

ON the 26th of November last, in the French island La Réunion, near Mauritius, a part of a mountain slipped down, seventy-two persons having been crushed by the falling rocks.

THE additions to the Zoological Society's Gardens during the past week include an Emu (*Dromæus novæ-hollandiæ*) from Australia, presented by Mr. E. J. Dawes; a Palm Squirrel (*Sciurus palmarum*), a Manyar Weaver Bird (*Ploceus manyar*), two Nutmeg Birds (*Munia undulata*), two Amaduvade Finches (*Estrelda amadava*) from India, presented by Mr. W. D. Baker; a Cinereous Sea-Eagle (*Haliaetus albicilla*), European, deposited.

SCIENTIFIC SERIALS

THE current number of the *Journal of Anatomy and Physiology*—the second under the new system—commences with a paper by Dr. G. Thier and Mr. J. C. Ewart, entitled "A Contribution to the Anatomy of the Lens." The fibres of that organ are stated to be composed of a number of flattened bands, termed primary fibres, and to be covered with elongated flat cells resting on a structureless membrane.—Dr. McIntosh describes the central nervous system, the cephalic sacs, and other points in the anatomy of the Lineidæ, demonstrating that in the Nemerteans the nervous system is highly developed, and that the cephalic sacs are special organs of sense, their internal surface being in direct communication with the surrounding water by the ciliated duct, whilst the fibrous peduncle places their cells in continuity with the central nervous system. The paper is profusely illustrated.—Prof. Rutherford, who has been assisted by M. Vignal, records his experiments on the biliary secretion of the dog. In almost every case the animal had fasted about eighteen hours. Under the influence of curare a tube was tied into the bile duct. The amount of bile which flowed in each quarter of an hour was measured. The cholagogue action of croton oil is shown to be *nil*; that of podophylline considerable; that of aloes powerful; that of rhubarb well marked; that of senna feeble; that of colchicum considerable, by making the bile watery; that of taraxacum very feeble; that of scammony feeble; that of calomel probably *nil*; that of gamboge *nil*; that of castor-oil *nil*. The memoir, with its valuable diagrams, deserves special attention.—Dr. Galabin contributes an article on the pulse-wave in the different arteries of the body. The author, we are glad to see, has modified his previous statement as to the modification of a double wave the result of a single impulse, in the explanation of the predicrotic undulation in the sphygmograph trace. He gives an explanation of this as well as of the predicrotic wave. Some of his arguments are, we think, based on too few facts, whilst others are complicated by their pathological nature.—Mr. D. J. Cunningham has some notes on the broncho-œsophageal and pleuro-œsophageal muscles of man, first described by Hyrtl. —Dr. Stirling contributes a memoir on the summation of electrical stimuli applied to the skin, in which, from an excellent series of experiments on the frog, he demonstrates, according to the view of W. Baxt, that *reflex movements can only be liberated by repeated impulses communicated to the nervous centres*.—Mr. F. M. Balfour commences a series of papers to ultimately constitute a monograph on the development of Elasmobranch Fishes. Commencing with the ripe ovarian ovum, its description is followed by that of the segmentation, in the volume before us. This monograph will be an invaluable adjunct to that on the hen's egg, by Dr. M. Foster and the same author, and is a most promising production of the Biological school of the University of Cambridge.—Prof. Huxley writes on the nature of the craniofacial apparatus of *Petromyzon*, a specially favoured region of that author. The plates are unfortunately delayed for three months.—Mr. S. M. Bradley has a note on the secondary arches of the foot.—Prof. Turner, lastly, gives a note on the placental area in the uterus of the cat after delivery, in which he shows that in delivery not all the mucosa of the placental area comes away, its deeper structures being partly left. —Prof. Turner and Mr. Cunningham's report on the progress of anatomy concludes the part.

Archives des Sciences Physiques et Naturelles, Oct. 15, 1875.—In this number is concluded an important paper by Prof. Lemström, of Helsingfors, on the theory of Aurora Borealis, *àpropos* of some phenomena of Geissler tubes. The phenomenon from which he set out was that a Geissler tube is illuminated when near the pole of an electric machine, without the tube touching the poles. Air, at a pressure of 5 to 10 mm., acquires its maximum electric conductivity, and Prof. Lemström conceives the air in the upper regions of the atmosphere, rarefied to about 5 mm., as forming a great conductor concentric with the earth; its height some 3,000 kilometres less at the poles than at the equator, and the electric density (on both conductors) 9 per cent. greater, while the force with which the electricity of the atmospheric conductor is attracted to the earth is 42 per cent. greater (at poles than at equator). Thus there is accumulation of atmospheric electricity at the poles, and the auroras are produced on its combination with that of the earth. The theory regards aurora as a phenomenon entirely of our globe; but the possibility is not excluded of an action of the sun, causing a periodical variation of auroras, through meteorological phenomena, such as evaporation on the earth's surface.—Prof. Schnetzler contributes some observations on Bacteria.—M. Cellerier investigates mathematically the simultaneous movement of a pendulum and its supports; and a *résumé* is given of the proceedings at the extraordinary session of the Geological Society of France, held in the end of August at Geneva and Chamounix.—In the "Bulletin Scientifique" there is a description of a curious phenomenon observed by M. Gumœlius in Sweden, viz., intercrossing rainbows.

Journal de Physique, November, 1875.—This number contains the second part of M. de Romilly's paper on the conveyance of air by a jet of air or of vapour. He investigates the effects of the jet when driven against the lateral wall of the receiver, the orifices of the discharge-pipe and the receiver forming, if projected on a plane parallel to them, two circles exteriorly tangent. The form and separation of the two instruments are varied.—M. Angot, in another continued paper, gives a good account of Thomson's quadrant electrometer.—There are also short mathematical notes on the verification of the law of Huyghens, by M. Abrin; and elementary demonstration of the formula of La Place, by M. Lippmann, together with the usual amount of matter abstracted from other serials.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, Jan. 6.—On the Expansion of Sea-water by Heat. By T. E. Thorpe, Ph.D., and A. W. Rucker, M.A. (Fellow of Brasenose College, Oxford), Professors of Chemistry and Physics in the Yorkshire College of Science.

The extensive contributions which have recently been made to the physical history of the ocean have shown the desirability of exact knowledge of the relations of sea-water to heat. The authors have accordingly made observations in order to determine the law of the thermal expansion of sea-water.

The only attempt hitherto made to solve this problem which can lay any real claim to consideration is due to the late Prof. Hubbard, of the United States National Observatory. The results of his investigation are contained in Maury's "Sailing Directions," 1858, vol. i. p. 237.

Muncke, nearly fifty years ago, determined the expansion of an artificial sea-water at various temperatures between 0° and 100° C.; but our confidence in the results as applicable to natural sea-water is affected by the circumstance that the solution was prepared from data furnished by the imperfect analyses of Vogel and Bouillon La-Grange.

The observations of Despretz were confined to temperatures below 13°·27, as the main object of his inquiry was the determination of the point of maximum density of sea-water. The subsequent investigations of Neumann and Rossetti were equally limited, as they were undertaken with the same view.

The water used in the authors' observations was collected from the Atlantic, in lat. 50° 48′ N. and long. 31° 14′ W.; and its specific gravity at 0° C., compared with distilled water at the same temperature, was found by the bottle to be 1·02867.

The method of experiment was precisely the same as that already employed by one of the authors in determining the expansion of the liquid chlorides of phosphorus. It was essentially that already used by Kopp and Pierre; *i.e.* the expansion was observed in thermometer-shaped vessels (so-called dilatometers), graduated and accurately calibrated.

Three of these instruments and two sets of thermometers were employed. The latter were made by Casella; the length of a degree in different instruments varied between 9 and 13 millims.; they had been compared (the one set directly, the other indirectly) with Kew standards.

Three perfectly independent sets of observations were made with the water in the state in which it was collected; but as Mr. Buchanan, of H.M.S. *Challenger*, has found that the specific gravities of different sea-waters lie between the extreme values 1·0278 and 1·0240, and since, in order to be of value in the investigation of the physical condition of the ocean, the observations on their value and the formulæ of reduction ought to be correct to the fourth decimal place, quantities of the sea-water were diluted with distilled water, so as to have specimens of approximately the specific gravities of 1·020 and 1·025; and a third quantity was concentrated by evaporation until its specific gravity was increased to 1·033; two series of independent observations were made on the expansion of each solution.

Empirical formulæ were calculated to express the results of

each series of observations; and in the original paper full details of the observations are given, together with tables, showing the agreement between the calculated and observed results, and also (after the necessary corrections and reductions have been made) between the volumes calculated from the formulæ from different series of observations in the same solutions.

Finally, a general formula of the form

$$v = \phi(t) + \psi(t) f(s)$$

was found, giving the relation between the volume (v), temperature (t), and specific gravity at 0° C. (s) of any solution of the same composition of sea-water the specific gravity of which at 0° C. lies between 1·020 and 1·033, the volume at the same temperature being taken as unity; in which expression

$$\phi(t) = 1 + \cdot 00008097t + \cdot 0000049036t^2 - \cdot 000000012289t^3,$$
$$\psi(t) = -10^{-6}(\cdot 5509t - \cdot 020198t^2 - \cdot 00033276t^3),$$
and
$$f(s) = 11 \cdot 95 - 940(s - 1 \cdot 02).$$

In the original paper it is shown that if σ be the specific gravity at any temperature t and of a solution the specific gravity of which at 0° C. is s, $\frac{d\sigma}{ds}$ may without sensible error be assumed to be constant; whence, by means of the above formula, the authors are able to give in a table all the data necessary for calculating the specific gravity of sea-water of any degree of salinity at any temperature between 0° and 36°.

The authors conclude by discussing the discrepancies which occur between their results and those of Prof. Hubbard; and they point out various circumstances in the methods employed in making and reducing the latter observations which appear to them to explain in a great measure the divergences which exist.

On the Action of Light on Tellurium and Selenium. By Prof. W. G. Adams, F.R.S.

A small bar of tellurium, an inch long, whose resistance was half an ohm, forming part of one of the resistances in a Wheatstone's Bridge, was exposed to the light of a paraffin lamp at a distance of half a metre from it. At first, on exposure, the heat from the lamp increased the resistance of the tellurium.

When a rectangular vessel of water was placed between the lamp and the tellurium there was found, on exposing as before, to be no perceptible change in the resistance. On removing the rectangular vessel and putting a cylindrical beaker of water in its place, so as to focus the light on the tellurium, the resistance of the tellurium was found to be diminished.

When it had been kept in the dark for several days the tellurium was much more sensitive to light. When exposed to the paraffin lamp the resistance of the tellurium was now found to be as much *diminished* without using the beaker of water as it had previously been when the beaker was used. On introducing the beaker of water between the tellurium and the lamp, the resistance of the tellurium was still further diminished, the change produced in the resistance by the exposure being $\frac{1}{300}$th part of the whole.

When the selenium bar was exposed to the same lamp at the distance of 1 metre, the change in the resistance was $\frac{1}{8}$th of the whole.

On exposing the selenium to a constant source of light at different distances, the change in the resistance of the selenium is *inversely as the distance*, *i.e.*, directly as the square root of the illuminating power.

The following results were obtained with one candle and an argand lamp, whose illuminating power is equal to sixteen candles:—

	At $\frac{1}{4}$ metre.	At $\frac{1}{2}$ metre.	At 1 metre.	At 2 metres.
With argand lamp	—	170	83	39
With 1 candle	—	41	18	8
With 1 candle	82	39	18	8

These and other similar experiments clearly show that the change in the resistance of the selenium is *directly* as *the square root* of the illuminating power.

Mathematical Society, Jan. 13.—Lord Rayleigh, F.R.S., vice-president, in the chair.—Major J. R. Campbell, Mr. R. F. Scott, and Prof. H. W. Lloyd Tanner were admitted into the Society.—The following communications were made:—Mr. J. W. L. Glaisher, F.R.S., on an elliptic-function identity.—Prof. H. W. Lloyd Tanner on the solution of partial differential equations of the second order with any number of variables when there is a complete first integral.—Prof. Clifford, F.R.S., on free motion of a rigid system in an n-fold homoloid; expression of the velocities by Abelian functions.—The following abstract of Prof. Clifford's paper will give some idea of the mode of treatment employed:—Equations corresponding to Euler's are obtained for the $\frac{1}{2}n(n-1)$ rotations p_{hk}; these are $\lambda_{hk} d_t p_{hk} = \Sigma p_{hl} p_{kl}$ where the λ are expressed in terms of the n constants α, namely, $\lambda_{hk}(\alpha_h - \alpha_k) = \alpha_h + \alpha_k$; it is understood that $p_{hk} = -p_{kh}$. It is then shown that similar equations are satisfied by quotients of θ-functions of $n-2$ arguments, one argument being $at + \epsilon$. The solution of the problem for the rotational velocities in n variables carries with it the determination of the position in the case of $n-1$ variables; the co-ordinates of the principal points are thus expressed in terms of the combinations of θ-functions which Rosenhain used for the inversion of integrals of the third class.—Lord Rayleigh, F.R.S., on the approximate solution of certain potential problems.

Royal Astronomical Society, Jan. 14.—Prof. Adams, president, in the chair.—A paper by the Astronomer Royal was read on the present state of his calculations for his new lunar theory.—Capt Orde Browne read a paper on the times of the phenomena of the Transit of Venus. He compared the times given by the observers at the different Egyptian stations, and showed that the observations might be divided into three classes, in the first of which it seemed probable that the observers had noted as the time of internal contact the moment at which a *shadowy* ligament was first formed between the limbs of the planet and the sun. In the second class it appeared that the observers had noted as the time of internal contact the moment at which a *black* ligament, as dark or nearly as dark as the planet's disc, was first seen between the limbs of the planet and the sun; observers of the third class had waited for what he termed geometrical contact, or the moment when the discs of the planet and the sun appeared to have a common tangent. Mr. Burton said that the chief difficulty which he had experienced in noting the exact moment of internal contact at ingress arose from the bright line which was seen surrounding the dark limb of the planet before it entered upon the sun's disc, this prevented him from determining the moment when the solar cusps actually met around the disc of the planet.—Mr. Christie described a new form of solar eye-piece which he had devised. It consisted of a series of glass prisms placed between the eye-piece and the eye of the observer in such a manner that the light was reflected nearly at the polarising angle, and when the prisms were turned round relatively to one another, the intensity of the ray entering the eye could be adjusted with great nicety. The chief advantages of this plan were that by placing the prisms between the eye-piece and the eye the reflecting surfaces could be kept small and the eye-piece could be used as a photometer for comparing the intensity of very bright lights, as it was evident that the intensity of the reflected and emergent rays could be easily calculated directly the positions of the prisms were known.

Geological Society, Jan. 5.—Mr. John Evans, F.R.S., president, in the chair.—John Kenworthy Blakey, Frederick Hovenden, and Thomas Lovell, M. Inst. C.E., were elected Fellows of the Society.—The following communications were read:—Historical and personal evidences of subsidence beneath the sea, mainly if not entirely in the fourteenth and fifteenth centuries, of several tracts of land which formerly constituted parts of the Isle of Jersey, by Mr. R. A. Peacock, C.E.—In this paper the author brings forward a great number of details, derived in part from personal observations and in part from ancient documents, to prove that a considerable submergence of land has taken place round the island of Jersey within comparatively recent times. He referred principally to the existence of a submerged forest in the Bay of St. Ouen, evidenced by the existence of stumps of trees in the sea-bottom there, and by the traditional fact that up to quite a late period fees were paid for privileges connected with the forest of St. Ouen, although the forest itself had long previously disappeared beneath the sea. From the evidence it would appear that the submergence took place at the end of the fourteenth or the beginning of the fifteenth century. The author also noticed the occurrence of peat and submarine trees in the little bay of Grève de Lecq on the north side of Jersey, and especially referred to the evidence afforded by the Ecrehous rocks and Maitre Isle, there having been in the latter a priory or chapel, supported by rents derived from the parish of Ecrehous, which is now represented only by a small islet, with the ruins of an ecclesiastical building upon it, and a range of rocks protruding but little above the sea.—The physical conditions under which the Upper Silurian and succeeding Palæozoic Rocks were probably

deposited over the Northern Hemisphere, by Mr. Henry Hicks. In this paper the author, after pointing out the lines of depression explained in his former paper to the Society, now further elaborated the views then propounded by him by carrying his examination into the higher Palæozoic series and into more extensive areas. Beginning at the top of the Lower Silurian, where he first recognises any evidence of a break in the Palæozoic rocks, he proceeded to show that this break was restricted to very limited areas, and almost entirely confined to the parts which had been first submerged, and where the greatest thickness of sediment had accumulated on both sides of the Atlantic, and hence where the pre-Cambrian crust had become thinnest. On the European side this break occurred where volcanic action had taken place, and has doubtless to be attributed to the combined action of upheaval of portions of the crust and the heaping up of volcanic material, the latter in some cases forming volcanic islets of considerable extent. He strongly objected to look upon these breaks, even in the British area, where they are most marked, as evidence of a want of continuity over other and far greater areas; or to admit that even where there was conformity in the rocks at this point, "great intervals of time are indicated, unrepresented by stratified formations." The conformity found in extensive and widely separated areas is proof also that a gradual contraction took place of an enormous portion of the crust in the northern hemisphere in Palæozoic times; and the breaks at the close of the Lower Silurian and in the Devonian are not indications of an arrest in the general subsidence. After indicating the changes which must have taken place in the climate from this gradual spreading of the water and the evidence to be derived from the consideration of the deposits and the faunas, the author drew the following general conclusions:—1. That the condition of the northern hemisphere at the beginning of Palæozoic time was that of immense continents in the higher latitudes, traversed by mountainous ranges of great height, but with a general inclination of the surface, on the one side (European) to the south-west and south, and on the other side (American) to the south-east and south. 2. That these continents were probably covered, at least in their higher parts, with ice and snow; and that much loose material had consequently accumulated over the plains and deeper parts, ready to be denuded off as each part became submerged. This would account for the enormous thickness of conglomerates, with boulders, grits, and sandstones, found in the early Cambrian rocks, and also to a certain extent for their barrenness in organic remains. 3. That the depression over the European and American areas was general from at least the latitude of 30° northwards; that the parts bordering the Atlantic were the first to become submerged; the lower latitudes, also, before the higher. 4. That the depression could not have been less altogether, for the whole of the Palæozoic, than 50,000 feet; and that conformable sediments to that extent are found over those parts of the areas first submerged, and which remained undisturbed. That volcanic action was chiefly confined to parts of the regions which became first submerged; that the immediate cause of these outbursts was the weakness of the pre-Cambrian crust at those parts, from the great depression that had taken place, it being too thin there to resist the pressure from within, and to bear the weight of the superincumbent mass of soft sediment. 5. That the seat of volcanic action at this time was at a depth of probably not less than twenty-five miles, as sediments which were depressed to a depth of from nine to ten miles do not indicate that they had been subjected to the effect of any great amount of heat, and are free from metamorphosis. 6. That the climate at the early part of Palæozoic time was one of very considerable, if not extreme cold, and that it became gradually milder after each period of depression. That towards the close of the Palæozoic, in consequence of the elevation of very large areas, and to a great height, the climate became again more rigorous in character. 7. That the various changes which took place over the northern latitudes during Laurentian and Palæozoic times allowed marine and land life to develop and progress in those areas at interrupted periods only; consequently most of the progressive changes in the life had to take place in more equatorial areas, where the sea-bottom was less disturbed, and where the temperature was more equable. Any imperfection, therefore, in the Palæontological record belonging to these early times should be attributed to these and like circumstances; for wherever an approach to a complete record of any part of the chain is preserved to us, the evidence points unmistakably to an order of development, through a process of evolution from lower to higher grades of life.

Anthropological Institute, Jan. 11.—Mr. A. W. Franks, F.R.S., vice-president, in the chair.—Messrs. H. A. Husband, E. Croggan, J. B. Lyons, and W. R. Cornish were elected members.—Mr. W. S. W. Vaux, F.R.S., read a paper on the Maori race of New Zealand. There were three sources from which some information as to the origin of the Maoris might be gained. Firstly, from traditions, among which a very general and remarkable uniformity prevails, pointing to the conclusion that the ancestors of the Maoris came from the north and north-east in small numbers and a few at a time, the names of some of the canoes in which they arrived having been preserved. The author thought that the evidence in favour of those traditions was conclusive. Secondly, from their ethnology and customs. With regard to the former, appearances were at first sight in favour of a mixed origin, the diversities in physiognomy and colour being considerable; but to that view the author thought the linguistic evidence furnished an unanswerable objection. As to the customs of the Maoris, they did not differ much from those found in other groups of Polynesian Islands, indicating a former intimate connection between them all. Thirdly, from language. The general conclusion of the author from that argument was that there was one Polynesian language which had been broken up into many dialects, the Maori being one. That opened out the larger question as to who the Polynesians were, and it was in that direction that inquirers must search for the origin of the Maoris. Evidence finally pointed to Asia for the solution of the problem.—Dr. Hector, F.R.S., exhibited and described at length the collection of stone and other implements he had recently brought from New Zealand, and went minutely into the circumstances of their discovery, their varieties, and uses. He also entered into a discussion on the traditions of the Maoris, their population in the two islands, their manners and customs, their language and physique, drew a comparison between them and the Moriories, and treated of many other topics relating to the past history and present condition of the people.

Physical Society, Jan. 15.—Prof. Gladstone, F.R.S., president, in the chair.—The following candidates were elected members of the society:—Sir David Lionel Salomons, Bart., Arthur R. Granville, and Capt. Abney, R.E.—Prof. Woodward, of the Midland Institute, Birmingham, exhibited and described a novel form of apparatus for showing either the longitudinal motion of sound-waves or the transverse vibrations of those of light. It consists essentially of a series of balls suspended in a horizontal line by strings. These balls rest against a series of transverse equidistant partitions in a wedge-shaped horizontal trough, which can be raised and depressed parallel to itself. If, while a ball is placed against each partition, the frame be drawn aside in the plane in which the balls hang, and then slowly depressed horizontally, the balls will be successively liberated, the order in which this takes place being regulated by the heights of the partitions. As these gradually increase from one end to the other, the appearance presented is that of a series of condensations and rarefactions, as in the ordinary acoustic wave. If the frame be drawn aside parallel to itself prior to depressing it, the balls will rest against one side of the trough and can be liberated in succession, causing them to oscillate in planes parallel to themselves. By this means a vibration of the particles is set up resembling that of polarised light.—Prof. Guthrie suggested that Mr. Woodward should devise a similar apparatus for exhibiting stationary waves.—Prof. Woodward said he would remember the suggestion, and stated that he had endeavoured to adapt the apparatus to circular and elliptic wave-motion, but experienced considerable difficulty.—Mr. Lockyer then made a communication on some recent methods of spectroscopy. At the outset he mentioned that he brought these processes forward in the hope that others present might be induced to take up some branch of the work. The first subject of which he treated was the photographing of the solar and metallic spectra. Mr. Rutherford, of New York, who has produced some of the finest photographs of spectra extant, has shown that to obtain clear photographs the smallest possible portion of the surface of the prism should be employed. An excellent method for ensuring this is to bring the light on the slit by means of a common opera-glass (as large as possible), which should reduce the beam of parallel rays incident on the prism to not more than a quarter of an inch in diameter. Mr. Lockyer exhibited the four-prism spectroscope employed by himself, to which a camera about four feet long is adapted. By this apparatus a large series of comparisons has been obtained between the sun and metals, the slit employed being provided with five slides, so that the spectra can be

accurately arranged side by side. It is advisable always to observe the image of the electric arc when comparing the spectra of metals with that of the sun, rather than direct light. It is also found very advantageous to place the poles of the lamp at right angles to the slit, as by this means the long and short lines in the spectra are more sharply defined than when observed in the ordinary manner. In the photograph comparing the spectra of aluminium and calcium it is noticeable that certain lines are common to the two, but those which are thick in the aluminium spectrum are thin in that of calcium, and *vice versâ*. This depends on the quantities of impurity present. It has thus been shown that there are no proper coincident lines in the spectra of any two simple substances, and that there is no substance spectroscopically pure. The relation between the lengths of the lines and the amounts of metals employed to produce the spectrum convinced Mr. Lockyer that it would be possible to employ the spectroscope for quantitative analysis. The earlier experiments in this direction were then referred to, as well as those on which Mr. Lockyer has recently been engaged in conjunction with Mr. W. Chandler Roberts, of the Royal Mint, with a view to ascertain how far it is possible to detect small differences of composition in gold-copper alloys such as that used for the coinage. The method employed was then described. It consists in measuring, by means of a micrometer in the eye-piece of a four-prism spectroscope, the relative lengths of certain gold and copper lines when the image of an induction coil spark passing from the alloy under examination is focussed on the slit. Although the results obtained have not been uniformly comparable, and therefore reliable, it is nevertheless certain that a difference of composition as minute as the $\frac{1}{10000}$th part is recognisable by this means. Another method of spectroscopic research which Mr. Lockyer next described was the study of the absorption spectra of metals when they are not subjected to so violent an action as that of the electric arc. Observations of this nature have been made at low temperatures by Roscoe and Schuster, and by Mr. Lockyer, and at the highest temperatures produced by the oxyhydrogen blow-pipe by the latter in conjunction with Mr. Roberts. These experiments, which have been fully described in the Proceedings of the Royal Society, show that the absorption spectra of metals may be divided into five classes, which, for any particular metals, depend on the amount of heat applied. They suggest that in passing from the liquid to the most perfect gaseous state, vapours are composed of molecules of different orders of complexity; and that this complexity is diminished by the dissociating action of heat, each molecular simplification being marked by a distinctive spectrum.—The President inquired whether the iridium line to which Mr. Lockyer had referred, and by means of which the metal was originally discovered, was absolutely identical with a hydrogen line.—Prof. McLeod asked if Mr. Lockyer had found that the incandescence of the air made any difference in the character of the spectra, and drew attention to the advantage of a small lens placed in front of the slit.—Mr. Woodward inquired whether any mechanical means were adopted for ensuring that the lamp gave a constant light while in the horizontal position.—Dr. Guthrie referred to the spectrum observed when light traverses the vapours resulting from the action of copper on nitric acid. He wished to know whether the number of bands observed stands in any relation to the number of possible oxides of nitrogen at a given temperature; or must one oxide of nitrogen be considered as being capable at that temperature of giving bright and dark bands according to the way in which the light acts on it?—Mr. Lockyer, in reply to the president's question, said that, so far, no difference has been observed between the refrangibility of the hydrogen line and that of iridium. He is anxious to ascertain whether any occluded hydrogen exists in the metal. Little or nothing is known as to the subject referred to in Dr. Guthrie's question. The use of the electric lamp eliminates all difficulty with reference to air lines, as its "atom-shaking" power is not sufficient to break up to the line stage the molecules of nitrogen and oxygen. It was found necessary to make the adjustments referred to by Mr. Woodward entirely by hand.

Victoria (Philosophical) Institute, Jan. 17.—On the Scientific Conclusions and Theological Inferences, in a recent work entitled "The Unseen Universe," was read by the Rev. Prebendary Irons, D.D., the Bampton Lecturer for 1870.

PARIS

Academy of Sciences, Jan. 10.—Vice-Admiral Paris in the chair.—The following papers were read:—Experimental critique on the formation of saccharine matter in animals, by M. Cl. Bernard; an *aperçu* of his researches on the subject.—Researches on aldehyde, by M. Berthelot. He measures the heat liberated in transformation of aldehyde into acetic acid, and into oxalic acid, the heat of vaporisation, &c.—Union of carburets of hydrogen with hydracids and halogenic substances, by M. Berthelot.—Micrometric measurements taken during the transit of Venus, by M. Mouchez.—On the causes of failure in searching for minimal quantities of iodine, by M. Chatin.—New considerations on the regulation of slide valves, by M. Ledieu.—M. Mouchez presented some new maps of the coast of Africa.—Report on the project of a physical observatory on the top of the Pic du Midi de Bigorre, submitted to the Academy by General de Nansouty, in name of the Société Ramond. This peak (in the Pyrenees) is 2,877 metres in height, and only 527 short of the highest. It is somewhat isolated, and receives the direct shock of the great Atlantic air-currents; and it is easily accessible. A small hotel on the Col de Sencours (511 m. lower) has been provisionally used for observations since 1873, but amid great difficulty, from avalanches, &c.—Report on a memoir entitled "Problème inverse des brachistochrones," by M. Haton de la Goupillière.—Influence of tempering on magnetisation, by M. Gaugain. The bars hardened most are those which take the greatest magnetism, when one uses the most powerful means of magnetisation; but annealed bars are magnetised most powerfully where less energetic means are employed.—On the recent falling in on Bourbon Island, by M. Velain. The disaster was due to disaggregation of certain volcanic rocks under atmospheric agencies.—On a subterranean commotion in the centre of the isle of Réunion; disappearance of a hamlet of sixty-two persons, by M. Vinson.—On a pocket telemeter with double reflection, by M. Gaumet.—On the winter egg of Phylloxera, by M. Boiteau.—M. Carvalho presented a model of an ozonogenic apparatus, for rendering apartments wholesome in hot and unhealthy climates. It is a kind of condenser of the electric effluve. M. Thénard gave a warning on the poisonous action of ozone.—Generalisation of the theory of an osculating radius of a surface, by M. Lipschitz.—Note on a particular class of left decagons, inscriptible by an ellipsoid, by M. Serret.—Note on the application of recurrent series to investigation of the law of distribution of primary numbers, by M. Lucas.—On the spectrum of gallium, by M. Lecoq de Boisbaudran. With chloride of gallium he gets two narrow lines, α 417·0 and β 403·1.—On the decrease of sugar in beets during the second period of their vegetation, by M. Cosenwinder.—On the installation of the Meteorological Observatory of the Puy de Dôme, by M. Alluard. Observations (every three hours) were commenced on Dec. 20, 1875. A station on the plain, at Clermont, 9 kil. distant, and 1,100 m. under the summit, is supplied with the same instruments, and the two stations are connected telegraphically.—On the periodic movements of leaves in *Abies nordmanniana*, by M. Chatin.

GEORGE POULETT SCROPE, F.R.S.

YET another of the old lights of Geology gone from us !—one that shone out brightly more than half a century ago, and has kept its place and done its work even up to the last. At the ripe age of almost fourscore years, and with his faculties and sympathies still fresh and active, Mr. Scrope has passed away. Living his last years in the quiet retirement of his pretty country-house, he may be said to have taken some time ago his farewell of the scenes of his early scientific friendships. But that he kept up his interest in all his old pursuits was shown by his occasional letters on geological matters, which continued to appear until only a few weeks ago. The friends with whom he corresponded and who saw him from time to time in his retreat will not soon forget the eagerness with which he listened to every new fact in his favourite studies, and the friendly and large-hearted liberality with which he stimulated and assisted younger labourers in his own domain.

As far back as the winter of 1817-18 Mr. Scrope's attention was drawn to geological pursuits by the accident of his residence at that time in Italy when Vesuvius was in a state of constant eruption. Having leisure to indulge his taste, he gave himself up to the task of watching the progress of the Neapolitan volcano. He was led to extend his observations to the relics of older volcanic vents in the same neighbourhood, and in the following year spent some time among the Lipari Islands and in Sicily. Having now learnt a great deal both of existing and extinct volcanoes, he explored the old volcanic tracts lying to the north of Naples and west of the Appennines, and returned to England with a far larger experience of volcanic phenomena than any of his contemporaries possessed.

In this way he came to recognise how important a part has been taken by volcanic action in the past, as well as in the present, history of the earth. He was therefore naturally surprised to find views of a totally opposite kind not only in vogue, but advocated with a force and persistence which refused to consider volcanoes as anything more than modern and abnormal interferences with the settled order of nature, and as of no more real significance than subterranean coal-seams somehow set on fire. These dogmas of the Wernerian school had gained such an ascendency that many staunch adherents of that school—men like G. B. Greenough, the founder of the Geological Society—seemed to regard volcanoes with a kind of personal dislike, and violently opposed any attempt to elevate them into important geological agents. Mr. Scrope, on his return to England, spent some time at Cambridge; and finding his views supported and encouraged there, among others by Sedgwick, he determined to give himself up to the study of a district of extinct volcanoes, where the phenomena to be observed bore close relation to those of the basalts and similar rocks of Britain and Germany, and where, nevertheless, manifest relics of true volcanic cones and craters existed. He selected for this purpose the marvellously interesting tract of Auvergne in Central France, and established himself there in the summer of 1821. A campaign of six months made him thoroughly familiar with the volcanic geology of that region, and enabled him to bring home such a series of pictorial sketches and diagrams as could not, he felt, but carry conviction home to even the sturdiest Wernerian, that the basalt plateaux of Auvergne, instead of being portions of the universal precipitate of a primeval ocean, were in truth only fragments of lava-flows erupted at different times and at different levels in the gradual erosion of the valleys. He prepared a narrative of his researches, and an atlas of most admirable views and sections. But expensive geological works had not yet readily found either publishers or purchasers. He had, therefore, to keep his manuscript beside him for several years.

Meanwhile, however, the eagerness of his volcanic quest had by no means abated. Passing from his labours in France once more into Italy, his enthusiasm for volcanoes blazed out with renewed ardour in the autumn of 1822, when he had the good fortune to be an eye-witness of the great eruption of Vesuvius, which took place in the October of that year. His views of the general principles of volcanic geology had gradually broadened under the influence of the ample experience which he had now gained. He felt himself not only at liberty, but even called upon to put these views clearly before the world as a contribution to sound knowledge and a step towards the demolition of the pernicious errors still prevalent on the subject. Accordingly, after his return to this country in 1823, he prepared, and in 1825 published, a small volume, "Considerations on Volcanoes." It shared the fate of most books which are far in advance of their time; that is, it was regarded as crude, extravagant, and theoretical, and gradually suffered to pass out of mind. And yet, turning back to that early volume, and contrasting its earnest and observant pages with other writings of the same date on similar subjects, it is impossible not to admire the keen powers of observation and the happy faculty of generalisation which its author manifests. Even though some of the speculations are confessedly immature, others have stood well the test of time, and form now part of the familiar knowledge of every geologist. Above all, it must never be forgotten that in this volume, published before Lyell had written one of his works, the broad principle is laid down that the method of explaining the past geological history of the earth by reference to supposed violent and extraordinary catastrophes or general revolutions stops all true inquiry, and effectually bars the advance of science by involving it in obscurity and confusion. Mr. Scrope boldly maintained that instead of such vague guesses as to the possible causes and nature of the ancient changes of the earth, "the only legitimate path of geological inquiry" lay in "examining the laws of nature which are actually in force," and that until existing operations, with all possible variations and every conceivable allowance of time, have been proved to be wholly inadequate to explain the past, "it would be the height of absurdity to have recourse to any gratuitous and unexampled hypothesis." How truly does this passage express the philosophical stand-point of modern geology; and yet how rash and "theoretical" it must have appeared to the first readers of the "Considerations on Volcanoes." Mr. Scrope used not unnaturally to think that his earlier writings had not been without their influence in giving

tone to the "Principles" of his friend and fellow-labourer Lyell.

Two years after the "Considerations" appeared, Mr. Scrope published his great monograph on the volcanic districts of Central France—a work which placed him in a high rank as an accurate and philosophical observer, and one which did more, perhaps, than any other of its day, to destroy the Wernerian prejudice against volcanoes, and to establish the true volcanic origin of basalt rocks of every age. In another respect it marked an epoch in geological literature, inasmuch as it brought forward clear and detailed proofs of the gradual excavation of valleys by the action of the rivers still flowing in them—a doctrine taught indeed by Hutton, but for which there were still needed those very proofs which Mr. Scrope's memoir so admirably supplied.

After this early promise of an active and brilliant scientific career, Mr. Scrope's energies passed over into another and wholly different mode of life. He entered Parliament, and continued an active member for some thirty-four years. So thoroughly did he give himself up to political questions, that for fully a quarter of a century he seems to have retired from science altogether. About twenty years ago (1856), finding that the old notion of Humboldt and Von Buch about volcanic craters being merely big tumours or blisters pushed out by the expansion of the subterranean vapours, was still sufficiently in vogue to call forth an active opposition from Lyell, Mr. Scrope, who had long before exposed the untenability of this dogma, returned to his first love, and produced a paper upon "Craters and the Nature and Liquidity of Lavas." Other papers of a similar kind followed. In 1858 he brought out a second and revised edition of his memoir on the Auvergne volcanic region, and in 1862 he published a second—much altered and improved—edition of his general work on volcanoes. Since then he has communicated from time to time numerous brief letters and notices on his favourite subjects, showing how fully he retained his firm grasp of all that related to volcanic geology, and how young and fresh he could keep his powers.

This brief notice of his labours may fitly end with a tribute to that courtesy and kindliness which ever marked his relations with other men. A more leal-hearted friend could not be. How gladly would he say a kind word when a kind word would be of service! How ready, too, to help with more than words!

The founders of English geology have been truly a noble band—generous, helpful, and enthusiastic; but few of them will be more sincerely mourned than George Poulett Scrope.

A. G.

SOMERSET HOUSE AND THE PUBLIC ANALYSTS

EVER since the proposal was first made that disputed cases under the Sale of Food and Drugs Act should be referred to the analysts of the Board of Inland Revenue as adjudicators, there has been a strong feeling in the minds of most persons competent to form an opinion on the subject, that should such a course be ultimately adopted, the probable results would be great dissatisfaction on all sides. It was foreseen that the gentlemen most meritoriously engaged at Somerset House in testing the strength of alcoholic liquors, in examining the genuineness or otherwise of tobacco, tea, and excisable articles generally, and such like pursuits, would have great cause for complaint if work out of their ordinary department were thrust upon them, in the performance of which, even if no discredit should accrue to them by mistakes almost unavoidable in inexperienced hands, a considerable amount of professional odium would be probably incurred. It was clearly evident that the Public Analysts would be unjustly dealt with by the establishment of a system whereby the reports of men, frequently well known in the scientific world, and of great skill and experience in the special work requisite, would be liable to be superseded by those furnished by Government *employés* of far less professional and scientific standing, and specially qualified to a much lower extent. Finally, it was anticipated that a considerable injury to the public at large would be imminent, from the high probability that such an arrangement would lead to results not at all in harmony with the object of the Act. The checks on adulteration, it was feared, would be greatly diminished, partly through the bringing into more or less discredit the analysts appointed under the Act, and thus rendering their existence a far less effectual moral deterrent; and partly through the probable resignation of the higher class of analysts, and hence through the deprivation of the public of the special skill and experience acquired by these gentlemen.

That these dismal forebodings were not wholly groundless is shown by a recent case in the Southwark Police Court, the first, it may be mentioned, in which the Inland Revenue analysts have been appealed to under the new Act. On the 14th of last month, a large cheesemonger in the Borough appeared to answer a summons charging him with selling as butter a substance alleged to contain no butter, but to be a mixture of foreign fats not injurious to health. The proof of the purchase of the substance, and of the delivery of a sample to Dr. Muter, Public Analyst for the district, and the certificate of Dr. Muter to the above effect, were then given. The defendant demurring to the certificate, the case was adjourned in order that the third portion of the sample might be forwarded to Somerset House for examination by the Inland Revenue officers. On the 18th inst. the case came on for further hearing, and a certificate from Mr. Bell, of the Inland Revenue, was put in, stating that in his opinion the substance in question was genuine butter. This certificate was objected to by the presiding magistrate (Mr. Partridge) as being "extremely vague and unsatisfactory," inasmuch as it did not indicate that any analysis at all had been made, but only a cursory inspection. Mr. Bell thereupon gave an explanation of his certificate, stating that he had found the sample to contain water, 9·83; salt, 3·70; casein, 0·93; and fat, 85·54 per cent; that the fat yielded over 88 per cent. of fatty acids, and possessed the same specific gravity as butter fat, whence he concluded that there was no evidence of adulteration. In answer to questions, however, Mr. Bell admitted that although he had previously examined sundry specimens of genuine butter, and had seen some samples of "Bosh," he had never tested any specimen of the various artificial butters sold under the

name of "Butterine." He also stated that his method of analysis was one unknown outside the Inland Revenue laboratory, and that the only test on which he placed much reliance was the specific gravity of the fatty matter, whilst he had been unable from the few experiments he had made to corroborate the statement of Messrs. Hehner and Angell, that genuine butter fat never yields more than about 86 per cent. of fatty acids on saponification.

Although the case could not be reopened, the evidence of several Public Analysts who had examined the sample was taken, and in most respects distinctly showed that the secret method of examination adopted by Mr. Bell was utterly unreliable. Dr. Dupré, F.R.S., Mr. Wigner, and Mr. de Konigh each found that the butter-fat contained close upon 94 per cent. of fatty acids, genuine butter not yielding more than 86, and ordinary fats giving about 95 per cent. On microscopic examination a crystalline structure (evidence of fusion) was noticeable; the melting point was 4° C. lower than genuine butter; the matter mistaken by Mr. Bell for caseine was no such substance, but only fragments of woody tissue and similar vegetable organised matter; the physical structure of the substance was different from that of genuine butter, as it possessed on the tongue the peculiar granular feeling of "butterine," and also tasted like the latter. The same results were also arrived at by other analysts, six having examined the sample, and all agreeing with Dr. Muter that the substance contained either no butter at all or very little.

On the other hand, Mr. Harkness and Mr. Lewes (assistant to Mr. Bell) stated that they could see no crystals under the microscope, but admitted that woody fibre and other vegetable matter was present.

Finally, the case was dismissed, the Vestry being ordered to pay the costs of the Somerset House analysis; the magistrates, however, consented to grant a case for appeal if the Vestry desired to adopt that course.

Comment on the above would seem almost superfluous; but the question naturally arises, of what use is it in Government taking up valuable time in passing Acts, and in counties, districts, and parishes going to the expense of appointing analysts in accordance with these Acts, if the operations of these gentlemen are to be rendered nugatory by being liable to be overthrown by appeal to an authority which, however competent in reference to its own particular department, is nevertheless by its own showing scarcely possessed of sufficient experience, and is certainly not of sufficient standing and position to be admissible as a final adjudicator on such matters? The position of Public Analysts was surely bad enough without this indignity and injustice; most of the offices are grossly underpaid; the appointments are often in the hands of persons utterly incompetent to judge of the respective merits of candidates, and who not infrequently elect, not the applicant of highest scientific and professional standing, but the one who sinks his self-respect lowest by canvassing and flattering the electors. As a consequence many of the best known chemists refuse to have anything to do with such appointments, and the public loses the chance of valuable services. Further, when mistakes and blunders are made by persons who never ought to have been elected at all, there is a general cry against "the incompetence of Public Analysts," and discredit is brought on the whole class, worthy and unworthy alike. The inevitable results of insisting upon the analysts of Somerset House or any other set of men (unless specially trained and adapted for such a position) being made referees whose decisions shall override the results of careful and conscientious chemists, will be that the best and most accurate work of the Public Analysts will be wasted, that they themselves will be brought into contempt, that many of the best of them will be forced to resign their appointments, and finally, that the Act will become to a great extent a dead letter.

HARTLEY'S "AIR AND ITS RELATION TO LIFE"

Air and its Relation to Life. By Walter Noel Hartley, F.C.S., Demonstrator of Chemistry, and Lecturer on Chemistry in the Evening Class Department, King's College, London. (London: Longmans, Green, and Co., 1875.)

Of all the so-called improvements which have been effected from time to time in the means by which we make ourselves comfortable and render ourselves independent of the limitations which nature would impose upon us—perhaps the introduction of gas was hailed and has been looked upon as among the greatest. It wants but little experience, however, of the manner in which people live in towns, to convince us that the reverse of this is the case, and that the pain and misery which it has been the means of inflicting must far outweigh its advantages. If anyone doubts this let him examine his sensations in a morning, after having spent the previous evening in a close room blazing with gas, and compare them with what he feels after having spent the corresponding hours in the open air, or in a fresh room moderately lighted with oil or candles. There are but few people to whom such experience would not show that the effect of the gas was a feeling of lassitude and depression, if not a downright headache; and if they were to repeat the experiment, who would not suffer a general loss of tone. Yet wherever gas is to be procured this is precisely the misery to which people subject themselves. In nine out of ten houses in the neighbourhood of towns, if one goes from the fresh air into a room in which the people are sitting on a winter evening, the first breath is enough to suffocate one, and yet the people within the room are entirely unconscious; they may be more or less restless and depressed, but as this is their normal state they do not recognise the cause. In this way, to say nothing of what takes place in theatres and places of amusement, the evils which gas is answerable for are incalculable, though if they could be estimated they must far outweigh the blessings which accrue from the abundance and cheapness of its light.

The fact is that the money cost of the fuel forms only one part of the expense of light; there is the consumption of oxygen, and in this gas is very extravagant; so that although we now obtain tenfold the light in our rooms which we had before the introduction of gas without any increase of expense in money, we have to pay for it by a tenfold vitiation of the air. Three or four gas flames consume as much air as a moderate fire, yet who would live in a room with a fire or even a pan of charcoal without a chimney. Yet it is a common thing to go into

a room in which three, four, or five gas flames have been burning for hours without either door or window having been open; that the people who live in these rooms escape the evil effects is not to be supposed. The only thing is that they have not sense or courage enough to trace the effects to their cause. Rather than give up their warmth and light they wilfully close their eyes to what follows. When people inflict these miseries on their friends, whether consciously or not, they become a positive nuisance, and are fit subjects to be dealt with by the sanitary inspector. To have to dine with them is a punishment: a headache is sure to follow, however abstemious one may be.

Many of these people are doubtless innocent, but there are those who know the evil, yet who do not make any attempt to remove the cause. They have only to turn down the gas. But no; they clamour for what they cannot get—good ventilation with the gas—and numberless are the quack remedies which one sees applied. But whether impossible or not, it is certain that at present there is no proved means which will supply sufficient air, free from draughts, to keep a room blazing with gas decently fresh. It may be that in time, when the clamour of quacks has sufficiently subsided to allow the voice of reason to be heard, some method of constructing houses with chimneys for gas may be introduced which will allow of all the desired warmth and light, and at the same time ensure a sufficient supply of fresh air. But in the meantime, the obvious remedy is to forego some of the luxuries, to be content with moderate light and warmth, and to set off against the evils (mostly fancy), which arise from occasionally opening a window, the certain and disgusting effects of sitting in a closed room.

The effect of gas is not the only evil to be remedied by improved ventilation. Modern science has brought to light things concerning the origin of disease of which our fathers never dreamed, and which must render people dissatisfied with the state in which they live. But to do this they must be known. Ignorance, if it is not the sole cause of the evils which people inflict on themselves, is at least their excuse. As a rule people have much more faith in what is told them with authority than in that which they themselves dimly perceive, and hence it does not follow that because the evidence of their noses has been disregarded that the voice of a prophet will not be listened to. Unfortunately, the subject of practical ventilation is one which by reason of its complexity has offered little attraction to scientific men, and consequently has been much neglected. It was therefore with great pleasure that we received the work before us. Written in ordinary language, and in a very clear style, this little book contains an account of all that has been done in the way of scientific research on the relation of air to life. It is written from a scientific point of view, but no pains have been spared to trace the possible applications of the science and the practical lessons which may be learnt from it. It is just the book for those who, without any particular chemical or physical training, have undertaken the control of sanitary matters.

In the first two chapters the author gives a very interesting historical sketch of the discovery of the constituents of the atmosphere, in which the experiments which have led to the various discoveries are not only described, but illustrated by very perfect drawings, and thus the reader is conducted by easy steps to a very complete view of the subject, including the most recent discoveries. A very full account is given of the amounts (and the means of determining them) of ozone, carbonic acid, and the organic impurities in the air at different times and in different places. The degree of accuracy to which this class of research has been carried is very striking. Dr. Angus Smith has examined the air under almost all conceivable circumstances, and his methods will compare in delicacy with the sense of smell. Thus in place of our impressions, we have now definite chemical proof as to the degree of impurity in the air which produces evil effects.

Having given tables of the amounts of carbonic acid to be met with in closed places, the author proceeds:—

"Here it is easily seen that the air in the theatres is very bad; but after the doors had been open for a short time between the acts it rapidly improved; indeed, in Covent Garden, in the second case, near an open door, the people exclaimed, by force of contrast, how delightful the fresh air was; nevertheless, this *fresh air* contained 14·8 parts of carbonic acid in 10,000, or from 2½ to three times as much as it should have had. Drury Lane was the first place experimented on; and having entered at the commencement of the performance, the bad effect of the air as it became vitiated was only gradually experienced, but it produced a listlessness and headache. All the audience around were evidently affected in the same manner, and appeared to be constantly sighing and gaping, or, in other words, gasping for breath."

. . . . . .

"The bad effect of carbonic acid in the air alone, without taking into account organic matter, has been shown by Dr. Angus Smith, who ascertained that one part of the gas in 1,000 of air produced in fifteen minutes an increase in the number of respirations from eighteen to nineteen per minute, which increase remained the same up to forty-five minutes; the pulse was lowered in twenty-five minutes from seventy-three to seventy-one beats; while at forty-five minutes it was seventy-two per minute. With 2½ volumes of carbonic acid in 1,000 of air the pulse at first seventy, increased to seventy-three at the end of ten minutes, and at the end of half-an-hour was lowered to sixty-nine, while the respirations increased from seventeen to twenty-one per minute. With five volumes of carbonic acid the pulse at first seventy-six and the inspirations seventeen, at the end of forty minutes were represented by the numbers seventy-one and twenty-four."

The results of this research, therefore, fully bear out the conclusions of experience as to the evils of our present system of lighting our dwellings, and it is to be hoped that, supported by this authority, people will no longer snub their noses and disregard their evidence.

The author then goes on to discuss the laws relating to the motion of gases, and to detail what little is known as to the best means of getting the air into and out of our rooms. He calls attention to the very striking result of some experiments (Pettenkofer's) as regards the quantity of air which passes through the solid walls of a room; and he finishes the chapter by pointing out how in our badly-constructed houses we are drawing poisonous air into them from the ground on which they are built, and the drains beneath them.

The latter part of the book is devoted to setting forth the results of the researches of Dr. Angus Smith, Pasteur, and others, on the power of the air to suspend and

transport living germs, and the many important lessons with which the subject is fraught. This subject has already been so much discussed in the columns of NATURE, that is not necessary to enlarge upon its importance in this review. Suffice it to say, that a knowledge of it is essential to the comprehension of the full importance of having pure air within our houses.

In conclusion, we strongly recommend the book, which, while it contains all the information to be obtained, sets forth nothing but what is based on sound principles, advocates no hypothesis, and in no way attempts to disguise the difficulties and imperfect state of our knowledge of the subject. OSBORNE REYNOLDS

THE RECENT ORIGIN OF MAN

The Recent Origin of Man, as illustrated by Geology and the Modern Science of Prehistoric Archæology. By J. C. Southall. 8vo. Pp. 606. (Philadelphia: J. B. Lippincott and Co.; London: Trübner and Co., 1875.)

THE work published under this title is a laborious compilation of heterogeneous materials derived from history, archæology, and geology, in which the writer attempts to prove "that primeval man commenced his career six or eight thousand years ago in a civilised condition in the temperate regions of the East." In it the irresponsible dicta of anonymous journalists, and the records of local societies in America, Britain, and France, unchecked by criticism, are taken to be of equal value with those facts which have run the gauntlet of the criticism of the civilised world, and not been found wanting. A work written in this manner must necessarily be a huge pile of wheat and chaff, in which the former can only be got at by a process of careful winnowing. In this particular case we fail to discover any wheat which has not been taken out of somebody else's barn.

Mr. Southall tells us, in his preface, that he is the champion of the Bible against the speculations of "Science," and that as such he is very much hurt "that many literary and scientific men should avoid mention of the Hebrew Scriptures." "I do not recollect," he writes, "that 'The Antiquity of Man' even recognises that the Book of Genesis is in existence; and yet every one is perfectly conscious that the author has it in mind and is writing *at* at it all the time." This quotation illustrates the spirit of the book and the one-sidedness of the writer. Why should Sir Charles Lyell include Genesis among his geological evidences as to the antiquity of man, and enter into the barren discussion which has been before the world for the last half century? Mr. Southall does not recognise the fact that even if he proves scientific men to be wrong he does not add to the authenticity of the Scriptures, or that even if man be but six or eight thousand years old, that fact again is a point of small importance, except as relates to Archbishop Usher's chronology. We for our part protest against the assumption in this work that there is any real antagonism between religion and science, and we believe that its writer has contributed perhaps the most elaborately untrustworthy contribution to a dead controversy which has yet been made; for in it are involved, as in a great whirlpool, facts relevant and irrelevant—every waif and stray, in fact, that has come within its reach. And these are carried round so swiftly that it is almost impossible for the reader to see clearly whither the argument is tending. Of course Mr. Darwin and the doctrine of evolution are drawn in, which the author takes to imply "that Napoleon Buonaparte was evolved from a Corsican crab," and which we respectfully decline to discuss in this connection.

In the attempted proof of man's recent origin, Mr. Southall first of all appeals to history. The records of Phœnicia, Babylon, and Egypt go back some three thousand years, more or less, before Christ, and civilisation then was as complete and elaborate as it was at any subsequent time. He argues that there is no graduated process from the savage state in any of these cases, and "that there is not a particle of evidence that man in his earliest seats in the East was a savage." He then asks (it may be jocularly), "Did the pyramids and the Chaldæan astronomy emerge from the Danish Kjokkenmöddings abruptly and instantaneously?" It is certainly true that we have not yet discovered any proof of the gradual development of the arts and of civilisation in those comparatively inaccessible regions, not necessarily because they do not exist, but because the exploration has been imperfect. In them there may be, and probably are, treasures to be revealed by the pickaxe and spade quite as rich as those of Hisarlik, and showing as complete a sequence. The statement that no traces of a rude and imperfect civilisation have been met with in the East is refuted by the discovery of enormous quantities of flint implements in Egypt and of Neolithic axes in Asia Minor and in India. In the river gravels of both these regions Palæolithic *hâches* have been found of the same type as those of Amiens and Abbeville. In the face of testimony of this kind he assumes that there are no traces of savagery, and accounts for the ancient civilisations by the supposition that they were inherited from the antediluvian world through Noah and his sons, and that the long-lived patriarchs were, by virtue of their experience, "very remarkable men." We would hand over this argument as it stands to Mr. Galton, for use in his next edition.

Having fixed the age of the most ancient peoples known, including the Chinese, by an appeal to history, the author assumes that the ancient inhabitants of Western Europe, whom he admits to have been savages, were descended from the same stock as the Babylonians, Egyptians, and Chinese, and that the date of the former is identical with that of the latter—a statement which is equivalent to the saying that children of the same father are always of the same age. Before we leave this part of the work behind, we would remark that Mr. Southall gravely tells us, that Central America had been visited by the Chinese, Japanese, Irish, and Welsh before the voyage of Columbus, as if these were well-authenticated facts. He evidently believes in the Irish legends, and in the story of Prince Madoc.

If, however, history fares badly at the hands of Mr. Southall, archæology fares worse. He devotes one chapter to the "premature announcements of Science with regard to the antiquity of man," in which such statements as the existence of a race of pigmies in Tennessee, proved from the small graves, the presence of man in the Pleiocene age, based on the perforated sharks' teeth in the crag of Norfolk, the asserted discovery of a fossil man in

palæozoic schist in Quebec, are included among the beliefs which have been accepted and then given up by scientific men. Having thus discredited their judgment, he proceeds to contradict himself as to the conclusions of Evans, Lubbock, and Lyell with regard to the division of time past, before the dawn of history, into the stages of rude stone, polished stone, bronze, and iron. A large portion of the book, the entire argument, so far as we can make it out, is devoted to proving that these stages were simultaneous, and not older than the six or eight thousand years of history and tradition. In p. 400 he allows that they are consecutive almost as distinctly as Mr. Evans.

In proving that "the ages" are simultaneous he adopts the same kind of reasoning as that by which Mr. Fergusson arrives at the post-Roman age of the Megalithic monuments, and Mr. Wright concludes that the Britons during the time of the Roman invasion used bronze swords. It is a very simple process. You find a certain set of things in a cave, in a cairn, or a tumulus, or in diggings near a Roman station, and you at once conclude that they were used at the same time by the same people. In every one of the cases cited there is no proof that the deposit in which the articles occur has not been disturbed. Before any association of the kind quoted is of the least value we must be certain that there has been no subsequent disturbance; such proof, for example, as we get in some of the pile-dwellings of Switzerland; such proof as we do not get at Solutré, where a Merovingian cemetery happened to be planted on an old "station" of the Palæolithic age, as the writer of this review was informed by Dr. Broca at the French Association at Lyons in 1873. In this case, which is made the basis of the attack on the high antiquity of Palæolithic man, the human skulls are comparatively modern, and the refuse heap of an untold age.

We have followed Mr. Southall into a labyrinth, and we have been unable to find a single shred of proof of the recent origin of man. We lay down his book with regret that he should have expended so much labour, with the practical result of leading the unwary reader into errors as to facts—for example, that Busk stated the Cave-bear to be identical with the Grizzly, or that Brandt believes that the Irish Elk lived in Central Europe down to the fourteenth century, two cases which occur to us. We trust that few Americans will take the views ascribed to the leading archæologists of Europe, in this handsome and well-printed book, without verification by an appeal to their writings. W. B. D.

OUR BOOK SHELF

The Indian Alps, and how we crossed them; being a Narrative of Two Years' Residence in the Eastern Himalayas and Two Months' Tour into the Interior. By a Lady Pioneer. Illustrated by herself. (London: Longmans and Co., 1876.)

THE plucky authoress of this handsome work makes no pretensions to give any scientific account of that portion of the Himalayas into which she penetrated; this, however, is the less to be regretted as, from a scientific point of view, much of the ground over which she passed has been rendered classic by Dr. Hooker. Her starting-point was Darjeeling, and the first portion of the work describes a pleasant preliminary trip which she and her husband made to the east as far as Dumsong. On returning from this outing, she, her husband F., and a friend C., accompanied by a small army of attendants, set out to penetrate, and if possible cross, the Eastern Himalayas. Their route was westwards by Mount Tongloo, and then almost directly northwards by Mount Singaleelah, the Dumgongla Pass, and onwards as far as the base of Mount Junnoo. The party took a large quantity of provisions with them, but depended upon a chief in the interior to supplement this supply about half-way. The chief failed them, and a guide whom they picked up on their route, after leading them all astray into a most inhospitable region, decamped, leaving them in a most perilous position. Happily, after much murmuring and danger of mutiny on the part of their attendants, they managed to extricate themselves without any loss or serious damage to anyone. Returning by the same route as far as Mount Singaleelah, the venturesome tourists turned eastwards and then southwards, along the Great Rungeet River, and so back again to Darjeeling, after a journey which, notwithstanding a few hardships, all seem to have enjoyed immensely. Although there is no formal attempt to describe either the fauna, flora, or geology of the region passed through, the authoress's descriptions are so minute, and her references to the characteristic animal and plant life of the various stages so frequent, that the reader will have a fair notion of the general features of the line of march. The Lady Pioneer's artistic attainments are of a high order, and her sympathy with nature from this point of view intense; her descriptions are, moreover, so clear and intelligible, and the illustrations are so numerous and well executed, that the book from beginning to end is a delight. A marked feature of the work is the chromolithographs, creditable alike to the artist and printer, affording better than any verbal description an idea of the character of the unequalled Himalayan scenery. The invariable sweetness of the author's style, and we may say of her temper under all circumstances, and her strong sense of humour, add to the charm of her narrative. The reader may learn a great deal from her book about the country passed through and about the various classes and tribes of people she met and mixed freely with, for she is a shrewd observer of men and manners. One cannot help thinking, we may venture to say, that F., whom she dutifully brings to the front on almost every page, is a lucky fellow. As might be expected, there is a good deal of moralising under the awful influences of the "Abode of Snow;" perhaps too much of it, though this natural failing will be overlooked, considering the genuine attractions which the work possesses.

Quite recently we reviewed Mr. Wilson's delightful work the "Abode of Snow," describing a journey which he made through the Western Himalayas; that, along with the present work, is very suggestive of the development of English ideas at least with regard to that class of scenery to which the term "grand" is usually applied.

It is well known that the tourist fever is of quite modern origin. It is only within the present century that an appreciation of wild and mountainous scenery has become anything like general. It would be difficult to find much in the way of admiration for such scenery in any poet who wrote before Wordsworth and Scott; an intelligent and well-educated officer of Engineers who lived in the midst of some of the now most admired Highland scenery in the early part of last century, wrote of it with something like horror; he could see "no beauty in it that it should be desired." While in this country the two poets above mentioned have no doubt had a principal share in originating the modern taste, there are other causes, connected with the general advance in intelligence and elevation of taste, which it would be instructive to trace. We are inclined to believe that the very modern science of geology has something to do with it; and certainly he who has a fair knowledge of the facts and principles of that science, not to mention the other natural

sciences, will be able to read infinitely grander legends in wild and mountainous scenery than he who looks upon it alone through the glamour thrown over it by mythology or genius. At all events, we welcome the spreading love of travel as one of many signs of a great intellectual awakening, although doubtless at present it has a good deal about it which lays it open to the sneer of the cynic, as have all new movements. There is a considerable, and we think ill-natured outcry in certain quarters, that all the accessible tourist grounds will become more and more crowded by the followers of the beneficent Cook. But there will always be some spot to which he who does not wish to be counted one of the common herd of tourists can retreat until he has gained vigour and nerve enough to feel in a mood to mix again with "the kindly race of men." Such a retreat is, and will for long be afforded by the "Abode of Snow" which Mr. Wilson and this Lady Pioneer have so attractively described; by and by, no doubt, it will be made more accessible by roads either from our own or from the other (is it premature to say the Russian?) side.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The Article "Birds" in "Encyclopædia Britannica"

MR. GARROD's article on the new edition of the "Encyclopædia Britannica" in last week's NATURE contains the following passage:—

"As another example of the different teaching of the artificial and the natural classifications, the Swifts (*Cypselidæ*) and the Humming Birds (*Trochilidæ*) may be referred to. These two groups, from the details of their internal structure when examined one by one, are most certainly related as intimately as are the Woodpeckers with the Toucans. There is, in fact, not a family difference between them, and yet, from their palates, Professors Huxley and Parker place them in quite different divisions, because the vomer is truncated in the one and pointed in the other."

In a previous part of the article Mr. Garrod refers to my paper on the Classification of Birds, published in the Proceedings of the Zoological Society in 1867, which he criticises as if he had studied it with a care proportioned to the labour it cost. Nevertheless, I can but think that his acquaintance with its contents must be somewhat superficial, inasmuch as any careful reader will find at p. 459, the following passage under the head of *Cypselomorphæ*, or Swift-like birds:—

"This group contains three very distinct families—the *Trochilidæ*, the *Cypselidæ*, and the *Caprimulgidæ*. The first two families have a length of the manus and a brevity of the humerus which is peculiar to themselves."

Thus, so far from placing the Swifts and the Humming Birds in "quite different divisions," I placed them in the same division, and took pains to point out their close affinity; and in asserting the intimate relations of the *Cypselidæ* and *Trochilidæ*, Mr. Garrod is reiterating a view which, unless I mistake, was first definitely put forward by myself, and not, as the readers of his article would be led to imagine, controverting my opinions.

Mr. Garrod takes pains to show that "the structure of the skull does not alone suffice to determine the mutual affinities of birds." The implication appears to be that Mr. Parker and I assert the contrary. I have no right to speak for Mr. Parker, but I may remark that my knowledge of his works would not have led me to Mr. Garrod's conclusion, while it would have compelled me to treat any opinion of his, however much I might be disposed to differ from it, in a manner different from that adopted by Mr. Garrod. As to the facts, so far as I am concerned, those who will take the trouble to read my paper on the Classification of Birds, and an article by the editor of the *Ibis*, with a letter addressed to him by me, published in the *Ibis* for 1868, will see that the classification in question is not based upon cranial structure alone, and that, seven years ago, we went a little deeper into the question of the principles to be followed in taxonomy than the point at present attained by Mr. Garrod.

Jan. 23 T. H. HUXLEY

D-Line Spectra

IN reply to a question propounded to you by a correspondent (vol. xiii. p. 224) as to my reasons for believing that sodium is free in the flame of a spirit-lamp with salted wick, I have to state as follows:—

1. We now know that the flame exercises a specific absorption, and is capable of producing dark D. If this were due to vapour of chloride of sodium, we should expect, in accordance with what observation shows in other cases, that solution of chloride of sodium, or at least the solid chloride, would more or less absorb the orange or yellow part of the spectrum, though not in the same definite way, and we find it does not.

2. We know, by direct experiment, that vapour of sodium does exert the very peculiar absorption indicated by dark D. Different salts of the same metallic oxide agree in the mode in which their solutions absorb light, or at least there is a strong family likeness; but when we pass from one oxide to another of the same metal, there is a complete change. Much more should we expect a complete change when there is such a profound difference of chemical character as there is between sodium itself and chloride of sodium.

3. Lastly, Mr. A. Mitcherlich has proved, by direct experiment, that vapour of chloride of sodium within a tube heated to bright redness neither emits bright D nor produces dark D by absorption (*Poggendorff's Annalen*, vol. 116, pp. 504, 505).

It need not surprise us that sodium should be temporarily free in an ordinary flame, since the metal is prepared by heating carbonate of soda with charcoal, and in the flame we have hydrocarbons at a high temperature. Perhaps the heat alone would suffice to set it free by dissociation. G. G. STOKES

Cambridge

The True Nature of Lichens

THE editorial note on this subject in NATURE, vol. xiii. p. 168, was thoroughly disappointing to those who, like myself, may have had hopes that the confident allusion by the reviewer of Haeckel to the "clearing up" of the "true nature of Lichens" had reference to some demonstration—of which we had not heard—of the part played by *Spermogonia* and *Pycnidia* in *Lichen-Reproduction*. Having long had in contemplation the publication of a volume of "Outlines of Lichenology," it has been my business for years to note carefully all publications of any importance on the Natural History of Lichens. Those of Prof. Schwendener of Bâle and his disciples could scarcely have escaped me; so that I find the papers mentioned in the editorial note aforesaid, as well as others, duly recorded, with abstracts and relative criticisms, in my Lichenological memorandum book.

My opinion of the speculations of Schwendener and his followers has all along been, and still is, that so far from "clearing up" the "true nature of Lichens," they introduce elements of very decided confusion; and that they are to be regarded merely as illustrations of German transcendentalism, comparable to the fanciful notions of his countryman Bayrhoffer, in 1851, concerning Lichen-Reproduction.* The dogmatic assertions of anonymous critics concerning the "clearing up" of the "true nature of Lichens," by mere Speculations notwithstanding—I hold what I have always held—that the Lichens as an Order are quite as natural, important, and distinct as any other Order of the Cryptogamia. And in so saying I do not forget the fact that they overlap both the *Algæ* and the *Fungi*. On the contrary, I have over and over again pointed out, in my own publications on the Natural History of Lichens, the affinities, or points of affinity, between Lichens, and Algæ on the one hand, Fungi on the other. In order that sight might not be lost of organisms of doubtful character, possessing elements of structure usually regarded as both algoid and lichenoid, or fungoid and lichenoid, or either the one or the other, I long since proposed the establishment of *intermediate and provisional groups of Algo-lichenes and Fungo-lichenes*. Such groups would have the advantage of attracting attention to those *passage-forms*, which appear to me to be of the highest interest to the philosophical botanist.

I have not myself had an opportunity of perusing Haeckel's

* "Einiges über Lichenen und deren Befruchtung," von J. D. W. Bayrhoffer, Bern, 1851; an illustrated 4to.

"History of Creation." But, according to a recent reviewer* of the said work, this is what he says of the "true nature of Lichens":—"Every Lichen is really composed of *two distinct plants*: of a low form of *Fungus* (Ascomycetes), which lives as a *parasite* upon the former (?), and upon the nutritive substance prepared by it. The green cells, containing chlorophyll (Gonidia), which are found in every Lichen (?), belong to the *alga*. But the colourless threads (Hyphæ), which, densely interwoven, form the principal mass of the body of the Lichens, belong to the *parasitic fungus*." (Vol. ii. p. 95.) Now, says the reviewer in question, "This doctrine, so dogmatically put forth . . . . is adopted but by a few outside of the extremely Hypothetical school of German botanists; and by the best Cryptogamists of this country and of the Continent is considered a pure Delusion:" a verdict much nearer the truth, it must be confessed, than the assertion that Prof. Schwendener has "cleared up" the "true nature of Lichens." Among "the best cryptogamists of this country" who have expressed themselves as unconvinced by, or opposed to, the dogmata of Schwendener and his admirers, regarding the "true nature of Lichens," are Berkeley, Thwaites, and Cooke—than whom we have certainly no botanists better qualified or entitled to form or to offer opinions on such a subject. The views of Berkeley and Thwaites are referred to in NATURE (vol. x. p. 541) as having been expounded before the Royal Horticultural Society; while those of Cooke are set forth vigorously in his recent "International Scientific Series" volume on "Fungi." See also what the sagacious President of the Linnæan Society (Bentham) says on this subject—*ex cathedrâ*, and therefore summing up judicially—in his anniversary address for 1873 (Proceedings of the Society for May 1873, p. 28):—"There is one part of Sachs' book † (says he) which is an illustration of a very common readiness to take at once as proved any *paradox* or theory opposed to general belief, when a new discovery appears to afford some plausible argument in its favour. In the article *Lichens* . . . he adopts, as an established fact, Schwendener's view that Lichens are Fungi parasitical upon Algæ . . . a series of conclusions founded on a very small number of facts . . . They require much observation and study before the conclusions derived from them can be taught as an established Theory. And whatever be the result, the Group of Lichens is so distinct in its vegetative characters, and at the same time so extensive and varied a one, that it seems more methodical to treat it, as heretofore, as a *distinct class*,‡ than to absorb it in that of Fungi, notwithstanding the close affinity shown by its reproductive organs."

But other German botanists themselves, not inferior in status or experience to Prof. Schwendener, regard, as Bentham does, the Hypothesis that Lichens are the product of a union of Parasitic Ascomycetes with Algæ as far from being proved. For instance, Prof. De Bary, of Halle, and Dr. Stizenberger, of Constance, point this out in the *Botanische Zeitung* for 1870 (pp. 42 and 53). If, by artificial cultivation, such a Union could be made to produce a Lichen, the Theory might be held as proven. But this has not yet been effected, and I venture to think and say it never will be.

There are several difficulties in the natural history of Lichens with which the Schwendenerians have to deal, and which they have not yet, so far as I know, explained away. For instance, the case of Athalline Lichens that have neither Hyphæ nor Gonidia—neither fungoid nor algoid elements—assuming Hyphæ to be necessarily fungoid and Gonidia to be algoid; Lichens that are represented only by Apothecia, which are avowedly lichenoid: though they too may be claimed for the Algæ, inasmuch as Archer has a recent paper "On Apothecia occurring in some Scytonematous and Sorisophonaceous Algæ in addition to those previously known." §

In short, the mantle of Bayrhoffer appears to have fallen on Schwendener; and his Parasitic Theory is merely the most recent instance of German transcendentalism applied to the Lichens!

W. LAUDER LINDSAY

OUR ASTRONOMICAL COLUMN

THE BINARY STAR γ CORONÆ AUSTRALIS.—Professor Schiaparelli has measured this star during the past year with the 8-inch Merz-equatorial of the Observatory of Brera, Milan, where its meridian altitude is less than 8°; an interval of twelve years had elapsed since the last published measures by Powell. The first micrometrical measures were made in 1834 by Sir John Herschel, and from 1847 to 1858 Jacob had given much attention to observations of this star. From the forty-two years' observations thus available, Professor Schiaparelli has calculated an orbit which agrees unusually well with observation, and may be written as follows:—

Peri-astron passage, 1882·774; node, 49° 9′; node to peri-astron on orbit reckoned in the direction of motion, 255° 24′; inclination, 68° 38′; excentricity, 0·6989: semi-axis major, 2″·40; period of revolution, 55·582 years; mean annual motion, −6°·477.

At the calculated peri-astron passage in the autumn of 1882, the distance of the components which was 1″·45 last summer will have diminished, according to the above orbit, to 0″·3. Professor Schiaparelli states that observations are already difficult in his latitude, and will soon become impracticable; the star must therefore be left to the southern observatories, whence measures may be looked for during the interesting period in its revolution now at hand.

It will be seen that γ Coronæ Australis has the shortest revolution of any southern binary, and is fourth on our list in respect of rapid motion.

THE SOLAR ECLIPSE OF 1876, MARCH 25.—It is quite possible that this eclipse, which is given as an annular one in the Ephemerides, may be total for an instant on the North Pacific Ocean in longitude 140° 16′ west of Greenwich, and latitude 35° 39′ north, or near this position it may prove one of those rare phenomena, characterised in our text-books as "total without continuance." The central line traverses the southern and largest island of the Sandwich group, where the eclipse will be annular for a few seconds. At a point in longitude 155° 56′ W., latitude 19° 28′ N., the eclipse commences at 9h. 30m. A.M. local mean time, at 130° from the sun's north point towards the west (direct), and the annulus is formed according to the *Nautical Almanac* elements at 10h. 49m. 10s., and continues ten seconds. This point is a little south of Kaavaroa, by the Admiralty Chart, and close to the spot where the monument to Capt. Cook was erected; the central eclipse leaves this island, Hawaii, near Manienie, also marked on the Admiralty Chart of this group. The eclipse will be central and annular also in Vancouver Island and British Columbia. The central line appears to enter Vancouver at Refuge Cove, Sydney Inlet, leaving it at Orange Point, Duncan Bay, whence its course is to George Point, British Columbia. In Vancouver Island the annulus may continue seven or eight seconds, being formed about 0h. 27m. P.M. local mean time. At New Westminster, British Columbia, calculation gives a large partial eclipse commencing at 11h. 22m. A.M., and ending at 2h. 3m. P.M. local times, magnitude 0·95; here the first impression of the moon upon the sun's disc is made at 127° from his north point towards the west. For further information on the track of the central line over these parts the large Admiralty Chart of Vancouver Island and vicinity should be consulted; the above names of points traversed by the central eclipse are taken from it.

On the central line this eclipse must prove one of very considerable and unusual interest.

BESSEL'S TREATISES.—The first volume of the collective edition of the more important astronomical and other memoirs by the illustrious Königsberg astronomer has been issued under the editorship of Dr. Rudolf Engelmann, of Leipsic. It is a handsomely printed volume in quarto, of nearly 400 pages, and doubtless will find its way into the library of every earnest student of the science.

Amongst the contents of this first volume may be mentioned Bessel's early work, undertaken at the instigation of Olbers, the reduction of Harriot's and Torporley's

* In the *Scotsman* (Edinburgh) for December 3, 1875.

† "Lehrbuch der Botanik," of which a well-known English translation has now been published.

observations of the comet of Halley at its appearance in 1607; his "Development of a general method for calculating the perturbations of comets" from his classical work on the great comet of 1807, published at Königsberg in 1810, and somewhat difficult to meet with now, in its original form; the well-known memoir on the physical condition of Halley's comet with the plates, taken from Vol. 13 of the *Astronomische Nachrichten;* the memoir presented to the Berlin Academy in 1824, entitled "Untersuchung der Theils der planetarischen Störungen, welcher aus der Bewegung der Sonne entsteht;" researches on the Saturnian system, the position of the plane of the rings and their dimensions, the figure and dimensions of the planet, the motions of the Huyghenian satellite and determination of the mass of Saturn therefrom, and the memoir on the theory of this system from Vol. 28 of the *Astronomische Nachrichten;* the Prize Essay "Untersuchung der Grösse und der Einflusses des Vörrucken der Nachtgleichen," to which was attached the motto, "Non frustra signorum obitus speculamur et ortus;" various papers on precession, aberration, &c., which appeared in the *Tabulæ Regiomentanæ,* and elsewhere, and the essay on the "Scheinbare figur eines unvollstandig erleuchteten Planeten scheibe."

The portrait of Bessel after Mandel is prefixed, with reminiscences of. his early life, from the correspondence with Olbers, and additional notes by the editor.

The work is entitled "Abhandlungen von Friedrich Wilhelm Bessel herausgegeben von Rudolf Engelmann, —Erster Band, Leipzig, 1875."

THE FLOWERING OF SPRING PLANTS *

DURING the past twenty years the Scottish Meteorological Society has been collecting data relative to the budding, leafing, flowering, and defoliation of trees and plants, and to the migrations of birds in connection with the periodical return of the seasons, and it was proposed some time ago to discuss the material which has been accumulated. As preliminary, however, to this very difficult line of inquiry, it was resolved to discuss in the first place the observations which have been made by Mr. McNab on the flowering of spring plants in the open air in the Edinburgh Royal Botanic Garden during the past twenty-six years, and which have been published in the Transactions of the Botanical Society of Edinburgh. These observations have been made by the same observer on the same plants, growing in the same situations, during the whole of the twenty-six years.

The average day of flowering of thirty-two spring flowers has been determined, of which the following are examples:—*Galanthus nivalis,* Jan. 25; *Eranthis hyemalis,* Jan. 30; *Hepatica triloba,* Jan. 31; *Corylus Avellava,* Feb. 2; *Rhododendron atrovirens,* Feb. 3; *Crocus susianus,* Feb. 4; *Leucojum vernum,* Feb. 10; *Daphne Mezereum,* Feb. 22; *Narcissus pumilus,* March 10; *Orobus vernus,* March 11; *Muscari botryoides,* March 18; *Ribes sanguineum,* March 22; *Narcissus pseudo-Narcissus,* March 31; and *Fritillaria imperialis,* April 1.

The lateness or earliness of the different springs, as determined from the times of flowering of the thirty-two plants in each year, is considerable. The latest spring was 1855, which was thirty days later than the average, and the earliest 1874, which was twenty-three days earlier, thus giving a difference of fifty-three days between the latest and earliest springs during the past twenty-six years. As regards particular flowers, the deviations are much greater. The largest deviations from the average dates of flowering occur before the time of the equinox, when deviations of from five to seven weeks either way are of repeated occurrence; but after the equinox the deviations are markedly less, seldom reaching three weeks.

The springs of 1855, 1856, 1857, 1865, and 1870 were late throughout; and on the other hand, the springs of 1851, 1862, 1863, 1868, 1869, 1872, and 1874 were early throughout. Great variations have occurred in other springs, such as 1864, which, being preceded by a very mild December, many spring plants came into flower in the end of 1863. But in January the temperature was $2^\circ{\cdot}0$ under the average, and in February, $5^\circ{\cdot}2$, and vegetation was consequently arrested. March was also under the average, and the weather did not improve till April 3, the mean temperature of this month being $1^\circ{\cdot}7$ above the average. The disturbing influence of this abnormal weather on the dates of flowering was in some cases very great. Thus, *Sisyrinchium grandiflorum* flowers on the average eleven days earlier than *Daphne Mezereum,* but in 1864 *Daphne Mezereum* did not come into flower till eighty-six days after *Sisyrinchium grandiflorum* had flowered. It is the occurrence of these disturbances which renders a long series of years necessary in order to arrive at a sufficiently close approximation to the true mean dates of flowering.

As regards Edinburgh, Jan. 11 may be considered as the turning point in the winter temperature, since previous to this date the temperature is, on the whole, falling, and after this date it continues steadily to rise.* Further, after this date the rainfall becomes less, clear weather is of more frequent occurrence, and the increase in the temperature is very largely due to an increase of sunshine. The extremely slow rate at which, up to the end of February, the mean temperature rises, and the small differences among the temperatures up to this date, and the large number of plants—fourteen in all out of thirty-two—which come successively into flower during the interval, suggest that it is not so much absolute temperature that calls for consideration as the accumulated amounts of the preceding daily temperatures, *in the extent to which these rise above freezing.* The accumulated temperatures, thus calculated, are, for *Galanthus nivalis,* $72^\circ{\cdot}7$, and *G. plicatus,* $146^\circ{\cdot}4$; for *Crocus susianus,* $125^\circ{\cdot}2$, and *C. vernus,* $179^\circ{\cdot}1$; for *Rhododendron atrovirens,* $120^\circ{\cdot}3$, and *R. Nobleanum,* $249^\circ{\cdot}3$; and for *Narcissus pumilus,* $347^\circ{\cdot}0$, and *N. pseudo-Narcissus,* $540^\circ{\cdot}1$. Similar data prepared for other places, in this and other countries, would be very instructive in showing how far the order of dates of flowering in Edinburgh is observed in other places, and what is the relation of the dates of flowering at each place to the accumulated temperatures at that place, and what modifications are brought about by purely climatic differences, particularly as these occasion different results as respects the heating and actinic rays of the sun.

The thirty-two plants, whose dates of flowering have been determined, include three-varieties of one species, viz., the *blue, white,* and *red* varieties of *Scilla bifolia.* Of these three varieties the *blue* flowers first, viz., on March 7; next comes the *white* variety, on March 17; and lastly, the *red* variety, on March 21, the *red* being thus a fortnight later than the *blue* variety.

An interesting question may in this connection be raised with reference to the relation which the colours of flowers have to the dates of flowering. With this view, our British wild plants have been grouped according to the different colours of their flowers and the months in which the flowers usually first expand, the data being taken from Dr. Hooker's "Students' Flora of the British Islands." In classifying the plants, *red* includes pink, crimson, and scarlet; and *green,* all greenish-white, yellowish-green, and greenish-purple flowers. *Grasses, carices,* and other groups, characterised by inconspicuous floral envelopes, are excluded. The list examined includes 909 species, of which there are 257 with

* Abstract of a paper read before the Edinburgh Botanical Society on the 13th inst. The paper itself is in type for the Journal of the Scottish Meteorological Society.

* See Prof. Forbes's paper on the climate of Edinburgh, in Trans. Roy. Soc., Edin., vol. xxii. pp. 348-349.

white flowers, 238 with yellow flowers, these two being nearly a half of the whole number; then follow red, 144; purple, 94; blue, 87; green, 51; and miscellaneous, 38. Taking each colour by itself, and calculating the percentages of that colour which has come into flower by each month from April to July, we obtain the following results for the first five classes:—

	April.	May.	June.	July.
Blue	16	43	71	93
White	14	36	70	97
Purple	4	28	61	92
Yellow	9	24	61	93
Red	9	25	62	94

Thus of these colours, the *blues* are, on the average, considerably the earliest in flowering; then follow in order the *whites* and the *purples*, and lastly the *yellows* and *reds*. It follows that the plants included in the British flora clearly tend to arrange themselves, as regards the dates of flowering, in the order of the colours of the spectrum, the average earliest being those which are nearest the part of the spectrum where the actinic rays are at the maximum. It will be observed that the differently-coloured varieties of *Scilla bifolia* are in the same order of flowering of the plants of the same colours in the British flora. Accurate observations, continued from year to year, of the exact dates of flowering of different plants, and particularly of differently-coloured varieties of the same species, could not fail to contribute valuable data to the inquiry referring to the influence of the solar rays, in the development of the more important of the vital functions of plants in different seasons. Whilst it is quite true, as has been pointed out by Mr. R. A. Pryor in NATURE (vol. xiii. p. 150), that flowers of all colours bloom in any of the spring or summer months, it is plain that it is only the method of inquiry by averages that can guide us in the search for the law or laws which regulate the seasonal distribution of colour among flowers. It is scarcely necessary to refer to the importance of this question in its possible applications in the rearing of early and late varieties of flowers and fruits.

ALEXANDER BUCHAN

THE WORK OF THE "CHALLENGER" AND THE "VALOROUS"

THE Admiralty have just issued Reports on the Soundings and Temperatures taken by the *Challenger* in the Pacific, and by the *Valorous* during her voyage out with the Arctic Expedition and home again.

Captain Thomson's Report is dated from Honolulu, August 8, 1875, and refers to operations in the Inland Sea and to the section from Yokohama to Honolulu. After some days' cruising in the Inland Sea in May, Captain Thomson returned to Yokohama, nothing of interest to the scientific branch having been obtained. The deepest water found in the longitudinal section during the voyage to Honolulu was 3,980 fathoms, whilst that from the turning-point at 156° west longitude down to Honolulu was 3,025 fathoms. The bottom of this section of the North Pacific showed on nearly every occasion red clay, with manganese and pumice-stone in great quantities; the latter greatly increased as the approach to the Sandwich Islands was made.

Staff-Commander Tizzard makes his preliminary Report on the Temperatures of the North Pacific. From Samboangan nineteen soundings and serial temperatures were obtained in the western part of the North Pacific, from which two sections have been constructed, one from the Meangis Islands to the Admiralty Islands, and the other from the latter to Japan. It was found that when the depth exceeded 1,500 fathoms, the thermometer which regulated the bottom temperatures gave the same results as they did at 1,400 fathoms, viz. 34°·4 (corrected). At a little to the southward of Tongatabu, the bottom temperature was 32°·9, and as the U.S. officers appear to have obtained colder temperatures at the bottom than any yet obtained by the *Challenger* in the North Pacific, Commander Tizzard thinks it probable that the bed of the Pacific is divided into at least three deep basins by ridges of a not greater depth than 1,400 fathoms from the surface. In the southern part of the western portion of the North Pacific the surface-temperature varied from 80° to 84°, and that in February and March, considerably higher than any yet registered by the *Challenger* in the open ocean.

The Report contains a table of the soundings in the above sections, and four beautifully-constructed sectional charts. The two first show the soundings and isothermal lines from the Meangis to the Admiralty Islands, and between the latter and Japan. The third is intended to illustrate Staff-Commander Tizzard's remarks on the surface temperature of the section referred to above; and the fourth shows the soundings and isothermal lines between Nosema Head, Japan, and the 180th meridian. One of the most notable features of these charts is the occasional sudden increase in depth; between Japan and the Admiralty Islands, for example, the bottom sinks at one place all at once from about 2,000 fathoms, on both sides, to a depth of 4,500 fathoms.

The *Valorous* on her outward voyage took nineteen soundings in Davis' Straits between 63° 45′ and 68° 57′ N. lat., the depth being found to vary from 58 to 200 fathoms. The bottom was mostly fine grey sand, mixed with shells, gravel, and stones. On returning south, lower soundings were obtained along the Greenland coast, with much the same results as to bottom. On getting clear of Cape Farewell the course was shaped to cross the Atlantic Ocean between the parallels of 59° and 55°, and to join the soundings westward of Ireland obtained in the *Porcupine* in 1862. The greatest depth obtained was 1,860 fathoms in lat. 57° 50′ N., and 44° 52′ W. long., with a bottom of Globigerina ooze, and a bottom temperature of 33°·4. In 56° 11′ N. lat. and 37° 41′ W. long. a depth of 1,450 fathoms was obtained, the bottom Globigerina ooze, and next day in lat. 56° 1′ N., long. 34° 42′ W., a submarine ridge of 690 fathoms was sounded on with the same description of bottom. On the day following this, in lat. 55° 58′, long. 31° 41′ W., the depth increased to 1,230 fathoms, mud; the deep sounding of this day and that of the second day previous being equidistant (103 miles) from the intervening shoaler ridge of 690 fathoms. On reaching the 26th meridian of W. long., a westerly gale commenced, which prevented further proceedings. Globigerina ooze, with occasional fine sand and mud, are the main characteristics of this section. Two sectional charts exhibit graphically the data obtained.

SCIENCE IN GERMANY

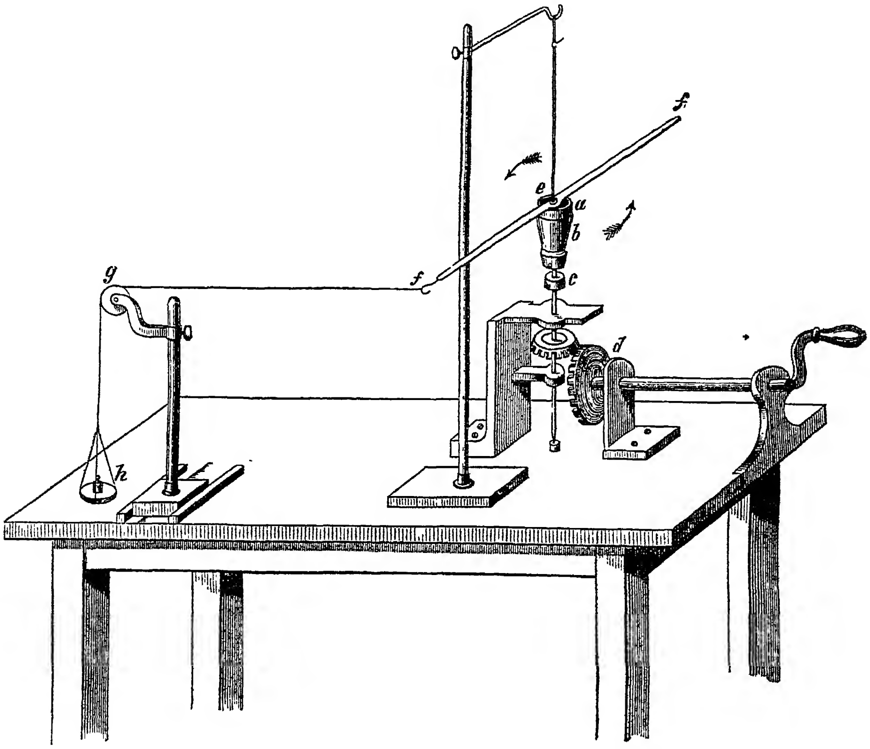
(*From a German Correspondent.*)

M. PULUJ, of Fiume, has recently published a description of a school-apparatus for determining the mechanical equivalent of heat. The apparatus is of very simple construction, and consists of a calorimetrical and a dynamometrical part, which is connected with a rotating arrangement, such as may be found in any physical laboratory.

The calorimetrical part of the apparatus is formed of two truncated hollow cones of cast iron, fitting the one into the other. The inner one, *a*, does not quite reach to the bottom of the outer, *b*, and it projects a little above it. The outer cone, *b*, can be fixed, coaxially, into the spool of the driving machine. The inner cone contains mercury. If, now, the driving machine be set a-going and the inner cone held fast, heat is produced through friction of the touching surfaces of the cones.

For measurement of the work transformed into heat, the arrangement is as follows:—To the wooden lid, *e*, of

the inner cone, is screwed a light wooden beam, *f*, horizontally. Through the beam and lid passes a perforation for receiving the thermometer. At a little distance from the beam, *f*, and at the same height, there is a fixed pulley, *g*, over which is passed a cord with a scale at its pendant extremity, while the other end is attached to the end of one arm of the beam (the second arm of the beam acts as counter weight). When the driving machine is put in action, the cones rub together, and the outer cone tends to carry the inner one and its beam round with it in the direction of rotation. With a certain weight in the scale, the horizontal part of the cord will form with the axis of the beam a right angle. From the length of the beam-arm, the amount of weighting, and the number of rotations, may be deduced the work that is transformed into heat; and from the water value of the calorimeter,



and the increase of its temperature, can be reckoned the quantity of heat produced.

From twenty-eight experiments (in which the amount of heat radiated from the calorimeter was taken into account), the average value obtained for the mechanical equivalent of heat was 425·2, with a mean error ± 5·4. A second series of experiments was made, with the arm of the beam in any position with reference to the cord. A simple arrangement—wooden triangle with arc-division—served for measuring the angle which the axis of the beam-arm formed with its normal position (in which it forms a right angle with the cord). From the observed values of this angle, and from the quantities already referred to, the number obtained for the mechanical equivalent of heat was 426·7, with a mean error ± 5·9.

The apparatus is especially to be recommended for lecture-experiments, because the method of experimenting is extremely simple, and the carrying out of the experiment takes very little time. A single experiment occupies 30–60″.

S. W.

THE PHYSICAL OBSERVATORY ON THE PIC DU MIDI

AT a recent sitting of the Paris Academy of Sciences M. Ch. Sainte-Claire Deville made a communication, with reference to the proposed Physical Observatory on the Pic du Midi, in the Pyrenees. He referred to the increasing importance of meteorology, and to its manifold extensions and development in recent years, and to the growing necessity of establishing numerous fixed stations at as high an altitude as is practicable. This has already been done to a considerable extent in India, in America, and in some parts of Europe; in France, as we have already intimated, the Puy de Dôme Observatory is nearly completed. M. Deville then referred to the importance of having a station on the Pyrenees, and to the difficulty of choosing a suitable site. The Pic du Midi de Bigorre, however, unites in itself all the most favourable circumstances. Situated towards the middle of the chain of the Pyrenees which receive directly the shock of the Atlantic storms, the Pic du Midi stands out from the general crest, and rises to a height of 2,877 metres, only 527 metres below the highest summit of the chain. It commands a magnificent and extensive panoramic view, and is easily accessible from various points. From the sixteenth century downwards it has attracted tee attention of men of science, and during the last and th- present century a considerable number of notable ob servers have resorted to the Pic for the purpose of carrying on observations. Darcet, in 1786, obtained from Philippe d'Orleans the promise of 80,000 francs to found an observatory on the mountain, but the political events which rapidly succeeded prevented the scheme from being carried out. Even then a small hut existed on the spot where the Commission, charged by the Ramond Society with carrying out the present scheme, have built another; the former had been built by Vidal and Reboul, who in 1786-7 surveyed the Pic. Ramond, in the early part of

the present century, made about thirty-six ascents of the peak, for the purpose of making barometric observations.

In 1854 a society at Bagnères founded on the Col de Sencours, 511 feet below the Pic, on a hill immediately above the Lake Oncet, a hotel for tourists. It is this hotel which the Ramond Society has used as a temporary observatory, until the Government provide the means of erecting a proper building on the summit of the Pic. On August 1, 1873, the Commission appointed by the Society provided a tolerably complete set of meteorological apparatus on the Col de Sencours. Regular observations were carried on till October 10, when want of funds cut them short. On June 1 of the following year an observer, along with the President of the Commission, General de Nansouty, installed themselves and remained till December 25, when, as we recorded at the time, the severity of the winter, for which they were insufficiently provided, compelled them to beat a precipitate retreat. On June 1 last year, General de Nansouty and M. Baylac again established themselves in the temporary observatory, and it is to be hoped they will be able to remain throughout the whole of the winter. An avalanche did considerable damage to the meteorological hut, and injured several of the instruments; fortunately, however, the observers managed to repair most of the damage done. The instruments which have been provided are of the best kind, and already observations of great value have been made, some of which have been published by the Ramond Society.

This Society determined to accomplish the erection of a proper observatory on the Pic du Midi itself, and has appealed to every quarter from which funds are likely to be obtained. The work of construction has already been begun. The building will be composed of three parts. The dwelling-house, situated seven metres below the summit, is in part subterranean, and will open only on the south side. It communicates by a tunnel with a circular vaulted erection, which will contain the barometer, the magnetic apparatus, &c. At a little distance will be solidly built the Montsouris hut, intended to cover the instruments which must be subjected to the direct influence of the atmosphere.

The work is thus in progress, and there is every reason to believe that it will soon be successfully completed, and the station become one of the most important physical observatories, not only in France, but on the globe.

PROF. TYNDALL ON GERMS*

THE author refers in an introduction to an inquiry on the decomposition of vapours and the formation of actinic clouds by light, whereby he was led to experiment on the floating matter of the air. He refers to the experiments of Schwann, Schröder and Dusch, Schröder himself, to those of the illustrious French chemist Pasteur, to the reasoning of Lister and its experimental verification, regarding the filtering power of the lungs; from all of which he concluded, six years ago, that the power of developing life by the air, and its power of scattering light, would be found to go hand in hand. He thought the simple expedient of examining by means of a beam of light, while the eye was kept sensitive by darkness, the character of the medium in which their experiments were conducted, could not fail to be useful to workers in this field. But the method has not been much turned to account, and this year he thought it worth while to devote some time to the more complete demonstration of its utility.

He also wished to free his mind, and if possible the minds of others, from the uncertainty and confusion which now beset the doctrine of "spontaneous generation." Pasteur has pronounced it "a chimera," and expressed the undoubting conviction that this being so it is possible to remove parasitic diseases from the earth. To the medical profession, therefore, and through them to humanity at large, this question is one of the last importance. But the state of medical opinion regarding it is not satisfactory. In a recent number of the *British Medical Journal*, and in answer to the question, "In what way is contagium generated and communicated?" Messrs. Braidwood and Vacher reply that notwithstanding "an almost incalculable amount of patient labour, the actual results obtained, especially as regards the manner of generation of contagium, have been most disappointing. Observers are even yet at variance whether these minute particles, whose discovery we have just noticed, and other disease germs, are always produced from like bodies previously existing, or whether they do not, under certain favourable conditions, spring into existence *de novo*."

With a view to the possible diminution of the uncertainty thus described, the author submits without further preface to the Royal Society, and especially to those who study the etiology of disease, a description of the mode of procedure followed in this inquiry, and the results to which it has led.

A number of chambers, or cases, were constructed, each with a glass front, its top, bottom, back and sides being of wood. At the back is a little door which opens and closes on hinges, while into the sides are inserted two panes of glass, facing each other. The top is perforated in the middle by a hole 2 inches in diameter, closed air-tight by a sheet of india-rubber. This sheet is pierced in the middle by a pin, and through the pin-hole is passed the shank of a long pipette ending above in a small funnel. A circular tin collar 2 inches in diameter and $1\frac{1}{2}$ inch high, surrounds the pipette, the space between both being packed with cotton-wool moistened by glycerine. Thus the pipette, in moving up and down, is not only firmly clasped by the india-rubber, but it also passes through a stuffing box of sticky cotton-wool. The width of the aperture closed by the india-rubber secures the free lateral play of the lower end of the pipette. Into two other smaller apertures in the top of the case are inserted, air-tight, the open ends of two narrow tubes, intended to connect the interior space with the atmosphere. The tubes are bent several times up and down, so as to intercept and retain the particles carried by such feeble currents as changes of temperature might cause to set in between the outer and the inner air.

The bottom of the box is pierced with two rows, sometimes with a single row of apertures, in which are fixed air-tight, large test-tubes, intended to contain the liquid to be exposed to the action of the moteless air.

On Sept. 10 the first case of this kind was closed. The passage of a concentrated beam across it through its two side windows then showed the air within it to be laden with floating matter. On the 13th it was again examined. Before the beam entered, and after it quitted the case, its track was vivid in the air, but within the case it vanished. Three days of quiet sufficed to cause all the floating matter to be deposited on the sides and bottom, where it was retained by a coating of glycerine, with which the interior surface of the case had been purposely varnished. The test-tubes were then filled through the pipette, boiled for five minutes in a bath of brine or oil, and abandoned to the action of the moteless air. During ebullition aqueous vapour rose from the liquid into the chamber, where it was for the most part condensed, the uncondensed portion escaping, at a low temperature, through the bent tubes at the top. Before the brine was removed little stoppers of cotton-wool were inserted in the bent tubes, lest the entrance of the air into the cooling chamber should at first be forcible enough to carry motes along with it. As soon, however, as the ambient temperature was assumed by the air within the case, the cotton-wool stoppers were removed.

* On the Optical Deportment of the Atmosphere in reference to the Phenomena of Putrefaction and Infection. Abstract of a paper read before the Royal Society, January 13th, by Prof. Tyndall, F.R.S. (Communicated by the author.)

We have here the oxygen, nitrogen, carbonic acid, ammonia, aqueous vapour, and all the other gaseous matters which mingle more or less with the air of a great city. We have them, moreover, "untortured" by calcination and unchanged even by filtration or manipulation of any kind. The question now before us is, can air thus retaining all its gaseous mixtures, but self-cleansed from mechanically suspended matter, produce putrefaction? To this question both the animal and vegetable worlds return a decided negative.

Among vegetables experiments have been made with hay, turnips, tea, coffee, hops, repeated in various ways with both acid and alkaline infusions. Among animal substances are to be mentioned many experiments with urine; while beef, mutton, hare, rabbit, kidney, liver, fowl, pheasant, grouse, haddock, sole, salmon, cod, turbot, mullet, herring, whiting, eel, oyster have been all subjected to experiment.

The result is that infusions of these substances exposed to the common air of the Royal Institution laboratory, maintained at a temperature of from 60° to 70° Fahr., all fell into putrefaction in the course of from two to four days. No matter where the infusions were placed, they were infallibly smitten. The number of the tubes containing the infusions was multiplied till it reached six hundred, but not one of them escaped infection.

In no single instance, on the other hand, did the air, which had been proved moteless by the searching beam, show itself to possess the least power of producing Bacterial life or the associated phenomena of putrefaction. The power of developing such life in atmospheric air, and the power of scattering light, are thus proved to be indissolubly united.

The sole condition necessary to cause these long-dormant infusions to swarm with active life is the access of the floating matter of the air. After having remained for four months as pellucid as distilled water, the opening of the back-door of the protecting case, and the consequent admission of the mote-laden air, suffice in three days to render the infusions putrid and full of life.

That such life arises from mechanically suspended particles is thus reduced to ocular demonstration. Let us inquire a little more closely into the character of the particles which produce the life. Pour Eau de Cologne into water, a white precipitate renders the liquid milky. Or, imitating Brücke, dissolve clean gum mastic in alcohol, and drop it into water, the mastic is precipitated, and milkiness produced. If the solution be very strong the mastic separates in curds; but by gradually diluting the alcoholic solution we finally reach a point where the milkiness disappears, the liquid assuming, by reflected light, a bright cerulean hue. It is, in point of fact, the colour of the sky, and is due to a similar cause, namely, the scattering of light by particles, small in comparison to the size of the waves of light.

When this liquid is examined by the highest microscopic power it seems as uniform as distilled water. The mastic particles, though innumerable, entirely elude the microscope. At right angles to a luminous beam passing among the particles they discharge perfectly polarised light. The optical deportment of the floating matter of the air proves it to be composed, in part, of particles of this excessively minute character. When the track of a parallel beam in dusty air is looked at horizontally through a Nicol's prism, in a direction perpendicular to the beam, the longer diagonal of the prism being vertical, a considerable portion of the light from the finer matter is extinguished. The coarser motes, on the other hand, flash out with greater force, because of the increased darkness of the space around them. It is among the finest ultra-microscopic particles that the author shows the matter potential as regards the development of Bacterial life is to be sought.

But though they are beyond the reach of the microscope, the existence of these particles, foreign to the atmosphere but floating in it, is as certain as if they could be felt between the fingers, or seen by the naked eye. Supposing them to augment in magnitude until they come, not only within range of the microscope, but within range of the unaided senses. Let it be assumed that our knowledge of them under these circumstances remains as defective as it is now—that we do not know whether they are germs, particles of dead organic dust, or particles of mineral matter. Suppose a vessel (say a flower-pot) to be at hand filled with nutritious earth, with which we mix our unknown particles; and that in forty-eight hours subsequently buds and blades of well-defined cresses and grasses appear above the soil. Suppose the experiment when repeated over and over again to yield the same unvarying result. What would be our conclusion? Should we regard those living plants as the products of dead dust or mineral particles; or should we regard them as the offspring of living seeds? The reply is unavoidable. We should undoubtedly consider the experiment with the flower-pot as clearing up our pre-existing ignorance; we should regard the fact of their producing cresses and grasses as proof positive that the particles sown in the earth of the pot were the seeds of the plants which have grown from them. It would be simply monstrous to conclude that they had been "spontaneously generated."

This reasoning applies word for word to the development of *Bacteria* from that floating matter which the electric beam reveals in the air, and in the absence of which no Bacterial life has been generated. There seems no flaw in this reasoning; and it is so simple as to render it unlikely that the notion of Bacterial life developed from dead dust can ever gain currency among the members of a great scientific profession.

A novel mode of experiment has been here pursued, and it may be urged that the conditions laid down by other investigators in this field, which have led to different results, have not been strictly attended to. To secure accuracy in relation to these alleged results, the latest words of a writer on this question, who has influenced medical thought both in this country and in America, are quoted. "We know," he says, "that boiled turnip or hay-infusions exposed to ordinary air, exposed to filtered air, to calcined air, or shut off altogether from contact with air, are more or less prone to swarm with *Bacteria* and vibriones in the course of from two to six days." Who the "we" are who possess this knowledge is not stated. The author is certainly not among the number, though he has sought anxiously for knowledge of the kind. He thus tests the statements in succession.

And first, with regard to the filtered air. A group of twelve large test-tubes were caused to pass air-tight through a slab of wood. The wood was coated with cement, in which, while hot, a heated "propagating glass" resembling a large bell-jar was imbedded. The air within the jar was pumped out several times, air filtered through a plug of cotton-wool being permitted to supply its place. The test-tubes contained infusions of hay, turnip, beef, and mutton—three of each—twelve in all. They are as clear and cloudless at the present moment as they were upon the day of their introduction; while twelve similar tubes, prepared at the same time in precisely the same way and exposed to the ordinary air, are clogged with mycelium, mould, and *Bacteria*.

With regard to the calcined air, a similar propagating glass was caused to cover twelve other tubes filled with the same infusions. The "glass" was exhausted and carefully filled with air which had passed through a red-hot platinum tube, containing a roll of red-hot platinum gauze. Tested by the searching beam, the calcined air was found quite free from floating matter. Not a speck has invaded the limpidity of the infusions exposed to it, while twelve similar tubes placed outside have fallen into rottenness.

The experiments with calcined air took another form. Six years ago it was found that to render the laboratory air free from floating matter, it was only necessary to permit a platinum wire heated to whiteness to act upon it for a sufficient time. Shades, containing pear juice, damson juice, hay- and turnip-juice, and water of yeast, were freed from their floating matter in this way. The infusions were subsequently boiled and permitted to remain in contact with the calcined air. They are quite unchanged to the present hour, while the same infusions exposed to common air became mouldy and rotten along ago.

It has been affirmed that turnip- and hay-infusions rendered slightly alkaline are particularly prone to exhibit the phenomena of spontaneous generation. This was not found to be the case in the present investigation. Many such infusions have been prepared, and they have continued for months without sensible alteration.

Finally, with regard to infusions wholly withdrawn from air, a group of test-tubes, containing different infusions, was boiled under a bell-jar filled with filtered air, and from which the air was subsequently removed as far as possible by a good air-pump. They are now as pellucid as they were at the time of their preparation, more than two months ago, while a group of corresponding tubes exposed to the laboratory air have all fallen into rottenness.

There is still another form of experiment on which great weight has been laid—that of hermetically sealed tubes. On April 6 last, a discussion on the "Germ Theory of Disease" was opened before the Pathological Society of London. The meeting was attended by many distinguished medical men, some of whom were profoundly influenced by the arguments, and none of whom disputed the facts brought forward against the theory on that occasion. The following important summary of these was then given :—"With the view of settling these questions, therefore, we may carefully prepare an infusion from some animal tissue, be it muscle, kidney, or liver ; we may place it in a flask whose neck is drawn out and narrowed in the blowpipe-flame, we may boil the fluid, seal the vessel during ebullition, and keeping it in a warm place, may await the result, as I have often done. After a variable time the previously heated fluid within the hermetically sealed flask swarms more or less plentifully with *Bacteria* and allied organisms."

Previous to reading this statement the author had operated upon tubes of hay- and turnip-infusions, and upon 21 tubes of beef, mackerel, eel, oyster, oatmeal, malt, and potato, hermetically sealed while boiling, not by the blowpipe, but by the far more handy spirit-lamp flame. In no case was any appearance whatever of *Bacteria* or allied organisms observed. The perusal of the discussion just referred to caused the author to turn again to muscle, liver, and kidney, with a view of varying and multiplying the evidence. Fowl, pheasant, snipe, partridge, plover, wild duck, beef, mutton, heart, tongue, lungs, brains, sweetbread, tripe, the crystalline lens, and vitreous humour of an ox, herring, haddock, mullet, codfish, sole, were all embraced in the experiments. There was neither mistake nor ambiguity about the result. One hundred and thirty-nine of the flasks operated on were exhibited, and not one of this cloud of witnesses offers the least countenance to the assertion that liquids within flasks, boiled and hermetically sealed, swarm, subsequently, more or less plentifully with *Bacteria* and allied organisms.

The evidence furnished by this mass of experiments, that errors either of preparation or observation have been committed, is, it is submitted, very strong. But to err is human ; and in an inquiry so difficult and fraught with such momentous issues, it is not error, but the persistence in error by any of us, for dialectic ends, that is to be deprecated. The author shows by illustrations the risks of error run by himself. On Oct. 21 he opened the back-door of a case containing six test-tubes filled with an infusion of turnip which had remained perfectly clear for three weeks, while three days sufficed to crowd six similar tubes exposed to mote-laden air with *Bacteria*. With a small pipette he took specimens from the pellucid tubes, and placed them under the microscope. One of them yielded a field of Bacterial life, monstrous in its copiousness. For a long time he tried vainly to detect any source of error, and was perfectly prepared to abandon the unvarying inference from all the other experiments, and to accept the result as a clear exception to what had previously appeared to be a general law. The cause of his perplexity was finally traced to the tiniest speck of an infusion containing *Bacteria*, which had clung by capillary attraction to the point of one of his pipettes.

Again, three tubes containing infusions of turnip, hay, and mutton, were boiled on Nov. 2 under a bell-jar containing air so carefully filtered that the most searching examination by a concentrated beam failed to reveal a particle of floating matter. At the present time every one of the tubes is thick with mycelium and covered with mould. Here surely we have a case of spontaneous generation. Let us look to its history.

After the air has been expelled from a boiling liquid it is difficult to continue the ebullition without "bumping." The liquid remains still for intervals, and then rises with sudden energy. It did so in the case now under consideration, and one of the tubes boiled over, the liquid over-spreading the resinous surface in which the bell-jar was imbedded, and on which, doubtless, germs had fallen. For three weeks the infusions had remained perfectly clear. At the end of this time, with a view of renewing the air of the jar, it was exhausted, and refilled by fresh air which had passed through a plug of cotton-wool. As the air entered, attention was attracted by two small spots of penicillium resting on the liquid which had boiled over. It was at once remarked that the experiment was a dangerous one, as the entering air would probably detach some of the spores of the penicillium and diffuse them in the bell-jar. This was, therefore, filled very slowly, so as to render the disturbance a minimum. Next day, however, a tuft of mycelium was observed at the bottom of one of the three tubes, namely that containing the hay-infusion. It has by this time grown so as to fill a large portion of the tube. For nearly a month longer the two tubes containing the turnip- and mutton-infusions maintained their transparency unimpaired. Late in December the mutton-infusion, which was in dangerous proximity to the outer mould, showed a tuft upon its surface. The beef-infusion continued bright and clear for nearly a fortnight longer. The recent cold weather caused me to add a third gas-stove to the two which had previously warmed the room in which the experiments are conducted. The warmth of this stove played upon one side of the bell-jar ; and on the day after the lighting of the stove, the beef-infusion gave birth to a tuft of mycelium. In this case the small spots of penicillium might have readily escaped attention ; and had they done so we should have had three cases of "spontaneous generation" far more striking than many that have been adduced.

(*To be continued.*)

NOTES

M. E. QUETELET has issued a Notice giving a brief account of the recent progress of the Brussels Observatory, which has been established only in the face of great difficulties. In 1833 meteorological observations were commenced to be made, and a few years after astronomical observations were added by the elder Quetelet. The work which is at present being carried on has for its object a general revision of the variable stars. Seventy

thousand positions have already been collected—forty thousand for right ascensions and thirty thousand for declinations. Two-thirds of these observations are published, the rest is calculated, and will be printed as soon as the resources of the Observatory permit. For fifty years a series of observations have been carried on in reference to the variations of the magnetic needle at Brussels, the results of which M. Quetelet hopes to be able by and by to publish. He, however, feels that if Brussels is to keep up with the science of the day, much remains to be done. A Commission appointed in 1874 to report on the Observatory gave in their report at the end of that year, and their principal conclusions are as follows:—To complete the magnetic system of the Observatory by the acquisition of self-registering instruments, to organise the International Meteorological Service, to obtain an equatorial of large dimensions with the accessories necessary to the spectroscopic investigation of the heavens, and to increase the number and improve the position of the observer. The Ministry have, unfortunately, not yet come to a decision on these conclusions, though we hope they may do so soon, and enable the valuable work of the Observatory to be carried on with complete efficiency, and the results be regularly given to the scientific world. Meanwhile, the work of the Observatory is being regularly carried on on the old lines.

THE new Aquarium at Westminster was opened on Saturday last by the Duke of Edinburgh; but though the building is sufficiently complete for concerts to be held, it will be many weeks before the tanks are in a proper condition to receive water. The arrangements connected with the aquarium proper have been under the direction of Mr. W. A. Lloyd, who planned the Crystal Palace and other aquaria. There are in this latest development of aquarium construction two or three new points worthy of attention. The water in flowing from one tank to another will overflow from one and pass down a tube, so that it enters the next at the bottom, by which means a more thorough mixture than has hitherto been attained will be ensured of the water that has been exposed to the surface aëration. The reservoir which occupies the space under the large hall is divided into nine compartments, so that in case of an accident to any part, it can be cleared of the water and repaired while the other sections remain in operation. The total capacity of the reservoir is 600,000 gallons, and the total amount of water in reservoir and tanks together will be 750,000 gallons. For the circulation eight rotary vulcanite pumps are erected, and they are capable of sending 56,000 gallons an hour through the tanks if needed, to meet any energency, though it is calculated that 15,000 to 20,000 gallons will be about the average amount. The plan of forcing downwards small jets of water into each tank, as at the Crystal Palace, is adopted. In the anemone tanks the water will be periodically emptied, representing, to some extent, tidal action. The salmon will have a fifty-feet run, and so will the wrasse. All the pipes, culverts, &c., are of vulcanite, but the glass fronts of the tanks are fitted in cork, with the exception of some of the limestone rock-work, which may probably be too soluble; everything that forethought could arrange in accordance with our present knowledge seems to have been attended to. It is to be hoped that the scientific results obtained will not be out of proportion to the cost of the undertaking. The official guide-book published on Saturday contains a useful article on aquarium management by Mr. Lloyd, and the *Gardeners' Magazine* of last week has also a contribution from his pen on the rise and progress of aquaria in England; the *Morning Post* of Saturday last contained an interesting article. The cover of the official guide-book is ornamented with a woodcut by Tenniel, which is quite equal to his happiest efforts in *Punch*.

THE Committee of Science of the Irish Academy will meet on Feb. 28 to take into consideration applications for assistance out of the parliamentary grant for the preparation of scientific reports; and it is requested that all such applications be forwarded to the secretary on or before that date.

THE Montsouris Observatory has been supplied with a number of recording apparatuses for barometric pressures constructed on new principles, and instruments for recording thermometric variations have been made on aneroid and bi-metallic principles. A steel needle guided by these dilatations traces a curve on a rotating cylinder. The anemometer records by a magnetic contrivance devised by M. Mangon. M. Marie Davy has also established an apparatus for recording the pressure exerted by the wind. A specially devised mirror has been arranged to indicate the direction of the clouds, which it is rather difficult to discover from direct inspection of the clouds themselves.

DR. SAMUEL BIRCH has been appointed to the Rede Lectureship in the University of Cambridge. He will deliver his lecture about Easter.

AT the January meeting of the Photographic Society, the hon. secretary read a note on the action of eosin on the photographic spectrum, by Captain J. Waterhouse, B.S.C., assistant surveyor-general of India. Tetrabromfluorescin, or eosin as it is termed commercially, is a dye remarkable for its intense fluorescence and beautiful pink colour. Its absorption spectrum is characterised by a very strong band between E and F, which fades off on either side and terminates half way between D and E, and half way between F and G. At the part of the spectrum indicated, photographic action was increased to a marked degree when the collodion was stained with the dye. Captain Waterhouse naturally inferred that greens, *e.g.* foliage, would exhibit more detail if photographed on eosin-stained plates, but this was not the case, the only effect was to make the whole action of the light slower. Vogel's observations have thus been confirmed so far as the spectrum effects are concerned; the want of action when coloured surfaces are photographed is however at variance with his results obtained, we believe, by photographing coloured papers. By the kindness of Mr. John Spiller, to whom Captain Waterhouse's letter was addressed, we have been enabled to see some of his spectrum photographs, and they certainly surpass any results of the kind we have yet seen.

The *Journal d'Hygiène*, No. 8, of Dr. Prosper de Pietra Santa, contains several articles of interest. The *Climat de Pau* gives a brief *résumé* of the meteorological characteristics of this place, in which special prominence is given to the chief feature of its climate, viz. the remarkable calmness of its atmosphere, which, combined with a light porous soil draining away the rains as they fall, and the great beauty of its environs, have made the reputation of Pau as a desirable winter and spring sanatarium. In *L'Emigration dans le Midi de la France* attention is directed to the varied climates of France in their therapeutic relations, which are classed, according to their characteristics in these respects, into sea-climates, such as Cannes, Menton, Ajaccio, and parts of Nice, Hyères, and Alger; hill climates, such as Pau, Orthez, Le Cannet, and parts of Nice, Hyères, and Alger; and mixed or intermediate climates, such as Arcachon, Vernet, and Amélie-les-Bain. The determination landward of sea climates which are considered as consisting in an atmosphere containing a minimum of miasmatic matters, a maximum of oxygen, the air impregnated with fine particles of chloride of sodium, and with a peculiar odour derived from marine plants charged with bromine and iodine, is a point of considerable importance.

THE *Bulletin International* of the Paris Observatory of the 18th inst. is the first number of a new issue, executed by the printing establishment of MM. Yves and Barrel, by the process of photo-engraving, of which a brief account is given. The

whole process occupies only from two and a half to three hours. The greatest care will continue to be taken to make the *Bulletin* a medium of the most recent information relating to astronomy and meteorology, particularly the meteorology of each of the regional districts, so as to secure that unity of action among French meteorologists without which nothing of real importance can be done.

IN the *Bulletin International* of the Observatory of Paris for the 13th inst. is given a table showing the depth of the water of the Seine at Paris on each day during 1875 by two gauges, one placed on the Pont de la Tournelle, and the other on the Pont Royale. The gauge on the Pont de la Tournelle is graduated from the point to which the water of the Seine fell during 1719. The mean height of the Seine during 1875 was $2\frac{1}{3}$ feet, the maximum height $10\frac{3}{4}$ feet on Jan. 28, and the minimum $\frac{1}{3}$ foot below the zero of the scale. The greatest flood hitherto recorded was 27 feet in 1658, and the greatest drought $3\frac{1}{3}$ feet below zero on Sept. 29, 1865.

IT is announced that the *Atlas Météorologique* for the years 1872-73-74 will appear in a few days, and it is hoped that the *Atlas* for 1875 will be ready for issue in the end of July next.

A MICROSCOPICAL club has been founded at Honolulu, which promises to be very successful. The visit of the *Challenger* to the Sandwich Islands seems to have been the immediate occasion of this laudable step being taken, as the late Dr. Von Willemoes-Suhm is mentioned in connection with it. Already there are forty members, who have subscribed 800 dollars to purchase a large microscope from Beck and Smith of London. The club will find plenty of work in the investigation of the natural history of these interesting islands, and we hope the members will not confine their investigations merely to microscopical subjects.

OUR readers no doubt know that we have a younger French sister who appears under the name of *La Nature*. We have just received from Germany a specimen of another of the family, rejoicing in the name of *Die Natur*. This seems, however, to be a new series of an old-established journal, but whether it has always appeared under its present name we cannot make out. It is conducted by Dr. Otto Ule and Dr. Karl Müller, of Halle, is mainly devoted to natural history, and the number sent us contains several interesting articles ; among these is one on the African Steppes, by Dr. Ule.

AT the Royal Geographical Society, on Monday night, Sir H. C. Rawlinson intimated that Lieut. Cameron was still at Loando, and would remain there until he saw his men safely embarked for their homes in East Africa. He will stay two months in Madeira to recruit his health before returning to England, where he is expected soon after Easter. Sir Henry stated that the map of Cameron's route would probably be ready by the time of the next meeting of the Society, as also the extremely valuable register of his observations. Major-General Sir F. M. Goldsmid then read a paper on the recent journey of Capt. G. Napier on the Turcoman frontier of Persia.

SUCCESSFUL experiments have been carried on by the French Great Northern Railway at Paris with electric lighting. With a steam-engine of three-horse power, a light equal to 100 ordinary lamps, each consuming 150 litres of gas per hour, has been obtained regularly for almost any length of time. It is contemplated by the engineers of the company to place four electric lamps in the large nave, which is 200 metres long and 60 metres high. The lighting of the company's workshops at La Chapelle will also be attempted with ten lamps. The buildings cover forty acres, and are now lighted by 700 gas lamps. It is stated that the Lyons Company will try to make use of Gramme's magneto-electric machines to light up the way.

THERE will be an examination at Gonville and Caius College, Cambridge, on the 4th of April, for two Shuttleworth Scholarships, each of the value of 60*l*. per annum, and tenable for three years. The subjects of examination are Botany and Comparative Anatomy in its most general sense (including Zootomy and Comparative Physiology). Candidates must be registered medical students of the University of Cambridge who shall have kept not less than eight terms, have passed the additional examination required for candidates for honours, and produce satisfactory testimonials of good conduct. For further information apply to the Rev. N. M. Ferrers, Tutor of the College.

THE trustees of the Johnson Memorial Prize, Oxford, propose the following subject for an essay:—"The History of the successive stages of our knowledge of Nebulæ, Nebulous Stars, and Star-clusters from the time of Sir William Herschel." The Prize is open to all members of the University of Oxford. Candidates are to send their Essays to the Registrar of the University under a sealed cover marked "Johnson Memorial Prize Essay," on or before the 31st day of March, 1879.

PROF. DEWAR commences his lectures as Jacksonian Professor at Cambridge on Tuesday next; the subject is Organic and Animal Chemistry.

WE have received a very significant publication from the Chief Inspector of Mines of Victoria, Australia, in the form of a large sheet printed in Chinese, and containing the provisions of the Regulation of Mines Statute for the colony. There are, we believe, 11,294 Chinese miners in Victoria, many of whom know nothing of the English language. In some of the districts they are employed in quartz and in alluvial mines of great depth, and the Victorian Government have acted wisely in taking this method to make them acquainted with the mining regulations.

THE Report of the Kew Committee for the year ending Oct. 31, 1875, shows that the usual work at the Kew Observatory has been diligently carried on during the past year.

WE have received from their respective publishers "The Year-Book of Photography" (Piper and Carter, Gough Square, E.C.) and the "British Journal Photographic Almanac" (H. Greenwood, York Street, Covent Garden). Both contain many admirable articles on photographic subjects, but it is to be regretted that, failing a more scientific treatment of the art and the development of new methods of manipulation, these annuals, instead of recording progress, serve up the same weary course of glass-cleaning, bath treatment, posing, lighting, and printing, year after year. The frontispiece to the "British Journal Photographic Almanac" is a charming child study by Faulkner, entitled "Simplicity," but is by no means an admirable example of photo-mechanical printing.

A FURTHER attempt is being made to introduce salmon into the Antipodes this year under perfectly new conditions. The New Zealand Government and Sir Samuel Wilson, of the Victoria Acclimatisation Society, had simultaneously asked Mr. Buckland to undertake the task of sending ova to Otago and Melbourne respectively. Mr. Buckland, in conjunction with Mr. J. A. Youl, arranged to make both shipments at once, and the eggs, collected in the Severn, Dart, Ribble, and other rivers, have accordingly been sent out, packed in moss and ice, by steamer, to Melbourne. The passage is estimated to occupy about fifty days. One portion of the eggs will be landed at Melbourne, and the others, if they are in good condition, will be at once repacked and transhipped for Otago, where they are estimated to arrive about a fortnight or three weeks after leaving Melbourne. The eggs were all in proper condition when they left London on board the *Durham*, and there is every prospect of their reaching Melbourne, at least, in safety.

By a curious coincidence, intelligence has just reached us of the safe arrival in Auckland, New Zealand, of 40,000 salmon eggs from the Columbia River, North-west America. These eggs were sent from San Francisco by steamer, consigned to the Napier Acclimatisation Society; but on arrival at Auckland they were found to be so far advanced that it was determined not to risk sending them all to Napier, but to distribute them immediately in suitable localities in the neighbourhood. One half was thus treated, and the remaining 20,000 were sent on to their original destination, Napier. There is every probability that an actual colony of salmon has now been planted in New Zealand, for the fry were in a very healthy condition, and great care was taken by Mr. Firth to protect those placed in the rivers from all possible enemies.

The last issued number of the Transactions of the Institute of Engineers and Shipbuilders of Scotland contains a paper, by Prof. James Thomson, on "Comparison of Similar Structures as to Elasticity, Strength, and Stability."

In a report published by General Chanzy, Governor-General of Algeria, it appears that the organisation of a sanitary service has been completed all over a country which is larger than Great Britain. In every district has been established a *médecin de colonisation*, who is appointed after having passed a special examination, is paid by Government, and is not allowed to take fees.

A paper on the *Batrachia* and *Reptilia* of Costa Rica, with notes on the reptiles of Nicaragua and Peru, by Prof. Cope, has recently appeared in the quarto journal of the Philadelphia Academy of Natural Sciences. Most of the Costa Rican materials were obtained from the researches of Dr. William M. Gabb, who was engaged for several years in exploring that country in behalf of the Costa Rican Government, by which he has added very largely to our knowledge of the geography, geology, general natural history, and ethnology of the region. He has already published many papers in all these departments, and it is to him we owe our only reliable information in regard to the Costa Rican aborigines. The first series of the collections made by Dr. Gabb have all been presented by him to the National Museum, in Washington, and they constitute a highly valued portion of the extensive collections of the establishment. Other collections employed in this memoir are those of Dr. Van Patten and Mr. C. N. Riotti, these covering the region extending from the Atlantic to the Pacific. Eighty-nine species were furnished by Prof. Gabb, of which thirty-seven were new to science. The total number of species known from all investigators in Costa Rica is 132, and it is probable that a large number yet remain to be discovered, showing that the region is rich in terrestrial cold-blooded vertebrates.

The additions to the Zoological Society's Gardens during the past week include a Leopard (*Felis pardus*) from Africa, presented by Mr. F. Elton; a Black Lemur (*Lemur macaco*) from Madagascar, presented by Mr. Dugald Gilchrist; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Master F. F. Goodliffe; two Gannets (*Sula bassana*), European, presented by Lieutenant-Colonel Dugmore; a Rose Hill Parrakeet (*Platycercus eximius*) from New South Wales, presented by Mr. J. Smith; a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Dr. Bree; three Brazilian Caracaras (*Polyborus brasiliensis*) from South America, deposited; a Coypu Rat (*Myopotamus coypus*), a Spotted Cavy (*Cœlogenys paca*), a Central American Agouti (*Dasyprocta punctata*) from South America, a White-spotted Crake (*Porzana notata*) captured at sea off Cape Santa Maria, three Geoffroys Terrapins (*Platemys geoffroyana*) from the Argentine Republic, a Maximilian's Terrapin (*Hydromedusa maximiliani*) from Brazil, purchased.

SCIENTIFIC SERIALS

The current number of the *Quarterly Journal of Microscopical Science* commences with a memoir, by Dr. G. Thin, on the structure of hyaline cartilage as found by immersing it in a solution of caustic potash at 107° F., and otherwise. A successful potash preparation shows flattened polygonal cells adhering to each other exactly like an epithelium. Much manipulatory experience is necessary for the demonstration of these, and it must be mentioned that the author has "a strong conviction of the uniformity of plan in the general structure of the tissues."—Mr. Hugh Price writes on a polystomatous condition of the hydranths of *Cordylophora lacustris*, and figures his specimens. His observations tend to show that the polystomatous condition may be due to injury of the parent hydranth.—Prof. E. R. Lankester, F.R.S., contributes two papers; the first, including further observations on a peach, or red-coloured Bacterium (*Bacterium rubescens*), in which a further account of that organism is given. The second is a valuable account of Prof. Haeckel's recent additions to the Gastræa-theory, illustrated by four important plates exemplifying the letterpress. The following terms are fully explained: Palingeny and Cenogeny, the tendency to recapitulation and to suppress the details of ontogenetic development; Heterochrony and Heterotopy, the perturbations in ontogeny as regards time and space. The conceptions with which these terms are associated must be fully mastered by all who study evolution from its developmental aspect. The four chief types of egg-cleavage and of Gastrula-formation are then explained, and the stages which each undergo, the monerula-, cytula-, morula-, blastula-, and gastrula-stages are recounted, the prefixes archi-, amphi-, disco-, and peri- being applied to the four respectively. The nomenclature, though at first apparently formidable, much simplifies this otherwise complex subject.—Mr. C. S. Tomes, in writing on the development of teeth, gives a summary of the many and important results at which he has arrived in his valuable researches, together with the investigations of others which bear on the subject. Goodsir's primary open dental groove is shown to have no existence. In reality an ingrowth is shown to develop from the deep layer of the epithelium, consisting of a double layer of cells burrowing down into the submucous tisssue, and looking in transverse section like a tubular gland. The next stage consists of an active growth of cells in the deepest end of the epithelial inflection, the immediately subjacent tissue at almost the same time becoming elevated at corresponding points where teeth are to be developed; the subjacent tissue forming a conical papilla, the enamel organ appearing with or even before the papilla. Many important points in the tooth-development of the lizard and fish are also discussed.—Dr. Percival Wright has a note on *Stenogramma interrupta*, in which the author proves that the tetrasporic fruit of that rare and beautiful Alga was described by Dr. W. H. Harvey, contrary to the assertion of Mr. E. M. Homes.—Mr. W. Bevan Lewis describes the best methods of making preparations of sections of cerebral and cerebellar cortex for microscopical examination.—Mr. H. C. Sorby, F.R.S., has a paper on the evolution of Hæmoglobin, based mainly on the fact that the centres of the hæmoglobin bands from the red blood of *Planorbis* lie two and a half or three millionths of a millimetre nearer the blue end of the spectrum than do those of vertebrate blood.—Reviews of Dr. Klein's "Anatomy of the Lymphatic System," Part II., and of the English translation of Frey's "Histology and Histochemistry of Man," are also given, followed by notes, proceedings of societies, &c.

The number for July 1875 of Siebold and Kölliker's *Zeitschrift für Wissenschaftliche Zoologie* opens with a valuable contribution by Dr. Claus, to our knowledge of the parasitic Copepoda, under the following headings:—The genus Hersilia; the classificatory value of the oral apparatus; the Ergasilidæ; the Nereidicolidæ; the Ascidicolidæ; the Siphonostoma, and the genus Lamproglena. Several excellent plates illustrate the paper. Dr. Claus concludes that a natural classification is at present impossible, because of the gaps in our knowledge of many points in the organisation and development of these remarkable parasites.—Dr. Ludwig Stieda gives a detailed description of the general and microscopic structure of the brain and spinal cord in the Chelonia, derived from the examination of *Testudo Græca* and *Emys Europœa*—a much-needed acquisition.—Dr. Ludwig Graff describes several new species of Turbellaria.—O. Bütschli, in a controversial article on the Infusoria, contests the received interpretations of the phenomena following their conjugation, and endeavours to show that Häckel and Claus have made no real

advance in the morphology of Infusoria by their recent researches.—Prof. Selenka contributes a concise but very interesting account of the development of *Phascolosoma elongatum* from impregnation to the fourth day, beyond which his specimens did not develop. The changes in the first few hours after impregnation are carefully figured at brief intervals; the formation of the alimentary canal by invagination was very clearly made out. Prof. Selenka contemplates publishing a monograph on the Gephyreans.—Prof. H. Nitsche gives a preliminary account of his researches on the structure and budding of *Loxosoma Kefersteinii;* the most important result he claims to have demonstrated is the exclusive origin of the bud from the ectoderm of the parent, so that there is a direct conversion of ectodermal elements of the parent into entoderm elements of the offspring.—Dr. Anton Dohrn gives a full account of the regulations and management of his zoological station at Naples.

The September number of the same journal opens with some very interesting observations made in the aquarium at the Naples Zoological Station by Prof. Koilmann, chiefly relating to the Cephalopods. The most notable paper is one by Dr. Malbranc on the lateral lines and their sense-organs in Amphibia. The positions in which these organs occur are described and figured for a number of species in each main division of Amphibia, the nerves which supply the lateral-organ system are traced, especially the distribution of branches of the vagus, and the microscopic structure of the organs is described and figured. He shows their intimate correspondence in structure with the taste-goblets of the Tadpole, the similarity of the characteristic cells being remarkable. The discovery of taste-goblets in many species of Amphibia is also recorded, and is to form the subject of another paper.—Prof. Kollmann contributes a paper describing his investigations on the circulation in Aplysiæ, Lamellibranchs, and Cephalopods. Among the most important of his conclusions are that Aplysiæ and Lamellibranchs have arterial hearts, and that there is not really any lacunar system in Cephalopods. He has also made very careful investigations as to the admission of water into the blood in many Mollusca.—O. Bütschli gives a brief contribution on the development of *Cucullanus elegans*, showing the formation of its embryo by a process of involution. It is connected in several important characters with the embryo of Sagitta.—Dr. Dohrn has a paper of fragmentary notices on Insect Development, devoted principally to points in the development of the Silkworm and the Mole-cricket.—One of Dr. von Willemoes-Suhm's letters from the *Challenger* concludes the number.

Reichert and Du Bois Reymond's Archiv, Nov. 1875.—This number includes a continuation of Robert Hartmann's contributions to the knowledge of the anthropomorphic primates, dealing with the osteology of a number of specimens of chimpanzee collected by Dr. Schweinfurth; the conclusion of Paul Mayer's elaborate account of the anatomy of *Pyrrhocoris apterus;* and an article by L. Dittmer on the theory of double monsters.

SOCIETIES AND ACADEMIES

London

Chemical Society, Jan. 20.—Prof. Odling, F.R.S., vice-president, in the chair.—Dr. Armstrong exhibited a specimen of pure crystallised glycerin from Messrs. Dunn and Co., of Stratford. —Mr. E. Neison then communicated a note on sebate of cobalt.—After which Dr. C. R. A. Wright gave an abstract of Part IV. of the researches by himself and Mr. G. H. Beckett on narcotine, cotarnine, and hydrocotarnine; on oxynarcotine, a new opium educt, and its relationship to narcotine and narceine.—The last paper was on a method for estimating bismuth volumetrically, by Mr. M. M. P. Muir.

Zoological Society, Jan. 18.—Mr. Robert Hudson, F.R.S., vice-president, in the chair.—Prof. A. H. Garrod read a paper on a peculiarity in the carotid arteries and on other points in the anatomy of the Ground Hornbill (*Bucorvus abyssinicus*).—Mr. Edward R. Alston read a paper on the classification of the order Glires. Lilljeborg's sub-orders *Glires simplicidentati* and *duplicidentati* were recognised, the former being divided into sections equivalent to Brandt's sub-orders *Sciuromorphi, Myomorphi*, and *Hystricomorphi.* A third sub-order was proposed for the reception of the fossil form *Typotherium*.—A communication was read from Mr. E. A. Liardet, containing notes on the Land Shells of Taviuni, one of the Fiji Islands, with descriptions of several new species.—Mr. E. A. Schäfer read a paper prepared by himself and Mr. D. J. Williams on the structure of the mucous membrane of the stomach in the kangaroos, in which he gave a minute description of the histological characters of the different portions of this organ.—A communication was read from Mr. W. H. Hudson, containing notes on the habits of the Rails of the Argentine Republic.—The Hon. W. H. Drummond read a paper on African Rhinoceroses, in which he gave reasons for believing in the existence of five species in Africa, including *R. oswelli*, which, however, might probably be merely a variety of *R. simus*.—A communication was read from Mr. E. Pierson Ramsay, containing a continuation of his remarks on the birds met with in North-eastern Queensland, chiefly at Rockingham Bay.—A communication was read from M. L. Taczanowski, containing the description of a spotted deer found in Southern Ussuri, district of Amoorland, for which he proposed the name *Cervus dybowskii*.—Mr. A. G. Butler communicated a revision of the Lepidopterous genus *Teracolus*, with descriptions of the new species.

Geologists' Association, Jan. 7.—Mr. Henry Woodward, F.R.S., vice-president, in the chair.—On the geology of New Zealand, with special reference to the drift of that country, by Dr. Hector, C.M.G., F.R.S. The author first drew attention to the geographical position of the islands, indicating on the South Polar chart their situation relative to known lands of the Antarctic area. Great ice-packs encumber the intervening ocean, circulating around the pole; travelling in a spiral, and thus increasing their distance from the centre. On the meridian of South Shetland, as low as 40° S. latitude, the seas are at all seasons crowded with icebergs, but there is an indentation of the ice-pack opposite Australia and New Zealand, though erratic masses escape sometimes. There are, however, five degrees of latitude off the extreme south of New Zealand, clear of the limit where icebergs are ever found. As regards latitude the islands occupy a position equivalent, in the Northern Hemisphere, to a line between Paris and Algiers. They lie parallel to Australia, 1,200 miles E. by S., and repose on a sub-marine plateau, which, along the west shores of the islands, is submerged to a depth of from 1,200 to 1,300 feet, but further westward terminates in water 6,600 feet deep. The edge of this plateau comes close in shore on the S.W. extremity of the Southern (middle) island. Thus New Zealand is a remnant of a once far more extensive land, whose eastern boundaries are not as yet clearly defined, but the author was disposed to include the Chatham Islands as a portion of it. *North Island*.—The eastern shore is the boldest; foul weather, and consequently denudation, coming from the N.E. The west side is more shelving; but the great volcanic boss of Mount Egmont, which rises at a gentle angle to a conical summit, protrudes its protecting buttresses of lava far into the western sea, and has thus been the means of preserving a great tract of Miocene tertiaries behind it; these constitute some of the best land in the country. *South Island*.—The denudation comes from the west: its western shores also approach nearer to the edge of the plateau, and the mountains of the south-west angle rise from a profound abyss to a height of from 4,000 to 5,000 feet. In the North Island a belt of hard rocks, consisting of the Upper Palæozoics, and the older Mesozoics, constitutes a sort of back-bone, occupying the east-central portions, against which the softer beds of more recent age recline. In the South Island this belt of Upper Palæozoic rocks, constituting the high mountain chain known as the Southern Alps, sweeps down through the centre with an incline towards the west, and then curves round towards the east again quite to the sea on that side. Against these also the Upper Mesozoics and Tertiaries recline. On the west and south of this easterly bend of the belt of the newer Palæozoics a great mass of foliated rocks occur in the province of Otago, constituting the well-known gold-field. In the far south-west we have only crystalline rocks, and these belong to a series which seems to reappear in much of the detached lands of the Southern Ocean, such as Kerguelen's Land, Auckland Islands, &c., where Miocene volcanic rocks also occur. The meteorology of the country, as having an important bearing on the denudation of the surface, was next considered. Referring principally to the Southern Island, we have here the mixing point of the N.E. and S.W. currents. On the west side, at Okitika, the annual range of temperature is 50°; on the east side, at Christchurch, 65°; moisture, west side, 90°, east side, 75°; rainfall, west side, 120 inches; east side, 25 inches; number of rainy days, west side, 202; east side, 91. Much of this enormous precipitation is deposited as snow in the Southern Alps, which

comb out the moisture from the westerly winds; hence the extensive glaciers of the mountain region and the comparative dryness of the Canterbury Plains. Mount Cook has an elevation of 14,000 feet; this is the principal snow area of the Southern Alps, and here the island is narrowest. In shape this snow-field is less compact than that of the Bernese Oberland and of the Mount Blanc region; their respective areas are: snow-field of Mount Cook, 160 square miles; Bernese Oberland, 140 square miles; Mount Blanc, 75 square miles. The crystalline mountains of the south-west do not contain nearly so much snow. The Tasman glacier is 18 miles long, and 2 miles wide at its terminal face; the terminal face of the Godley glacier is 3 miles across. The author then gave a description of the leading features of the glacier scenery, illustrated by very effective pictures; one of Milford Haven, with the half-snowed peaks of Mount Pembroke and its neighbours rising to a height of more than 5,000 feet, was very striking; he also demonstrated the erosive action of glaciers in cutting back cols—an action more energetic formerly, some of the cols having been worn down as low as 1,800 feet. The author pointed out on a map, specially constructed for the purpose, the immense extent of the snow area in former times as contrasted with that now existing. This is proved by the abundance of moraine matter. At present the glaciers on the west side of the Southern Alps are remarkably clean (as was well shown by a splendid series of sketches in colour by the Hon. Mr. Fox and lent for exhibition to the meeting), whilst those on the east side are largely charged with detritus. Following a given section in this direction away from the central ridges we find generally a rock basin, and still lower immense moraines extending to the Canterbury Plains, till they pass under the deposits of these plains, which are referred to Pliocene and Post-tertiary age. In further illustration of the former extent of the snow-fields, the author indicated old centres of glaciers in the north of the island. The reason for this contraction of the ice area is the great question for determination. Was it due to difference of climate the result of a great glacial period? The remains of the past fauna afford no evidence of this. We may, indeed, suppose that the whole fauna migrated to the north, but we must in that case invent the land and bring into play oscillations more extensive than those required for another alternative, viz., the alteration of level within the area itself. We might suppose a general alteration of level, even to the extent of 4,000 feet higher than at present, but the evidence afforded by the shore line is unfavourable to this view. There remains then the theory of unequal elevation, which, combined with a most enormous destruction of surface, the result of ages of glacier action, best explains the phenomenon. There can be no doubt that at present the south-west portion of the island, where the crystalline rocks prevail, is very much depressed in comparison with its position at some former period; the extraordinary depth of the sub-marine valleys proves this. The author was inclined to believe in a period of irregular elevation, the south-west portion having been elevated first, though possibly the Nelson region at a still earlier date. In conclusion, the author stated his belief that there had been no general change of climate, but many changes of relative level, resulting in a great destruction of surface, which had taken place in groups of peaks at different times; the areas of the crystalline rocks have been least affected in their relative changes of level, the oscillation having been greater in the other masses, which have been crumpled up against these.

Manchester

Literary and Philosophical Society, Dec. 28, 1875.—Edward Schunck, F.R.S., president, in the chair.—The following communication from Dr. Joule, F.R.S., was read:—Unsuccessful attempts have recently been made for the purpose of utilising a modification of the common kite as a means of obtaining a view of the surrounding country. The machine in each instance rose only to fall violently to the ground after remaining in the air a very short time. These trials have brought to my recollection some experiments I made more than six years ago, but of which I did not publish the results, imagining that all such matters must have been thoroughly elucidated by the Chinese, if not by our own more juvenile kite flyers. The usual method of making the skeleton of a kite is to affix a rather slender bow to the top of a standard, tying the extremities of the bow to twine fastened to the bottom of the standard. The steadiness of the kite in the air depends on the fact that the wings yield with the wind. If the bow is too stiff and the surface nearly a plane, instability results. A kite ought to have a convex spherical surface for the wind to impinge upon. Such a surface I readily made by fixing two bows crosswise. The string was attached to a point a little above the centre of the upright bow, and a very light tail was fastened to the lower end. The kite stood in the air with almost absolute steadiness. I found that by pulling strings fastened to the right and left sides of the horizontal bow, the kite could be made to fly 30° or more from the direction of the wind, and hence that it would be possible to use it in bringing a vessel to windward. One great advantage of such a mode of propulsion over ordinary sails would be that the force, however great, could be applied low down, so as to produce no more careening than that desired by the seaman.—E. W. Binney, F.R.S., said that in the Isle of Man there had been a prevalence of easterly winds throughout the months of October and November, such as he had never experienced during a residence of ten years. This appears to have influenced the migration of swallows. In the beginning of September the chimney swallows and the house martins assembled in great numbers on his buildings on Douglas Head, as they were accustomed to do prior to their annual departure, and disappeared. On Nov. 5, between 10 and 12 A.M., he observed a dozen house martins (*Hirundo urbica*) in front of his house and between it and the sea, busily employed in pursuing their prey. During the summer months the swift and sand martin are frequently seen in the same locality, but seldom the swallow or house martin, and he was inclined to believe that the presence of the latter was due to their having been driven out of their course by the easterly gales.

Jan. 11, Edward Schunck, F.R.S., president, in the chair.—Note on a method of comparing the tints of coloured solutions, by J. Bottomley, D.Sc.—On explosions of fire-damp, by Mr. Robert Rawson.

Calcutta

Asiatic Society of Bengal, Dec. 1.—Mr. Wood-Mason exhibited an interesting collection of crustaceans, including the materials for his monograph of *Paratelphus*, an Indo-Malayan genus of freshwater crabs, all the Italian species of which occur in localities the fauna of which is largely leavened with Malay forms. The three papers read were all by Mr. W. T. Blanford. The first contained a description of some lizards from Western Sind, comprising new species of *Ptyodactylus*, *Stenodactylus*, and *Trapelus*. The species described are *Hemidactylus coctæi; H. Macullatus; H. Persicus; Ptyodactylus homolepis*, sp. nov.; *Gymnodactylus; Stenodactylus orientalis*, sp. nov.; *Agama agilis; Trapilus rubrigulariz*, sp. nov.; *Stellio nuptus; S. Melanura; Mesalina pardalis; Acanthodactylus Cantoris; Ophiops Jerdoni*. Five are new to the fauna of India, and three of these have not, so far as Mr. Blanford could ascertain, been previously described. Two of the three represent genera of *Geckotidæ* not hitherto detected so far to the eastward, and it is doubtful whether either has before been found in Asia. In the second paper, a note on a large hare inhabiting high elevations in Western Thibet, the author shows that the hare previously identified with doubt as *L. pallipes* proves, on comparison with specimens of the latter received from Mr. Mandelli at Darjiling, to be distinct, and is described as new under the name of *Lopus hypsibius*, from its inhabiting very elevated regions. The description is taken from a specimen collected by Dr. Stoliczka, at an elevation of 15,500 feet, in the Chang-chenmo valley, Ladak. In the third paper Mr. Blanford states that a snake from Purneah with a local pit has been recognised as *Elachistodon*, a remarkable genus with angular teeth. *Platyceps semifasciatus* is identified with *Zamenis ventrimaculatus*, and *Ablepharus pusillus* is recognised as distinct from *A. agilis* (*Blepharosteres Agilis*, Stol.).

Berlin

German Chemical Society, Jan. 10.—A. W. Hofmann, president, in the chair.—The President announced the formation of a German Committee to further the objects of the Loan Exhibition of Scientific Apparatus at South Kensington, and the decision of the committees of the German Chemical Societies to co-operate with this Committee.—R. Blindow described an improved method of burning diamonds for lecture purposes. He puts the diamond on a piece of magnesium foil, and the latter on a piece of porcelain, into a combustion-tube filled with oxygen. Ignition of the magnesium is produced by a Bunsen burner, and is easily communicated to the diamond.—G. Braylants described a lecture experiment to show the combination of oxide of nitrogen with oxygen.—Th. Zincke has added the following observations to his studies on the action

of zinc on benzol, C_6H_6, and chloride of benzyle, $C_6H_5 . CH_2Cl$. Besides diphenyl-methan, $C_6H_5—CH_2—C_6H_5$, two isomeric hydrocarbons are formed of the formula :—

$$C_6H_5 . CH_2—C_6H_4—CH_2 . C_6H_5,$$

which by oxidation yield corresponding ketones :—

$$C_6H_5 . CO—C_6H_4—CO . C_6H_5$$

(dibenzoylbenzol), and two isomeric acids, viz., benzoylbenzoic acid (1 : 4), and benzoylbenzoic acid (1 : 2) :—

$$C_6H_5CO—C_6H_4—COOH.$$

—W. Leppert has succeeded in oxidising dibenzyl :—

$$C_6H_5 . CH_2—CH_2 . C_6H_5.$$

It yields benzoic acid. Two isomeric dinitrodibenzyls yield both paranitrobenzoic acids. Assuming the position of $CH_2 = 1$ the position of the two nitro groups appears as 4 : 4 and 4 : 2 in the two isomeric dinitrodibenzyls.—H. Salkowsky proved the existence of a double salt of paranitrobenzoate and benzoate of barium, and thinks that Fittica's pretended fifth isomeride of nitrobenzoic acid may be a mixture of nitrobenzoic and benzoic acids precipitated from double salts like the above.—H. Abelganz has studied the action of potassium on benzol. It appears to yield two compounds, C_6H_5K and $C_6H_4K_2$. With water (as well as with bromide of ethyl) it yields diphenyl-benzol, $C_6H_4(C_6H_5)_2$, and a small quantity of diphenyl; also an oil boiling at 222° of the composition $(C_6H_8)_n$.—E. Demole has tried the action of brominated ethylene, C_2H_3Br, on hypobromous acid, HBrO. The chief product appears to be $CHBr_2—CH_2OH$.—A. Hilger has studied hesperidine, to which he gives the improbable formula, $C_{18}H_{21}O_9$, and which he considers as a glucoside of an acid, $C_{12}H_{11}O_4$ (?).—A. Bannow showed a large specimen of solid formic acid in beautiful crystals of more than 5 cm. in length, obtained during the cold weather of the last days in Berlin. The fusing-point is + 2°.—E. Baumann has found in the urine of horses considerable quantities of phenol-sulphate of potassium.—Al. Saytzeff has produced the following interesting synthetical reactions: by the action of iodide of allyl and zinc on oxalic ether; diallyl-oxalic ether, $C(C_3H_5)_2OH—COOC_2H_5$, a liquid boiling at 210°; by the action of iodide of allyl and zinc on acetone; the tertiary alcohol, $C\left\{\begin{array}{l}—CH_3\\—C_3H_5\\—C_3H_5\\—OH\end{array}\right.$, boiling at 119°; by the action of iodide of allyl and zinc on acetic ether the tertiary alcohol, $C\left\{\begin{array}{l}CH_3\\C_3H_5\\C_3H_5\\OH\end{array}\right.$.

VIENNA

Imperial Academy of Sciences, Dec. 9, 1875.—The following (among other) papers were read :—On the different excitability of functionally different nerve-muscle apparatus, by M. Rollett. This contains myographic studies on antagonistic muscles, and replies to Fick's objections to former experiments.—Attempts to meet objections lately raised against an increase of temperature with depth in the earth, in connection with the low temperature at great depths in the ocean and in some bore holes, by M. Boué. The cold water must flow under the warmer, and the earth's crust under the sea-bottom must be equal to that in continents. As to the Speremberg hole, infiltration of cold water must be considered; also the fact that many chemical combinations produce cold, and such are very likely to occur in salt and gypsum regions with mineral springs.—On the growth and decrease of crystals in their own solution and in the solution of isomorphic salts, by M. Pfaundler. He discusses objections by Lecoq de Boisbaudran to his theory.—On nitroglycerine and the most important preparations from it, by M. Beckerhin. He determines the specific heat of nitroglycerine and of *Kieselguhr*. Another paper of his gives a determination of the efficiency of blasting agents in a theoretical way.—On the formation of a rational space-curve of the fourth order on a cone-section, by M. Weyr.—On the utilisation of solar heat for heat effects, by a new plane mirror reflector, by M. Güntner.—Discovery of a disorder in the bones analogous to hæmorrhagic infarction of other organs, by M. Chiari. The changes in the bones coincided with disorders in the lungs and the right kidney.—On the laws of nervous excitation, by M. Fleischl—(1) For chemical stimuli nerves are at all parts of their course alike sensitive. (2) For electric stimuli they are more sensitive at higher points than at lower, if the electric currents pass downwards; the case is reversed if they pass upwards. (3) The doctrine of an increase (*Anschwellen*) of stimulus in the nerves is untenable.—On phyllometric values as means for characterisation of plant leaves, by M. Pokovy.

PARIS

Academy of Sciences, Jan. 17.—Vice-Admiral Paris in the chair.—The following papers were read :—Experimental critique on the formation of saccharine matter in animals (continued), by M. Cl. Bernard.—On the *trombe* of Hallsberg (with general conclusions), by M. Faye. The author controverts M. Hildebrandsson's views on the subject.—Action of fuming sulphuric acid on the carburets of hydrogen, by M. Berthelot.—History of attempts at formation of an observatory on the summit of the Pic du Midi de Bigorre, by M. Sainte-Claire Deville. The first to conceive the idea was Plantade, who died on the mountain in 1741.—New considerations on the regulation of slide-valves (concluded), by M. Ledieu.—M. Nordenskjöld was elected correspondent for the section of Geography and Navigation in room of Mr. Livingstone.—Report on the work of M. Revy, English engineer, on hydraulics of great rivers, Parana, Uruguay, and the valley of La Plata.—Mission to Campbell Island, geological constitution of the island, by M. Filhol. During the Upper Jurassic and Lower and Middle Eocene, the land formed part of a large continent; in the Upper Eocene and Lower Miocene it was submerged; in the Middle Miocene it rose again (under volcanic influence), and has since been an island.—On the transit of Venus of December 1874, by M. André.—On a new analogy to the theorems of Pascal and of Brianchon, by M. Serret.—Transformation of cane-sugar in raw sugars and in sugar-cane, by M. Müntz. The reducing sugar in these bodies is generally formed by an inactive glucose, to which are often added variable proportions of normal glucose and of levulose.—On the optical inactivity of the reducing sugar contained in commercial products, by MM. Aimé Gerard and Laborde.—Observations on results already obtained in the magnetism of steels, by MM. Treve and Durassier.—Generalisation of the theory of an osculating radius of a surface, by M. Lipschitz.—On *trombes*, by M. Planté. In one experiment made, salt water is passed through a funnel into a shallow dish over the pole of an electromagnet; and the poles of a battery of 400 secondary couples are connected, one (+) with the water in the funnel, the other (−) with that in the dish. A luminous thread appears in the liquid vein; sparks pass at the bottom, and the water in the dish is put in rotation. This and other experiments described are thought to illustrate the action of *trombes*.—On the spectrum of nitrogen and that of alkaline metals in Geissler tubes, by M. Salet. We shall notice this at length next week.—On new derivatives of anethol, by M. Landolph.—On the synthesis of aniline black, by M. Coquillion (second note).—Crossing of nerve fibres which connect the brain with the spinal cord, by MM. Sappey and Duval.—On the embryogeny of the *Salmacina Dysteri*, Huxley, by M. Giard.—Undulations of the chalk in the north of France, second part; origin and general disposition of these undulations, by M. Hebert.

CONTENTS

THURSDAY, FEBRUARY 3, 1876

THE UNIVERSITY OF LONDON AND SCHOOL EXAMINATIONS

EXAMINATIONS, like fire and many other useful things within their proper limits, are good servants, but very tyrannous masters. It is excellent that knowledge should be tested; that men—and shall we say women—shall be found out for their souls' good if they innocently deceive themselves as to their acquirements, for the sake of the community if they assume knowledge they really do not possess. Unfortunately, what was once a means bids fair to become an end; and it is quite certain that a great deal of knowledge is acquired nowadays which finds its only use within the walls of the examination room. It is perhaps a law of human nature that those who have bitterly endured the harrow—not to suggest metaphorically another implement—are ever afterwards eager that all mankind should endure the same process with no feature of its asperity mitigated. In the Report of the Sub-committee of the Annual Committee of the Convocation of the University of London on the Examination and Inspection of Schools, this feeling makes itself curiously apparent :—

"The Universities of Oxford and Cambridge having for many years held local examinations, and having recently initiated a joint scheme, in accordance with which they have examined a progressively increasing number of schools, your Sub-committee fear, that unless this University is prepared to undertake a share in this great work, many schools, which have hitherto acted as feeders to this University, will grow into organic relation with the older Universities, and that, consequently, *the number of candidates for the London examinations will sensibly decrease.*"

The two ancient Universities having, it will be seen, started a system which has affected, most beneficially, the middle-class education of the country, and this system having worked successfully for many years, are now practically extending it to the higher grade schools. The Annual Committee have not a word to say as to the efficiency of the work, although, as we have frequently said in these columns, much is to be objected as to the position given to science in it. It might, then, be conceived, that there was no need for the modern University to do more than to wish the older ones God-speed. But no; there is no salvation in Oxford and little in Cambridge, and that students should from their youth upwards lean to these *almæ matres* and turn away from the *sicca nutrix* of the metropolis—the examining board with all its sternest features unmitigated by the prestige of a professoriate, or the ameliorations of a traditional culture—was a thing not to be endured. The University must be at least true to its principles. When on the eve of the elections of the present Parliament, people were dimly suspecting the beginning of the end of the Liberal administration, Mr. Lowe, addressing his constituents in Convocation, devoted all his powers to the task of portraying the terrible things that must happen if the Conservatives ever came to power. He passed lightly over the disappearance of a surplus—that was too normal a phenomenon with Tories. But he touched a chord on which he knew the response would not be doubtful, when he hinted that possibly the Conservatives might tamper with the principle of competitive examinations; with almost painful earnestness he pleaded hard for mercy as regards that cherished institution. He knew his audience well, and felt that they at least would never neglect the sacred charge, or forget that the true destiny of the human animal, from its youth upwards, is the examination room

It will perhaps be thought that in this matter we have spoken with undue irony, even it may be thought with undue levity. But is it easy to speak with reasonable seriousness of an attitude like that which the Annual Committee has adopted? Surely if the school-examinations were ill-conducted by Oxford and Cambridge the nation would owe the University of London a debt of gratitude if it undertook in good faith to do them better. But there is no evidence that they are ill-done; indeed, there has not been sufficient time to express any comprehensive opinion about them. A good deal is no doubt to be said as to the inadequate place which science holds in these examinations. But for the present the more dignified course for the University of London to adopt—and one which its actual rulers, the Senate, will, it is to be hoped, take into consideration—is to defer any action in this matter till the Oxford and Cambridge system has at least been tried. It is not by entangling schoolboys in its meshes, but by the high standing which is maintained for its superior degrees, that the prestige of Burlington Gardens will be sustained; and in the interests of learning, rather than of examinations, it is to be hoped that grounds of action so cynical will not be again put forward.

GUTHRIE'S "MAGNETISM AND ELECTRICITY"

Magnetism and Electricity. By F. Guthrie, Professor of Physics at the Royal School of Mines. (London and Glasgow: W. Collins, Sons, and Co., 1876.)

DR. GUTHRIE has evidently devoted considerable time and care to the preparation of this text-book. It has undoubtedly a freshness and originality of treatment which, though apt to shock electricians in parts, yet places this treatise in striking contrast to some science class-books of mushroom growth, that bear the mark of scissors and paste on every page. In such books the text too often seems written to illustrate the threadbare woodcuts; here, however, the illustrations are original, and usefully aid the author's meaning. It is true in some cases the cuts are rough and poorly engraved, *e.g.* Figs. 90, 105, 107, 112, 123, 183, and 274, and it is to be regretted that, in the case of instruments at any rate, the illustrations are not drawn to scale but often greatly out of proportion, the reason for which, the author states, is better to show principles; but this hardly applies to apparatus which the student or instrument maker may have to construct from the figures. We like, however, the quaintness seen in many of the terms employed; such as the use of "tandem" to describe cells grouped in simple circuit by "joining the family of zincs to the family of carbons" (p. 183), and the term "abreast," employed to indicate the compound circuit; a source of voltaic electricity is called an "electrogen," and the transport of the products of electrolysis is termed "migration

of the ions," &c. Some of the illustrative analogies given by the author are also very happy, as, for example, the ease with which the molecular transfer is effected in electrolysis is compared to the ease with which a chain hanging over a pulley is moved: "When the two sides are equal each link on one side may be conceived as keeping in equilibrium the opposite link on the other side. A slight force pulling one side down will bring each link opposite to a different one" (p. 137). Incidentally, one or two of the new things strike us as open to question: for instance, the habitual use of the word isolate instead of insulate; the former has a French aspect, and certainly is less familiar to English readers than the latter term. Again,

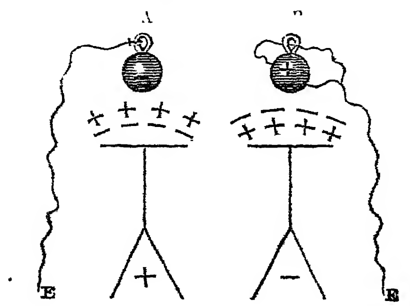


Fig. 1.

the omission of all names of discoverers, because, the author states in the preface, "the book is not a history of discovery;" nevertheless, is it not well that students should be able to associate with Faraday's name, for instance, the famous discoveries he gave to the world? and with all the author's care one or two less important names have crept in, that thus have an undue prominence given to them. On the other hand the unostentatious tone of the book and the entire omission of any reference to the writer, even in the description of the instruments he has devised or the facts he has discovered, are excellent traits, and quite characteristic of the author.

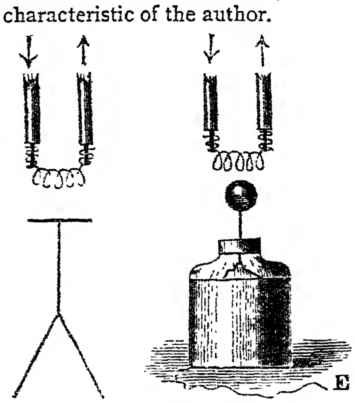

Fig. 2.

The following extracts will illustrate the remarks we have made, and afford our readers an idea of the experimental portion of this treatise. Here is an experiment of the author's which is of considerable interest, whatever explanation may be accepted:—

"When at a bright white heat, an iron ball refuses to receive, or at least to retain, even for a moment, a charge of either + or − electricity. On cooling down, but while still of a red heat, it acquires the power of receiving a − but not a + charge; and this distinction is maintained through a considerable range of temperature. At a lower temperature yet, but still at a dull red heat, the ball begins to be able to receive + electricity, and shortly after, as it cools, it accepts both kinds with nearly equal readiness. . . . Again, if we take two equally-charged gold-leaf electroscopes (Fig. 1), one charged with + and the other with − electricity, and if we bring earth-connected white-hot iron balls a few inches above the caps of each, they will be discharged with nearly the same facility. On repeating the experiment continually, as the balls cool, it is found that A, or the +ly charged electroscope, ceases to be discharged, though the ball is of a red heat, while B, or the − electroscope, continues to be immediately discharged, although the ball has lost all incandescence."

The explanation of this phenomenon Dr. Guthrie takes to be as follows:—"If we conceive the air-bathed and electrically air-straining masses of iron, A and B, to be respectively +ly and −ly electrified, and then to be gra-

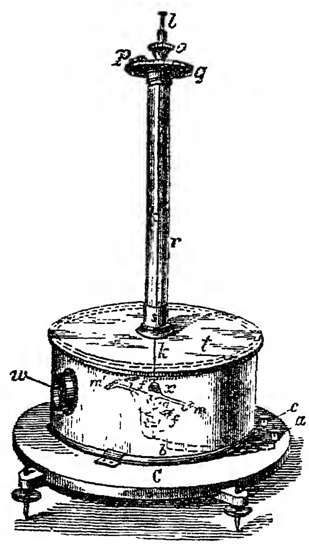

Fig. 3.

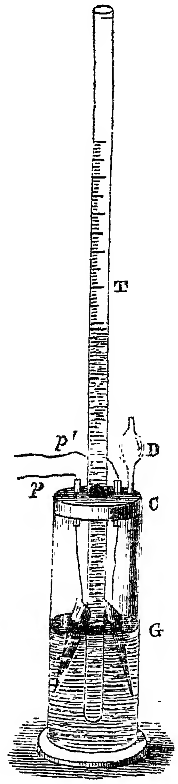

Fig 4.

dually heated, the air which we have already partly seen to have a greater attachment to + than to − electricity will, supposing the attachment between the metal and both kinds to be equally diminished, succeed first, in the molecular turmoil at the heated surface, in carrying away the +" (p. 81). Hence the apparently opposite effect seen in Fig. 1 is due to the inductive action of the charged electroscope upon the earth-connected ball over-head, so that the ball in A is negatively electrified and retains its charge, whereas in B the ball becomes positively electrified and dissipates its charge as fast as it is renewed, and hence in this case the electroscope is discharged as if by a point. The same power of discharge can be shown by replacing a hot ball with a platinum wire made white hot by a current. Fig. 2 shows an electroscope and a Leyden jar being discharged in this manner.

Fig. 3 shows an ingenious torsion galvanometer, devised, we believe, by the author, and which is stated to be free from many sources of error.

An ingenious contrivance, due to the author, is shown in Fig. 4. This is a so-called voltastat, an arrangement whereby the current interposes "by its own greater or less action a greater or less resistance in its own circuit," and thus the voltastat or automatic rheostat behaves like the governor of a steam-engine. There are of course several obvious disadvantages in the use of such an instrument, but we cannot recall any other continuous self-acting "voltastat." Helmholtz, in order to keep the disc of his siren rotating at a constant rate, employed an electro-magnetic arrangement with attached governor, but here the current was interrupted when it exceeded a certain strength.

In the electro-chemical portion of this treatise students will find much information concerning the reactions within various forms of batteries and in the electrolysis of salts, and some interesting facts on electric osmose. The explanation Dr. Guthrie gives of the prevention of "local action" by amalgamation of the zinc is new to us. The chief cause of local action—which the author describes as "a coasting trade"—is attributed to difference of hardness rather than metallic impurities on the surface of the zinc; mercury, it is asserted, removes this inequality of hardness due to irregular cooling, "for as the mercury penetrates, the mass softens and molecular strains are relieved, and uniformity results" (p. 141).

And here we would note one or two minor experimental statements in the book which we think it would be an advantage to modify, as readers might unintentionally be misled. In speaking of the electrolysis of water the author states that in the first portions of the gas collected the hydrogen is less than its theoretical proportion. "This is due to the 'occlusion' of hydrogen by platinum under these circumstances. The hydrogen is absorbed by the platinum. Very soon, however, the metal becomes saturated, and the exact combining ratio is observed" (p. 157). This effect, we imagine, must very promptly be masked by a contrary action—to which Dr. Guthrie does not allude—for, except under special circumstances, the amount of *oxygen* is perceptibly deficient in electrolysis, and, as is well known, is due to the formation of ozone. And is not the following electro-chemical statement also open to comment?—"Hydrogen, when freshly liberated, has, as is well known, an exceedingly powerful reducing action. Use is made of this circumstance to protect the copper sheathing of ships, ... the evolution of hydrogen on the copper surface deoxidises any oxidised portion" (p. 128). A student might from this be led to infer that the electro-negative metal in a cell would not be protected unless hydrogen were evolved on its surface. Again, in describing the evolution of electricity by an ordinary electric machine, it is merely stated that "the + electricity enters the prime conductor, and − leaves it; the prime conductor thus becomes +" (p. 52). A reference to the inductive action exerted on the prime conductor, the high tension at the points, and therefrom the discharge of the induced opposite electricity on to the machine, seems needed here.

We must now devote a few words to one feature wherein the present text-book differs from most of the ordinary manuals on electricity. Dr. Guthrie has sought to give the reader some acquaintance with terms and methods of measurement which in general are better understood by the practical electrician than the science teacher. Whilst every such effort cannot fail to be more or less useful, the present is, we regret to notice, open to criticism in several directions. But as we have neither the space nor the inclination to notice all the points we have marked, one illustration will suffice. On pp. 225 and 226 we have the unit of resistance set forth as follows: "Taking 1 second as unit of time, 1 metre as unit of length,* and 1 gramme as unit of weight, an 'absolute' unit of resistance is obtained by employing the above equations [viz., Q (or current strength) $= \frac{fd^2}{lm}$ and W (or current work) $= Q^2rt$], and this multiplied by one hundred million is the Ohm or B.A. unit." Here, irrespective of other considerations, there is the fundamental error of using the term *weight* instead of *mass*, and moreover, the student must fail to grasp the idea that electric resistance can be expressed as a velocity, and has nothing to do with either weight or mass. There is no hint of these considerations in the manual before us; the electrostatic system of units is not even referred to, nor is the student made aware of the precise nature of the units described.

This text-book is open to criticism also in some other portions which deal with more familiar questions. Notably, take for example a proof connected with Ohm's law, given on p. 185; or the paragraphs on linear resistance, § 243—247, which certainly will bewilder the reader unnecessarily, when a more general result can be deduced more easily and obviously in as many lines as pages are here devoted to the subject. Nor is it necessary for the particular proof, even if it were true, that the potential at the zinc end of the battery is = 0, as stated on p. 221.

In § 257, referring to the effect of heat on the resistance of liquid conductors, the fact is lost sight of that mercury (quoted as militating against a theory that is given) is not an electrolyte, and so has nothing in common with the generality of liquid conductors. On p. 224 the author shows how the diameter of fine wires may be deduced from their length and weight, and then adds: "The relative diameter of two wires can be deduced from their weights, lengths, and *resistances;*" here weight, no doubt, was meant to be omitted. There is also an earlier paragraph needing great amendment, viz. § 214, where electrical resistance is compared with the resistance experienced by water in flowing through pipes; but as any analogy there might be is destroyed by the definition adopted of water-resistance, it is, we think, a mistake to have introduced the elaborate and withal erroneous comparison that is given. And surely two woodcuts of the same tube on p. 179 were hardly necessary, as if turning the tube one way or the other could make any difference in the reasoning. In fact, the evident care everywhere taken by the author to make his meaning clear, has perhaps led him occasionally to the opposite extreme of unnecessarily laboured explanations, so that some really

* After the strong reasons which exist in favour of the C.G.S. system of units, it is to be hoped that the centimetre will become more generally used as the unit of length.

simple matters become invested with an air of great difficulty. Thus, to take one other example, we should have thought it needless to devote so much space to the difference between a right and left-handed spiral, as is given on p. 242, *et seq.*

There are also several clerical errors and misprints throughout the book, which we regret we have not space to point out, as they ought to be corrected in a new edition; some of the woodcuts, moreover, need alteration.

In conclusion, we must remark that, although a careful perusal of this work has led us to notice several things which ought to have been different, yet we are not insensible to the good features of this unpretending text-book, and we hope, therefore, that Dr. Guthrie will have a speedy opportunity of removing the blemishes which seriously mar the usefulness of his book. In the strictures we have ventured to offer we trust nothing offensive to the author has appeared, for whom we entertain, and are glad to be able to express, our sincere respect.

TWO AMATEUR EXPLORERS

"*The Great Divide.*" Travels in the Upper Yellowstone in the Summer of 1874. By the Earl of Dunraven. With Illustrations by V. W. Bromley. (London: Chatto and Windus, 1876.)

Yachting in the Arctic Seas; or, Notes of Five Voyages of Sport and Discovery in the neighbourhood of Spitzbergen and Novaya Zemlya. By James Lamont, F.G.S., F.R.G.S. Edited and Illustrated by W. Livesay, M.D. (Same publishers.)

THE number of works of travel published within the last few months is probably unprecedented. Scarcely a week has passed during that time in which we have not had occasion to notice one or more in these columns. One noteworthy feature about these narratives of travel is that few of them are by what may be called professional explorers, men who have led expeditions into unknown or little known lands and seas for the sole purpose of extending our knowledge of them. They are mostly written by men who, solely from a love of adventure and sport, have left all the comforts and luxuries which wealth and a high social position can bring to undergo many of the hardships and privations which fall to the lot of those who have adopted discovery as their work in life. No doubt improvements in modes of travel, and especially in steam navigation, have something to do with this, as has also the tedium which occasionally comes upon every intelligent man who has to plod the weary round of the duties, and especially the pleasures, of civilised life. But, as we said last week, we are inclined to attribute this growing love of travel, of amateur exploration, in some degree to the general advance of intelligence urging those who can afford it to gratify their craving for knowledge by stronger stimulants than can be obtained from books. Possibly also some may think this growing love of travel in wild regions, mingled as it often is with intense delight in dangerous sport, is to some extent a breaking out of remote ancestral habit, of a habit which still clings to us from a time when our ancestors, like existing savages, were explorers and hunters of the wildest animals for dear life—a habit which only requires a favourable opportunity to be re-developed, though with a different aim. Whatever may be the causes, there can be no doubt about the fact of the rapidly-growing love of adventure and discovery, involving dangers and hardships of a very real kind. No better examples could be found than those of the authors of the two works before us.

The scene of the Earl of Dunraven's wanderings is in and around that wonderful and interesting region of North America, on the borders of Montana and Wyoming, known as the Yellowstone Park, which the U.S. Government have had the wisdom to set aside as a "gigantic pleasuring ground." Anyone looking at a good map of the United States will perceive the appropriateness of the term "The Great Divide" as applied to the mountainous region in the neighbourhood of the Upper Yellowstone. It is indeed the geographical centre of North America; here the principal rivers of the United States take their rise and flow in all directions—north, south, east, and west. We have already (vol. vi., pp. 397, 437) given considerable details and several illustrations of this remarkable region of gigantic geysers, and boiling mud and sulphur springs, and not much has since been done to add to our knowledge of it. The Earl of Dunraven, during the few weeks he spent in the district with a few boon companions, made a pretty careful examination of some of the most remarkable phenomena, and the record of this, supplemented by copious extracts from the accounts of the U.S. exploring expeditions, will give the general reader a very fair idea of the characteristics of this strange region. The Earl reached the Upper Yellowstone region by travelling northwards from Corinne on the Great Salt Lake; and both on his journey northwards, during his hunting of the mountain-sheep or bighorn (*Caprovis Canadensis*), the wapiti, and other wild animals, and his exploration of the geyser and boiling spring region, he and his party occasionally endured considerable hardship, which, however, they all seemed thoroughly to enjoy as an essential part of the programme of the expedition. Considerable details are given as to the character and condition of the various tribes of Indians to be met with in the neighbourhood of the region traversed, and the Earl has much to say on the Indian question. We do not think, however, that our ignorance of the Indian, his habits and traditions, is so great as the Earl would make out to be the case. There really exists a vast amount of information concerning the aborigines of North America at least, and Mr. Bancroft is doing good service in collecting into one magnificent work all that is known of the natives of the Pacific States. Still there can be no doubt that the American Indians are rapidly dying out, and in the interests of science it would be well to use all diligence in supplementing the doubtless by no means complete information we at present possess. As to civilisation and conversion, the Earl of Dunraven has as bad an opinion of the Indian as Mr. Monteiro and Capt. Burton have of the nature of an African.

On the whole we may say that the Earl of Dunraven's work is a jolly rollicking narrative of adventure and sport, mixed up with a great deal of useful information concerning one of the most interesting regions in the American continent. The illustrations are interesting, and some of them help out considerably the descriptions in the text,

A good map of the territories around the Yellowstone region, and a large scale-map of the Upper and Lower Geyser Basins, enable the reader to follow the author in his wanderings and descriptions.

From a scientific point of view Mr. Lamont's book is more valuable than the one we have been speaking about. So long ago as 1858-59, Mr. Lamont made voyages, mainly for sport, to the Spitzbergen Arctic region; and in 1869-70-71 he made other three voyages. In the volume before us he has brought together some of the most valuable results of his observations during these voyages, and while devoting considerable space to his sporting adventures with the walrus, the seal, and the bear, he gives much information of scientific value. His sporting skill stood him in good stead, as from his large takes of walruses, seals, and bears, not to mention reindeer and smaller game, he must have been, in 1869 at least, considerably recouped for the expenses of his voyage.

Mr. Lamont, very naturally judging from his own success, is inclined to place more value on private Arctic enterprises than on elaborately equipped Government exploring expeditions. He refers to the expedition in the *Polaris*, commanded by a civilian, and which got further north than any ship had previously done. But we think that any one who reads the narrative of that unfortunate expedition unprejudicedly, must conclude that had the expedition been under strict naval discipline it would have reached a point still further north, would have accomplished more in the way of scientific observation than it did, and would not have ended with the disaster that befell it. The last Payer-Weyprecht expedition, though not a Government one, was practically under naval discipline, and the English Government expeditions referred to by Mr. Lamont, did not fail in their endeavours to push northwards because they were such. But Mr. Lamont speaks as if the main object of Arctic exploration were to get as far north as possible, whereas, in the eyes of scientific men, this is a point of minor importance; and they maintain rightly, we think, and their opinion is supported by past experience, that no Arctic expedition can be adequately equipped to collect all the scientific data which can be so abundantly obtained in these regions, unless it be sent out by Government and be conducted with all the method and strictness which naval discipline alone can enforce. Private enterprises like those of Mr. Lamont and the whale fishers, can do much to add to our knowledge of the Arctic regions, but if we had had to depend entirely on such means, what would have been the amount and value of our knowledge at the present day?
